Rearing of *Simulium damnosum* Theobald (Diptera, Simuliidae) in the Laboratory

ALTHOUGH adults of *S. damnosum* have been reared from larvæ, rearing from eggs does not appear to have been recorded. Hartley[1], however, was successful in rearing *S. venustum* adults from eggs. In view of the importance of *S. damnosum* as the main vector of onchocerciasis in Ghana and elsewhere, and the recommendation by the World Health Organization Expert Committee on Onchocerciasis[2] that the rearing of *Simulium* in captivity should be studied, it was felt that attempts should be made, when opportunity occurred, to rear *S. damnosum* in the laboratory. This communication describes the apparatus and method by which *S. damnosum* adults have been successfully reared from eggs.

The apparatus consisted of a trough of corrugated asbestos roofing material, inclined at an angle of 20°, in an aquarium tank containing three gallons of river water which was circulated via the trough by means of a water-circulating pump delivering approximately 60 gall. per hr. at an estimated velocity of 3·8 ft. per sec. Aeration was produced by maintaining the water-level 2 in. below the lower end of the trough to form a miniature waterfall, the inflow pipe being placed near this aerated water. Further aeration was obtained by piercing the polythene outflow pipe 1 ft. from the outlet with a suitably inclined M.R.C. type transfusion needle causing a stream of air to be drawn in.

In June (9 a.m.) a mass of some 10,000 eggs, apparently laid by many females in the manner described by Crisp[3] and Muirhead-Thomson[4], on submerged grasses, was obtained from Senchi rapids in the River Volta. 3 hr. later, by which time some eggs were already hatching, the grasses were placed in the trough and the water circulated. The eggs continued to hatch during the following day, comparing favourably with the hatching time of 36 hr. observed by Crisp[3]. Wanson and Henrard[5] state that in Leopoldville the eggs hatch within 4 hr. of deposition.

As the larvæ grew, the river water became clearer owing to the filtering out of plankton and suspended matter: at increasingly frequent intervals ½ gallon of water was removed from the tank and replaced by river water which had been concentrated approximately five hundred times by filtering through a fine plankton net. After 7 days many of the larger larvæ migrated up to 15 in. into the outflow pipe. Possible reasons for this migration were increased current velocity or greater depth of water (9 mm.).

Eight pupæ were formed, all in the outflow pipe, 14–17 days from hatching, the pupal stage lasting 2–3 days. Seven adults emerged successfully into a cage placed over the apparatus; but only three, all males, were collected, the remainder escaping. In field conditions in the Northern Territories of Ghana at a temperature of approximately 25° C., Crisp[3] found that the larval stage lasted 10–13 days and the pupal stage 4–5 days. In this experiment the temperature ranged from 21·1° C. to 31·1° C. with an average of 25·8° C.

On the nineteenth day all larvæ were found to be detached and dead; the pH of the water in the tank was now found to be 7·3 compared with 6·9 for fresh river water. It is thought that the accumulation of larval excreta in the tank was sufficient to account for the death of the colony.

Note added in proof. In a further rearing experiment in which the river water was changed completely every two days, the minimum length of the egg to adult cycle for males and females was 16 and 20 days respectively: the length of the larval stage varied from 14 to 40 days.

Relation of Colchicine to Chromosome Breakage

COLCHICINE affects the mitotic spindle in a variety of ways[1–3]. It has also been claimed that colchicine will induce chromosome breaks[4,5]; but this effect has never been confirmed. Chromosome breaks have been found after treatment with old solutions of colchicine, but this action can be attributed to bacterial toxins, which are formed as the solution ages, and not to the colchicine itself[6].

To test for the ability of colchicine to induce chromosome breaks in *Vicia faba*, I have grown beans in aerated distilled water in a cabinet at 20° C. When lateral roots had formed, the beans were kept in a 0·05 per cent aqueous solution of colchicine for 3 hr. After 24–30 hr., 60 diploid nuclei and 60 of the induced tetraploid nuclei were examined at metaphase. No chromosome breaks were seen in either diploid or tetraploid cells. Colchicine as such does not appear, therefore, to have a direct effect in inducing chromosome breaks. This confirms the results of Gaulden and Carlson[6].

In addition to its independent or direct effects, colchicine has been thought to alter the sensitivity of cells to X-rays, that is, to exert an indirect effect. Thus combined treatments have been said to result in: (1) a reduced frequency of 'chromatid aberrations'[7]; (2) an increased frequency of 'reunions and restitutions' among broken ends[8]; (3) an enhanced inhibition of root-tip growth[9]; (4) an increased mutation-rate[10].

In order to obtain evidence of an indirect effect of colchicine on the production of chromosome breaks by X-rays, I kept beans in 0·05 per cent colchicine for 3 hr. and then irradiated them. Other beans

Treated	6	62 (2)*	50	43	138	—	46	5	3	0·69	2·22	0·74
Control	24	72 (3)*	50	74	16	2	6	3	—	1·03	0·22	0·08
Treated	24	74 (2)*	50	77	21	4	5	5	2	1·04	0·28	0·06

* Unscorable

received no colchicine before irradiation (Table 1). Roots were fixed in 2BD and prepared as Feulgen squashes. The symbols used in scoring were those of Darlington and La Cour[11].

Breakages and reunions were scored in diploid nuclei. The mean frequencies of B'', B' and R' (6-hr. fixation) and B'' (24-hr. fixation) in roots with or without colchicine pretreatment are not significantly different ($P = 0·05–0·06$, about 0·56, about 0·5 and about 0·8 for the four types of aberration). Thus the evidence from this experiment is that pretreatment with colchicine has no effect on the frequency of chromosome breaks. At least this is true so far as concerns cells or chromosomes irradiated during the resting stage.

Now, if the chromosomes of diploid cells are held at metaphase by colchicine and then irradiated, any breaks which are induced can be scored in the tetraploid metaphases which occur 24 hr. later. The amount of breakage found in such tetraploid cells indicates that sensitivity to X-rays is higher at metaphase than at any other stage of mitosis[12]. (This observation I have confirmed.) This may come about, broadly speaking, in one of two ways. Either the colchicine increases the total production of chemical intermediates, which may form after irradiation, or it changes the state of the chromosomes thus changing their sensitivity.

In view of the lack of interaction during interphase the first possibility seems unlikely. We should have to postulate that the chemical intermediaries are increased, but only in the cytoplasm, and that they are unable to penetrate the nuclear membrane owing to a second effect of colchicine during the resting stage. The second possibility is that colchicine changes the state of the chromosomes. To test this, the obvious method would be to irradiate diploid cells arrested at metaphase by two kinds of treatment, by colchicine and by another agent, and to compare the breakage frequencies in the tetraploid metaphases which appear later. But this method cannot be used. Low temperatures, for example, lead to an increase in the number of chromosome breaks induced by X-rays[13]. Paradichlorobenzene produces arrested metaphases, but either fails to induce tetraploidy, or, like 8-oxyquinoline kills the root-tips. In these circumstances we can turn to cells which can be timed without being arrested, namely, to such synchronized cells as we have at meiosis.

In meiotic cells, in the absence of pretreatment, sensitivity to X-rays is higher at metaphase than at any other stage[14,15]. It seems reasonable to conclude therefore that in mitotic cells at metaphase, whether in root-tips or in animal tumours[16], pretreatment with colchicine is not responsible for the high sensitivity to X-rays: the effect is inherent in the stage. It remains to inquire whether what is inherent in the stage is the character of the cytoplasm or the chromosomes.

I am grateful to Mr. J. F. Scott for advice on statistical treatments and to the Nuffield Foundation for financial assistance.

Experimental Evidence for an Allergic Basis for Granuloma Formation in Man

GRANULOMA formation is one of the significant reaction patterns of the body in disease. Characterized by tubercles of closely packed epithelioid cells, granulomas are the basic alteration in such chronic diseases as tuberculosis, leprosy, syphilis, sarcoidosis, deep fungus infections and in reactions to foreign material. These epithelioid cells are of reticulo-endothelial origin and may be regularly produced by the introduction of colloidal materials[1,2]. Other than this, little is known concerning their origin. The present communication describes the production of a specific, hypersensitive, delayed reaction to zirconium which manifested itself as a granuloma.

Recently, axillary granulomas have been described as arising in association with the use of zirconium-containing deodorants[3]. In the course of an extensive study[4] of the nature of this new clinical entity we performed the following experiments on normal healthy adult male volunteers. Each of ten subjects received four injections of 0·02 ml. of a 1·0 per cent aqueous solution of sodium zirconium lactate into the skin and four into the subcutaneous tissue of the upper arms. In all the men a small, firm fibrous papule developed at the sites of the intradermal injections whereas the subcutaneous injection sites could not be identified clinically. Biopsy of one of the papules in each man at one month revealed a non-inflammatory fibrous mass, histologically resembling a scar. All the lesions remained unchanged clinically during the next six months and selected biopsies during this period showed simply fibrous tissue.

At the end of six months one of the subjects, No. 7, suddenly developed an enlarging mass at the site of each of the eight previous injections. The growth of these masses continued, and they eventually became nodules, approximately 5 cm. in width. Biopsy specimens disclosed a classical epithelioid granuloma in both the dermal and subcutaneous injection sites. The entire dermis was replaced by nests of epithelioid cells with minimal round cell infiltration. Quantitative spectrographic analysis of one of the nodules, in a site injected nine months previously, revealed zirconium persisting in a concentration of 10^{-5}. A control specimen from a nine-months old injection site (non-granulomatous) in another subject proved to have zirconium in a concentration of 3×10^{-6}, and in normal control skin zirconium could not be detected.

Careful study revealed that at six months No. 7 had acquired a state of allergic hypersensitivity to zirconium. Although the other members of the test group showed no clinical or histological response to intradermal injections of sodium zirconium lactate, No. 7 was now found to be sensitive out to a dilution of 10^{-8}. Repeated study of his response to 0·02 ml. of 10^{-6} revealed a clinical and histological response by seven days. At this time at the injection sites small papules appeared which on biopsy were found to be patchy, perivascular infiltrates consisting mainly of epithelioid cells. Gradually these papules enlarged due to the progressive development of a widespread epithelioid growth. These papules persist at the time of writing, four months after the injections. This response was reproducible in all areas of the skin. Furthermore, it was produced not only by sodium zirconium lactate but could also be elicited with dilute solutions of zirconium chloride and zirconium sulphate. However, no response was found after injecting silicon dioxide and beryllium sulphate in a concentration of 10^{-4}, thus indicating the specificity of the zirconium ion. It is to be noted that these two elements, silicon and beryllium, have been reported to cause granulomas[5,6].

Additional evidence for the concept that granulomas can have an allergic pathogenesis was provided by the study of six patients who had developed axillary granulomas following the clinical use of zirconium deodorants. In each of these patients it was possible to demonstrate delayed local granuloma formation at the injection sites of 0·02 ml. of 10^{-6} of sodium zirconium lactate. Twenty control subjects showed neither clinical nor histological response to this injection.

The allergic nature of these granulomas was apparent since:

(1) The state of hypersensitivity to zirconium was acquired. Subject No. 7 did not have an innate or inherited sensitization but developed it as a result of exposure to the injected zirconium. It is significant that in No. 7 the injected zirconium served both as a sensitizing and eliciting stimulus as proved by the spectrographic analysis of his tissue.

(2) The granuloma reaction was specifically elicited only by zirconium. The patients failed to react to dilute solutions of any of the other constituents of the deodorant preparations which they had used.

(3) Extremely high dilutions of the zirconium were capable of producing the granulomatous response. Classic allergic reactions are based on an antigen–antibody immunological reaction. No circulating antibodies could be demonstrated by us—but studies are now in progress concerning the passive transfer of cellular antibodies. It must be emphasized that the allergic state we have demonstrated was a generalized hypersensitivity not limited to one area of the skin. Moreover, it was not restricted to the dermis or true skin, but was also present in subcutaneous tissue.

Although an allergic basis for granulomas has been suspected[7,8], this, to our knowledge, is the first direct demonstration that the introduction of extremely small amounts of a substance may produce a delayed allergic reaction in the form of an epithelioid cell granuloma. There was no evidence that this was an Arthus or Schwartzman phenomenon. Furthermore, one must contrast this type of allergic response with the eczematous contact dermatitis seen as a result of an allergic reaction to metals such as nickel. None of the individuals studied showed any response to patch tests to zirconium. It is also to be noted that this allergic type of granuloma is to be distinguished from other non-allergic types which represent simple direct phagocytosis of exogenous or endogenous matter. Further study should reveal which of the granulomas seen in disease are allergic and which are non-allergic.

It has been possible, therefore, to demonstrate, both experimentally and clinically, that man may develop a delayed granulomatous epithelioid cell response as a result of a specific, acquired, generalized hypersensitivity to a simple metallic element.

The Clock Paradox of Relativity

THE clock paradox of relativity is, in my view, due to an error in Einstein's paper[1] which has not hitherto been noted and which may be more obvious to an experimental than to a theoretical physicist. Prof. H. Dingle has suggested[2] that there must be an error in this section of the paper without pointing out what I believe to be its true nature or giving the true explanation.

Einstein describes an imaginary experiment in which M makes a round trip from S and he concludes that the clock on M reads αT compared with the reading T of a clock on S. He does not give his reasoning, which must, however, have been connected with observations made on the two clocks. It is important, therefore, to distinguish between the two parts of a clock, the time standard which supplies regular impulses and the dial which counts them.

The time dilatation is an effect obtained when the rate of the clock on *M* is determined by observations made on *S*. These measurements cannot be made by reading the figures on *M*'s dial as this is simply reading the result of a measurement made on *M*. They must be made by receiving the impulses from *M*'s standard and counting them on a dial on *S*, and it is this dial which reads αT when the dial of *S*'s local clock reads *T*. The measurements do not give any indication of the reading on *M*'s dial; but this can be observed directly at the end of the journey, and it follows from the postulate of relativity, if acceleration effects are ignored as in Einstein's paper, that the reading will be the same as that of the local clock on *S*. If there is also a dial on *M* recording the impulses from *S* this will read αT. The observations on *M* and *S* are completely symmetrical and there is no paradox.

To anticipate possible criticism, two further points might be made. (1) The result is not in accordance with pre-relativity ideas of the nature of electromagnetic waves; but this is only to be expected, since these ideas are abandoned with the acceptance of the relativity postulate of constant velocity. (2) Many writers, including Einstein[3], accept the paradox result but attribute it to the accelerations which must be involved. This argument is, I think, illogical. An imaginary experiment can yield only a result which is already present in some form in the data given. Since no data concerning the effects of acceleration are included, the result cannot be a consequence of acceleration. The result may, however, be wrong because such data have been omitted.

If the views presented here are correct, the consequences are far-reaching. Many text-books need to be revised, and as the paradox seems to be confirmed by the general theory of relativity some aspects of this theory may need to be critically examined.

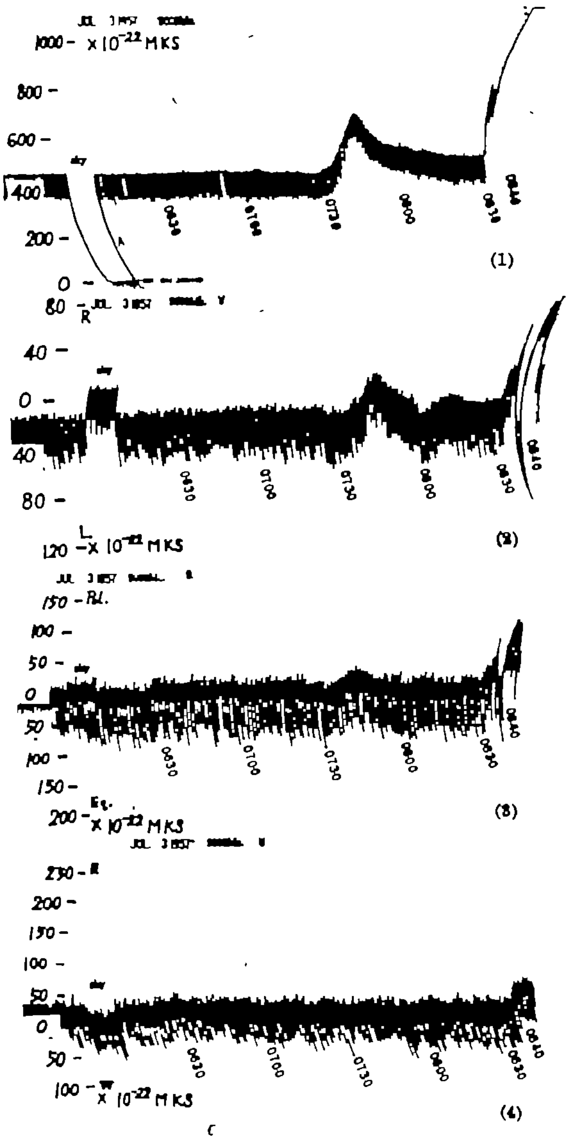
Polarization of Solar Radio Outbursts

It has been reported through the International Geophysical Year networks that three large solar flares were observed on July 3. Our radio observations at 9,000 Mc./s. showed some interesting phenomena in the polarization of radio outbursts which correspond to these optical flares. As is described elsewhere[1], our receiver working at this frequency is so designed as to record four of the Stokes's parameters of polarization directly by the method of phase-modulation. Figs. 1–4 show the tapes which record *I*, *V*, *Q* and *U*, respectively.



Figs. 1–4. Reproductions of tapes of solar radio emission on July 3. They represent the four components of Stokes parameter on polarization, namely, *I*, *V*, *Q* and *U*, respectively. *R* and *L*, in Fig. 2, refer to the right-handed circular and left-handed circular components, respectively. *Pol.* and *Eq.*, in Fig. 3, refer to the linearly polarized components in the direction of celestial equator and pole, respectively. *E* and *W*, in Fig. 4, denote the linearly polarized components in the direction inclined 45° to the east and west, respectively, from the direction of the celestial pole

At 0727 U.T. the flux started to rise and, passing the 20 per cent point at 0733 U.T. (the starting time by the usual definition), it reached a maximum of 710 × 10^{-22} M.K.S. units (including the background flux) or 230 × 10^{-22} M.K.S. units (excluding the background flux) at about 0742 U.T. The sense of the circular polarization of the general background on the day was left-handed, as is seen by reference to the position marked 'sky' on Fig. 2, but at the time of this outburst the polarization changed to 10 per cent right-handed. The starting time of the optical flare of importance 2 +, as reported by the Simeis Observatory, is 0726 U.T.

At 0800 U.T. there is a small kick in Fig. 1, and Fig. 2 shows a change of circular polarization at this time. This seems to correspond to the second optical flare of importance 3 reported by the Arcetri Astrophysical Observatory, starting at approximately 0802 U.T.

There is a sudden increase in flux at 0831 U.T. which sent the recording arm of the receiver off-scale a few minutes later. This corresponds to the third optical flare, starting at 0832 U.T., reported by the Arcetri observers. An interesting thing is that the state of polarization of the radio outburst changed considerably, as is seen from Figs. 2 and 3. Since this radio-telescope is driven quite automatically from morning until evening and then driven back to the morning position through the night, no record after 0844 U.T. was obtained.

The change of polarization of radio outbursts might be connected with the shift of the activity centre of the flare relative to the sunspot magnetic field. It is highly desirable that these observations should be compared with optical observations of the flares.

There is one more point which we would like to make: at about 0723 U.T. the flux decreased slightly. The polarization tapes, Figs. 2 and 3, also show simultaneous changes in polarization. A similar phenomenon was also observed on a smaller scale on July 1, just before the occurrence of a similar 'slow rise and fall' type of outburst which started at 0347 U.T.

Nuclear Magnetic Resonance of Methane adsorbed on Titanium Dioxide

NUCLEAR magnetic resonance can be used for studying the motions of molecules absorbed on surfaces. In this connexion proton-resonance derivative line-shapes have been obtained for methane adsorbed on titanium dioxide at various coverages from 0·1 to 4·0 monolayer, and also in bulk methane, as a function of temperature. The surface area of the titanium dioxide, determined by the BET method, was 230 m.^{2}/gm.

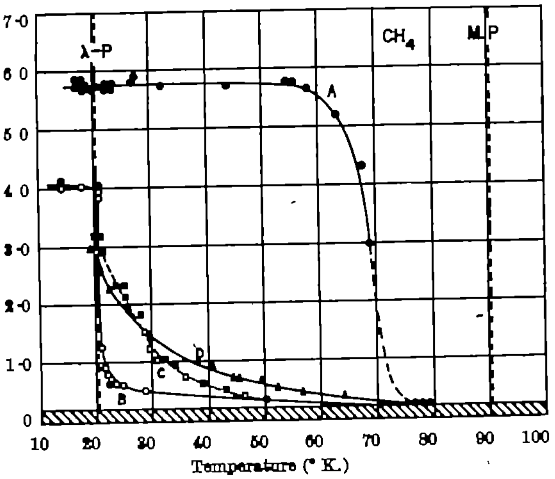

Fig. 1. Derivative line-width ΔH versus temperature for (*A*) bulk methane; (*B*) 0·9 monolayer; ○, temperature increasing; ⊖, temperature decreasing; (*C*) 0·6 monolayer; (*D*) 0·33 monolayer

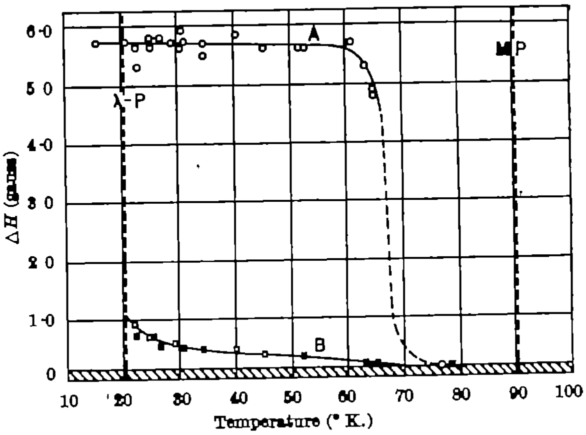

Fig. 2. Derivative line-width ΔH versus temperature at 3·9 monolayer of methane on titanium dioxide. (*A*) broad line component; (*B*) narrow line component

The results for bulk methane are shown in Fig. 1, and, as in the previous work[1,2], no change in derivative line-width ΔH is observed on passing through the λ-point at 20·4° K. A theoretical analysis by Tomita[3] has indicated that the 'flipping' of methane molecules to neighbouring equivalent orientations provides a good explanation of the small value of T_2 ($\sim 10^{-5}$ sec.) actually observed. Moreover, this re-orientation occurs with sufficient frequency to average out the intra-molecular contribution to the line-width even at temperatures well below the λ-point. Thus the absence of a line-width transition at this temperature cannot in itself exclude the possibility of hindered or free rotation[3,4] being associated with the λ-transition. The most effective mechanism for narrowing the line-width due to inter-molecular local fields is diffusion[5]. Thus the incidence of line-width narrowing, initiated near 60° K., to a value below the field homogeneiety of 0·3 gauss at 75° K. is probably to be ascribed to this cause. The low magnitude of the correlation frequency for line narrowing ($\sim 2·5 \times 10^4$ c./s.) and the spherical symmetry of the methane molecules indicate that this process may be interpreted as anticipating the more rapid diffusional processes known to accompany melting at 90° K.

At a coverage of 1·0 monolayer an unexpected line-width transition is observed at 20° K. The line-shape is, however, complex, and only a certain fraction of the molecules undergo the sharp line-width transition indicated in Fig. 1. As the coverage is reduced below a monolayer the transition becomes progressively more gradual with respect to increasing temperature.

Below the λ-transition the derivative line-width for both bulk methane and 3·9 monolayer coverage is 5·7. For one monolayer it is 4·1 gauss, which is lower than the value at higher coverages, as may be expected since a single monolayer will have fewer near neighbours. As the temperature is increased from 15° K. through the λ-transition the line-width remains at 5·7 gauss for the 3·9 monolayer coverage as it does for the bulk methane. However, at this coverage a central narrow line component of initial width 0·9 gauss had appeared at 20·8 ± 0·3° K.

This component proceeded to grow in intensity and gradually narrowed to the field homogeneity of 0·3 gauss as shown in Fig. 2 (curve B). At each temperature above the λ-transition the complex-line-shape could be resolved, though somewhat arbitrarily at the higher temperatures, into broad and narrow components. The broad line component, containing the majority of the intensity, is seen to give (curve A) to a close approximation the line-width temperature data for bulk methane. Thus, so far as the line-width versus temperature is concerned, the properties of bulk methane are well approximated at four monolayers under the conditions of the experiment with the exception of the narrow line component. This component is probably associated with diffusional motions initiated at the surface. As a rotational-type transformation at the λ-point increases the energy of a given methane molecule, it may also increase the probability for surface diffusion. This would explain the first appearance of the narrow line component at 20·9° K. A more detailed analysis of these effects is proceeding.

Supercontraction of Wool Irradiated with Ultra-violet Light or Iodinated

SUPERCONTRACTION of Corriedale wool fibres in solutions of lithium bromide (6 M–10 M), freed from bromine, has been shown to proceed in two stages, the first stage being complete at contractions of about 15 per cent and the second stage at about 40 per cent. It can be reversed up to the end of the first stage by washing out the lithium bromide with water. If supercontraction is allowed to proceed into the second stage, washing can at best only partially restore fibre-length[1,2]. The second stage has an activation energy deduced from the temperature coefficient of the process of about 30 kcal./mol. in the lithium bromide solution. Haly and Feughelman[1] concluded that the fibre, at the end of both the first and second stages, acted as an elastomer which had respectively 16 and 30 residues between 'vulcanized' sites. It was suggested that at the end of the first stage the 'vulcanizing' linkages are strong polar bonds or co-operative secondary bonds (such as exist in crystalline regions) and disulphide bonds, and that at the end of the second stage only the disulphides remain.

Wool fibres, after ultra-violet irradiation from a high-pressure mercury-in-quartz source, when heated in lithium bromide solution, supercontract much more rapidly than normal fibres, and there is no indication of two-stage behaviour. These phenomena remain when wave-lengths shorter than 2900 A. are eliminated, but a longer time of irradiation is required. In both cases the activation energy was substantially reduced.

The disulphides in wool absorb ultra-violet radiation[4]. Although it was found that the amount of cystine lost after irradiation for 2 hr. by wave-lengths above 2900 A. was approximately 25 per cent of the total, there was no further loss of cystine during 200 hr. exposure. On the other hand, increasing the time of irradiation from 2 to 20 hr. greatly increased the rate of supercontraction in lithium bromide solution. It therefore seems unlikely that this cystine fraction plays any part in the supercontraction process. Furthermore, no change in the load-extension curves of single fibres in water could be detected due to this loss of 25 per cent of cystine. Tyrosine and tryptophan at neutral pH absorb in the ultra-violet mainly between 2500 A. and 2900 A. in the free state. The maximum is at about 2750 A. Incorporation into peptides results in the loss of fine structure together with a shift of absorption to longer wave-lengths[3]. (The absorption spectrum of horn keratin was determined by Speakman and McMahon[4].) Phenylalanine, the only other aromatic amino-acid present in wool, absorbs mainly around 2600 A.

Further evidence was sought relating to the linkages which break to permit the second contraction stage. Corriedale fibres in which the tyrosine residues had been iodinated by the Richards and Speakman technique[5] were contracted in lithium bromide solution. Contraction behaviour was normal up to the end of the first stage, but the subsequent rate of contraction was extremely slow. In this respect the response of iodinated fibres was similar to that of normal wool supercontracted in solutions of lithium bromide containing bromine[2]. Wool fibres which had been exposed to ultra-violet radiation, however, supercontracted rapidly into the final stage in solutions of lithium bromide in which a normally effective concentration of bromine is present. As a further check, in case a reaction between lithium bromide and iodinated wool might be producing side-effects, some iodinated wool was supercontracted in calcium nitrate solution, with results similar to those obtained using solutions of lithium bromide.

This evidence suggests that tyrosine may be involved in the strong polar bonds or co-operative secondary bonds which, when broken in lithium bromide solution, allow the second supercontraction stage. The evidence of Richards and Speakman[5] that supercontraction of iodinated fibres in a disulphide bond-breaking reagent was approximately the same as that of normal fibres is consistent with the picture of the contraction process which is outlined above. Further experimental work is in progress, and a full report will be published later.

We thank Dr. J. P. E. Human for performing the cystine analyses.

Degradation of Cellulosic Fibres in Contact with Rusting Iron

INSTANCES of rapid degradation of textile materials in industrial use have been noted, the cause of which could not be attributed to the more usual degrading agencies, that is, micro-organisms, heat, light or acids. It was significant that in each of these occurrences there was evidence that the cellulosic material had been in contact with corroding iron under damp conditions. Similar degradation was observed in laboratory experiments in which cellulosic fibres were placed in contact with a clean iron surface and kept moist, a rapid fall in tensile strength being found as corrosion proceeded. The curves in Fig. 1 show the loss in strength of cotton yarn (8's × 5) damped with distilled water (curve *A*) and with 0·02 per cent sodium chloride solution (curve *B*) when wound on polished mild steel rods and kept in a moist atmosphere. Yarn wound on glass rods and exposed under the same conditions showed no significant change of strength in the same period (curve *C*).

An explanation of the cause of this degradation follows from consideration of the generally accepted electrochemical mechanism for the corrosion of iron wetted with a neutral salt solution. According to this mechanism, a flow of current occurs between separate regions of differing potential on the iron surface, the electrode reactions being expressible as:

Anodic reaction: $Fe \rightarrow Fe^{2+} + 2e$
Cathodic reaction: $O + H_2O + 2e \rightarrow 2OH^-$

If sodium chloride is present in the solution, the cathodic and anodic products can be regarded as sodium hydroxide and ferrous chloride respectively.

When cellulosic fibres are saturated with sodium hydroxide solution and exposed to the air, oxygen is consumed and the cellulose molecules are broken down. This reaction, which is the basis of the pulp 'ageing' process in viscose manufacture, has been studied fairly extensively[1,2], and it has been shown, and confirmed in this laboratory, that two of the main factors affecting the rate of cellulose degradation are: (*a*) the concentration of sodium hydroxide in the fibres; (*b*) the concentration of certain metals in the fibres, for example, iron, cobalt, nickel, etc., which are catalysts for the reaction. Moist cellulosic fibres in contact with rusting iron will thus be in an environment highly conducive to oxidative degradation by virtue of (*a*) the presence of local concentrations of alkali and (*b*) the presence of iron ions, which are active catalysts for the oxidation.

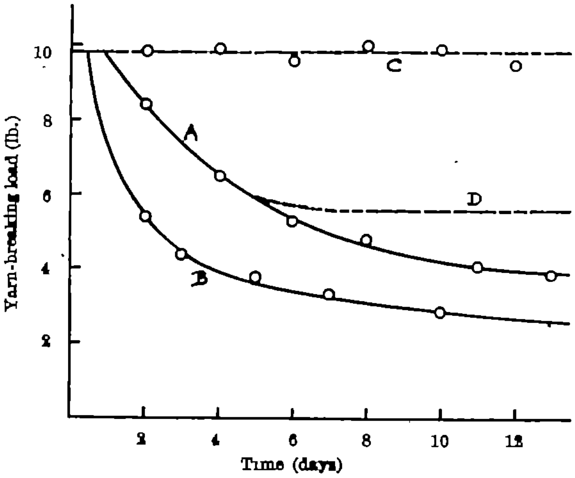

Fig. 1. *A*, yarn on iron, wetted with distilled water; *B*, yarn on iron, wetted with 0·02 per cent sodium chloride solution; *C*, yarn on glass, wetted with distilled water; *D*, yarn removed from iron

This explanation is supported by the following observations.

(1) Yarn wound closely on a rusting iron rod acquired a mottled pattern of rust-stained and unstained zones, the stained parts having a neutral and the unstained an alkaline reaction. Degradation of the fibres was most severe at the junctions of these zones.

(2) Yarn wetted with salt solution degraded faster than that wetted with distilled water. This is consistent with a difference in the level of alkali concentration reached in the cathodic zones resulting from the difference in conductance (and thus the rate of OH^- ion production) and in the availability of sodium ions to balance the hydroxyl ions. The results with distilled water suggest that enough alkali metal ions were present as impurities in the yarn (which was not specially purified) to produce sufficiently high local concentrations of hydroxide to promote the degradation observed.

(3) Yarn removed from rusting iron after losing 40 per cent strength, and thereafter kept moist, suffered no significant further loss in strength (curve *D*). Removal of the fibres from the alkali-generating sources on the iron surface would be followed by a fall in the local alkali concentrations by diffusion and reaction with iron ions to form rust, and the rate of cellulose oxidation would diminish rapidly.

(4) The strength of cotton yarn, saturated with a thick aqueous slurry of finely divided sulphur, was found to be unimpaired after 28 days in contact with an iron rod in a moist atmosphere. Under these conditions, in confirmation of Farrer and Wormwell's observations[3], very rapid and severe corrosion of the iron occurred and the yarn became heavily impregnated with a black corrosion product. In this system it may be assumed that the sulphur takes the place of oxygen in the normal cathodic reaction, sulphide ions being formed instead of hydroxyl ions, thus:

$$S + 2e \rightarrow S^{2-}$$

Since no alkalinity is produced, no oxidative breakdown of the cellulose would occur.

(5) Two samples of cotton yarn, the first impregnated with 5 per cent magnesium sulphate + 0·1 per cent sodium chloride, and the second with 0·1 per cent sodium chloride only, were damped and exposed on iron rods. The iron corroded rapidly in both cases, the rate being slightly less in the presence of magnesium sulphate, but while the yarn containing only sodium chloride degraded rapidly, the yarn treated with magnesium sulphate showed no loss in strength after 23 days. The precipitation of hydroxyl ions as magnesium hydroxide evidently prevented the development of sufficient alkalinity to promote oxidation.

Crystallography and Thermal Transformations of Cronstedtite

THE iron hydrous layer silicate cronstedtite is unique in having ferric iron substituted for silicon in positions of tetrahedral co-ordination. Previous investigations have been made by Gossner, and Hendricks[1], who described its crystallography as a kaolin-type structure with an orthorhombic three-layer unit cell.

Other iron-bearing layer silicates of the kaolin-antigorite and the chlorite groups have shown interesting reactions during the course of thermal decomposition. Certain of these phenomena have been observed by Holzner[2] in some chlorite minerals. In general, ferrous iron in these structures undergoes oxidation at about 300–400° C. without breakdown of the lattice. The charge balance is maintained by the alteration of a hydroxyl to an oxygen ion for each ferrous ion oxidized. This is accompanied on the X-ray diagram by a reduction of all *d*-values and a general deterioration of clarity with broadening of certain lines indicating the incidence of some disorder. At higher temperatures the hydroxyl ions remaining in the structure may be eliminated as water with partial or complete breakdown of the lattice to an amorphous state or to another crystalline species. This occurs with iron-bearing kaolin structures at about 500° C., and with chlorite minerals in two stages at about 550 and 700° C., representing degradation of the brucite- and talc-type layers respectively. The oxidation and dehydration mechanisms sometimes interfere in specimens with a high iron content because the loss of hydroxyl ions on oxidation renders the dehydration reaction much less clear.

In view of the importance of these reactions from the structural mineralogy point of view, cronstedtite was examined to compare its thermal decomposition behaviour with that of other iron silicates. Specimens examined from Cornwall and Rumania contained single crystals showing considerable polymorphism. Hendricks's three-layer structure was identified but appeared to be comparatively rare. One-layer orthorhombic, two-layer orthorhombic and six-layer orthorhombic types, and a somewhat disordered specimen which was substantially monoclinic, were identified. The one-layer structure had a straightforward kaolin-type orthorhombic unit cell, and the two-layer structure was very similar to that of the amesite described by Brindley, Oughton and Youell[3].

Powder photographs taken of specimens not good enough for single-crystal analysis showed a wide diversity of diffraction diagrams, in which orthorhombic and monoclinic reflexions were present, similar to the case of the chamosite described by Brindley[4,5].

The thermal decomposition of cronstedtite showed a number of novel and unexpected features. The oxidation of the ferrous iron took place at 275° C., substantially lower than for other ferrous silicates but with the usual contraction of the lattice which may be attributed to the small size of the ferric ion compared with the ferrous. On heating above this transition temperature there was a progressive change in the lattice parameters; a_0 and b_0 continued to decrease appreciably and c_0 increased to a value greater than that of the original cronstedtite. At about 700° C., this alteration in the unit cell dimensions had progressed to a stage where $c_0 = a_0\sqrt{2}$, giving orthorhombic parameters in the ratio $1 : \sqrt{3} : \sqrt{2}$.

At this temperature and, to some extent, at lower temperatures, a reaction occurred, producing a cubic spinel-type substance closely resembling γ-ferric oxide. An orthorhombic cell with the above dimensions is simply related spatially to a cubic cell with its diagonal (111) in the orthorhombic *c*-direction, which is a three-fold rotation axis for both structures. The (211) direction of the cubic unit cell is parallel to the *a*-axis of cronstedtite and the (110) direction of the cubic unit cell is parallel to the *b*-axis of cronstedtite. Certain of the stronger X-ray reflexions are identical in the two structures, notably the (060) of cronstedtite, which becomes the (440) of the spinel. The sites of the O and OH ions in cronstedtite are nearly coincident with the O sites in the spinel structure, but some rearrangement of the positive ions is necessary. There is no evidence either, by way of disorder occurring or of free silica appearing, that silicon ions have been removed from the lattice as a result of this transformation. It appears possible that the silicon ions may remain in the spinel structure, which has sites in tetrahedral co-ordination suitable for them. It is noteworthy that this spinel structure, although closely resembling γ-ferric oxide, has a higher decomposition temperature than the simple oxide, and this would appear to support the concept of silicon ions remaining in the lattice. The replacement of ferric iron in a spinel structure by silicon ions is unexpected, but the occurrence of the reverse substitution in cronstedtite has been generally accepted.

At above 750° C. a transformation to hæmatite occurs, with considerable disorder and powder streaking appearing on the single crystal X-ray photograph. Well-developed cristobalite is identifiable at higher temperatures. Sufficient single crystal reflexions can be identified to suggest that one of the possible directions of the *c*-axis of the hexagonal hæmatite unit cell is parallel to the *c*-axis of the original cronstedtite, the $13 \cdot 73\ kX$ c_0-dimension of the hæmatite unit cell corresponding to $14 \cdot 14\ kX$ for two cronstedtite layers.

The hæmatite structure, unlike the spinel type, has no tetrahedral cation sites suitable for Si^{4+} ions, and it appears possible that the disorder produced during the formation of hæmatite may be due to the expulsion of silica from the structure.

The two-layer orthorhombic cronstedtite undergoes similar thermal transformations but additional X-ray reflexions appear at the 700° transformation which cannot be reconciled with a simple cubic spinel lattice. This is what would be expected since a greater movement of ions would be necessary in the two-layer structure to produce a simple cubic lattice than in the one-layer structure. Further reaction producing hæmatite with disorder again occurs at a higher temperature.

A re-examination has been made of lattice parameters, and the following values have been obtained: original cronstedtite $a_0 = 5 \cdot 48\ kX$, $b_0 = 9 \cdot 50$, $c_0 = 7 \cdot 07$; for the oxidized form $a_0 = 5 \cdot 24$, $b_0 = 9 \cdot 08$, $c_0 = 7 \cdot 04$; immediately prior to the spinel transformation $a_0 = 5 \cdot 06$, $b_0 = 8 \cdot 72$, $c_0 = 7 \cdot 14 = a_0\sqrt{2}$. The *d*-values of the original cronstedtite are in substantial disagreement with those quoted by Bannister[6] but are very close to those of Frondel (private communication), who has been investigating cronstedtite independently of the present work.

We are indebted for the supply of specimens to Drs. Sabine and Dunning of the Geological Survey in London, Drs. Claringbull and Embrey of the British Museum (Natural History), London, and Dr. Hendricks, who kindly made available some of his original material. A full account of this work will be published later.

A Phase Change induced by Cold Work

A PHASE change has been produced in the ζ-phase of the alloy AgZn by cold work. The ζ-phase transforms to the β-phase on filing. The lattice parameter of the β-phase agrees with that found by Owen and Edmunds[1].

The structure of the ζ-phase has been determined by Edmunds and Qurashi[2] and confirmed by Bergman and Jaross[3]. The body-centred cubic β-phase and the ζ-phase hexagonal structure are closely related, the latter being obtained from the β-phase by displacement of the atoms mainly in the direction of one of the cube diagonals. Edmunds and Qurashi[2] have shown that both structures may be considered to have a unit cell containing nine atoms, and that in the ζ-phase the zinc atom at the origin has an abnormally high temperature vibration parallel to the hexagonal axis.

The rate of change is dependent on time and temperature, taking approximately four days for completion at room temperature. The β-phase reverts to ζ-phase on heating to approximately 130° C. Our present results suggest a nucleation and growth mechanism activated by stress.

A full account of this work will be published later.

Relationship of the Strength of High Solids Pectin Gels to the Concentration and Jelly-forming Capacity of the Pectin Present

IN 1940 Hinton[1] put forward a theory which was capable of explaining quantitatively many of the phenomena associated with the formation of high solids pectin gels. More recently, the assumptions on which Hinton based his theory have been criticized and an alternative explanation suggested which is more in keeping with current theories of the properties of macromolecules[2]. Neglecting the small variation in the degree of dissociation of pectin with concentration[1,2], for a given pectin in a gel of specified soluble solids content and pH, both theories indicate a linear relationship between gel strength and pectin concentration. However, a review of a number of the published curves relating the gel strength and the pectin concentration shows that when the strength is measured within the elastic limits of the gel and is expressed in units proportional to an elastic modulus, in each case the curve obtained is convex to the pectin concentration axis[4–11] (gel strengths measured by means of the ridgelimeter[8–11] may be converted from percentage sag to shear moduli by means of the curve given by Owens and Maclay[12]). Similar curves have been obtained by some workers measuring the breaking strengths of the gels[13–15], although in some instances a linear relationship was found[16,17].

Linear relationships between log (gel strength) and log (pectin concentration) have been demonstrated previously[4,5,13,14]. Some of the published curves from

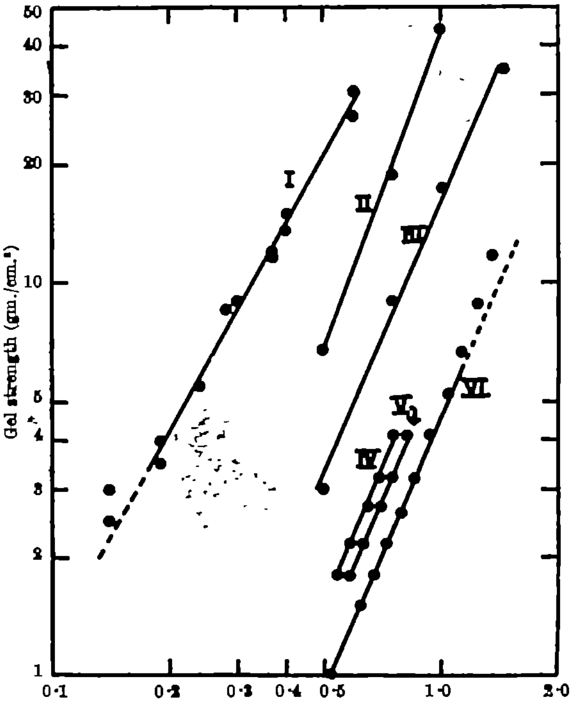

Fig. 1. Gel strength versus pectin concentration curves from various sources. Curve I from Hinton (ref. 6), II and III from Säverborn (ref. 8), IV from Joseph and Baier (ref. 9), V from Olliver *et al.* (ref. 11), VI from Lockwood (ref. 10). In curves IV, V and VI the pectin concentration has been expressed in terms of '100 grade' pectin as defined in the respective methods

other sources for which sufficient data are available have been replotted in this manner in Fig. 1. In each of these examples the gel strength was measured within the elastic limits of the gels. Strengths measured with the ridgelimeter have been converted from percentage sags to shear moduli as described above. In each case the results approximate closely to a straight line.

The curves shown in Fig. 1, and those mentioned previously[4,5,13,14], can be fitted by a general equation of the form:

$$R = AP^n - B \qquad (1)$$

where R is the gel-strength, P the pectin concentration and A and B are parameters, provided that B is small compared with AP^n. The inclusion of the parameter B is necessary in order that a positive value of P be obtained when $R = 0$. Zero gel strength is taken as the strength at the limiting pectin concentration where a gel just forms or just fails to form[1].

From their results, Lampitt and Money[4,5] showed that the gel strength was proportional to the square of the pectin concentration. The slopes of the lines in Fig. 1 also indicate that the value of n in equation (1) is approximately 2. The apparent linear relationship between gel strength and pectin concentration, giving $n = 1$, observed by some workers[1,16,17], may be due to the limited range of pectin concentration studied.

The values of the parameters A and B will depend upon a number of factors, including the pH and soluble solids content of the gel, and on the jelly-forming capacity (or 'grade'[9,18]) of the pectin (cf. Grover[2]). Data obtained with six commercial powder pectins from various sources, made into gels by the 'Teepol'-gel procedure[11], indicate a good correlation between the grades of the pectins and the values of $\sqrt{A}$ (correlation coefficient 0·906). No correlation was found between the values of the parameter B and the corresponding grades of the pectins.

Photochlorination of Chloroform

We have shown recently that the chain-breaking steps in the gas phase photochlorination of C_2Cl_4 and of C_2HCl_3 [1] are:

$$\left.\begin{array}{llll} C_2Cl_5 & + \ Cl & \rightarrow \text{inactive products} & (7) \\ 2C_2Cl_5 & & \rightarrow \text{inactive products} & (8) \end{array}\right\} \quad \text{(i)}$$

(The numbers of the reactions have been chosen so as to have a uniform representation of all reactions: vide infra (ii); the products of these reaction steps are not known with certainty.)

Reaction (8) is predominant in the case of C_2Cl_4 up to 430° K. and (7) between 520° and 560° K. In the substitution reaction below 400° K., (7) and (8) are of equal importance; above 430° K., dehydrochlorination (ref. 1, IV) occurs, with (7) as the chain-breaking step.

We have now studied the photochlorination of chloroform, and have applied to this case the general mechanism (ref. 1, II) proposed some time ago and which permitted us to explain all the results for the system C_2Cl_4, C_2HCl_3, Cl_2 thus:

$$\left.\begin{array}{llllll} & Cl_2 & \xrightarrow{k_1} 2Cl & & (1) & \\ Cl & + \ CHCl_3 & \rightleftharpoons CCl_3 & + \ HCl & (2) & (4) \\ CCl_3 & + \ Cl_2 & \rightleftharpoons CCl_4 & + \ Cl & (3) & (5) \\ 2Cl & + \ M & \rightarrow Cl_2 & + \ M & (6) & \\ Cl & + \ CCl_3 & \rightarrow CCl_4 & & (7) & \\ & 2CCl_3 & \rightarrow C_2Cl_6 & & (8) & \end{array}\right\} \quad \text{(ii)}$$

All results have been treated by van't Hoff's method, plotting log v_t vs. log $p(Cl_2)_t$, where v_t is the rate and $p(Cl_2)_t$ the pressure of chlorine at the time t. This yields n, the reaction order in the course of the reaction, and v_0, the initial rate of the reaction. A plot of log v_0 vs. log $p(Cl_2)_0$ for different initial chlorine pressures ($p(Cl_2)_0$) gives the reaction order $n_0 = 3/2$ in the initial conditions[2] (Fig. 1); n increases slightly with $p(Cl_2)/p(CHCl_3)$, having the value 3/2 for $p(Cl_2)/p(CHCl_3) = 1$. This result would be expected from the reaction sequence (ii), if, as in the case of C_2HCl_3, reactions (4), (5) and (6) are neglected and the steady-state treatment is applied:

$$v = I_a^{1/2}\, k_3(Cl_2)/[k_3k_7(Cl_2)/k_2(CHCl_3) + k_8]^{1/2} \qquad \text{(iii)}$$

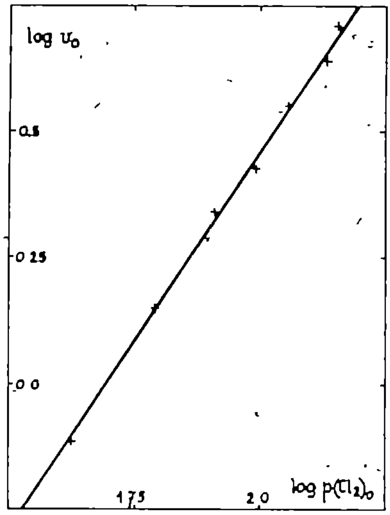

Fig. 1. Reaction order $n_0 = 3/2$ from a plot of log v_0 vs. log $p(Cl_2)_0$ for a ratio $p(Cl_2)_0/p(CHCl_3)_0 = 2$. v_0 in (mm. mercury) sec.$^{-1}$; p_0 in (mm. mercury). Measurements at 343° K.

Table 1

Reaction	log $k_2/k_6^{1/2}$	log $(k_3k_4/k_7)^{1/2}$	log $k_4(k_2/k_6k_7)^{1/2}$
$Cl_2+C_2Cl_4$ (ref. 1, III)	$-660/T+2\cdot 66$	—	$+1{,}725/T-1\cdot 20$
$Cl_2+C_2Cl_4+C_2HCl_3$ (ref. 1, VI)		—	—
$Cl_2+C_2HCl_3$ (ref. 1, VI)		$-675/T+3\cdot 05$	—
$Cl_2+C_2HCl_5$ (ref. 3)	$-1{,}060/T+3\cdot 71$	—	—
Cl_2+CHCl_3	$-1{,}156/T+3\cdot 96$	$-1{,}735/T+6\cdot 03$	—
Cl_2+CO (ref. 4)	—		$182/T+1\cdot 1$

According to (iii), a plot of $(Cl_2)^3/v^2$ vs. $(Cl_2)/(CHCl_3)$ yields a straight line, as shown in Fig. 2; the slope gives k_7/k_2k_3 and the intercept with the ordinate axis k_6/k_2^2. The plot of log k vs. $1/T$ (between 343° and 428° K.) gives the activation energy and the frequency factor. The results are collected in Table 1 and compared with the corresponding rate-constants for other substances.

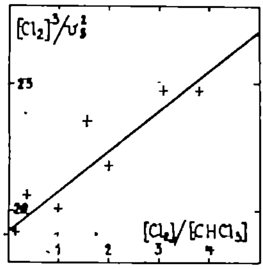

Fig. 2. Rate-constants k_7/k_2k_3 and k_6/k_2^2 from a plot of $(Cl_2)^3/v_s^2$ vs. $(Cl_2)/(CHCl_3)$. Concentrations in mole. l^{-1}; v_s in mole. l^{-1}) sec.$^{-1}$. Measurements at 380° K.

We conclude that:

(*a*) The van't Hoff method is a much more reliable and sensitive test for the mechanism of complex reactions than the integration methods used previously[5-7].

(*b*) The proposed scheme gives a better general picture of photochlorination reactions than the mechanism proposed by Schumacher[5,8] with chain-breaking step (8) for the reaction of C_2HCl_5 and

$$2CCl_3 + Cl_2 \rightarrow 2CCl_4$$

in the case of $CHCl_3$, this latter step being further in contradiction with Rollefson and Newton's observation[9] of C_2Cl_6 formation in the photochlorination of $CHCl_3$.

(*c*) We have also studied the competition reactions in a mixture of chlorine, chloroform and tetrachlorethylene. In this case the rate-equation is given by:

$$v = I_a^{1/2}(Cl_2)(k'_3 + k_3\beta/\alpha)(k'_7\beta + k'_6 + k_6\beta^2/\alpha^2 + k_9\beta/\alpha)^{-1/2} \quad \text{(iv)}$$

where the prime indicates the steps of the substitution reaction:

$$\alpha = (Cl)/(C_2Cl_5) = (k_3(Cl_2) + k_4)/k_2(C_2Cl_4) \text{ and}$$
$$\beta = (Cl)/(CCl_3) = k'_3(Cl_2)/k'_2(CHCl_3)$$

(9) is a new chain-breaking step:

$$CCl_3 + C_2Cl_5 \rightarrow \text{inactive products} \quad (9)$$

Table 2

Reaction	log k'_2/k_2	log k'_3/k_3
$C_2Cl_4 + Cl_2$	—	$-510/T-2\cdot 0$
$C_2Cl_4H + Cl_2$	—	
$C_2Cl_4H + C_2Cl_4 + Cl_2$	$-1{,}300/T+2\cdot 45$	
$C_2HCl_5 + Cl_2$ (ref. 3)	—	$-1{,}006/T-1\cdot 07$
$CHCl_3 + C_2Cl_4 + Cl_2$	$-1{,}540/T+3\cdot 20$	$-1{,}668/T+0\cdot 18$

which is, in fact, predominant. Thus this competition permits one to measure k'_2/k_2 and k'_3/k_3; the results are shown in Table 2[10].

Complementary information on rate-constants of elementary reactions of chlorine atoms and chlorinated hydrocarbon radicals can now be obtained by continuing this study, based on a general scheme of type (ii) of photochlorination reactions, including measurements in intermittent light, and of competition reactions (ref. 1, VI).

We thank Prof. P. Goldfinger for valuable discussions, the Institut pour la Recherche Scientifique dans l'Industrie et l'Agriculture and the Centre National de Chimie Physique Moléculaire (Brussels) for financial assistance.

In the previous communication[1] in Table 1, rate-equation A should read $(I_a^{1/2}\, k_2/k_6^{1/2})(Cl_2)$ instead of $(Cl_2)^{3/2}$. All rate-constants are in (litre mole^{-1})$^{n-1}$ sec.$^{-1}$.

Differentiation of α-Amino-Acids and Amines by Non-Enzymatic Transamination on Paper Chromatograms

Crumpler and Dent[1] devised a method based on the immobility of the copper complexes of the amino-acids in some solvent systems to differentiate α-amino-acids from other amines on paper. The behaviour of β-amino-acids is ambiguous, since they also form stable copper complexes, but occasionally yield visible mobile spots with ninhydrin[1]. α-Amino-acids[2,3] but not β-alanine[4] or most other amines undergo transamination with pyridoxal in aqueous solutions. Since the pyridoxamine formed gives a characteristic deep orange colour with ninhydrin it appeared that adaptation of the reaction to paper might provide a convenient means of differentiating α-amino-acids from β-amino-acids and other amines.

The mixture to be analysed is applied to duplicate papers, and the chromatograms are developed with the desired solvent. We have usually used the upper layer of *n*-butanol–acetic acid–water (4 : 1 : 5) as the developing solvent, although the reaction appears largely independent of the solvents used. After drying in air to remove the solvent, one chromatogram is sprayed with a solution prepared by dissolving 0·25 gm. pyridoxal hydrochloride in 100 ml. of 95 per cent ethanol and adding sufficient alkali so that an aliquot diluted in water has a *p*H of 5·5, then again drying in air at room temperature. Compounds that contain the primary amino group appear yellow at this stage, presumably due to Schiff's base formation; no such colour was seen with secondary (for example, proline, N-methylglycine) or tertiary (N,N-dimethylglycine) amines. The chromatogram is now heated at 90° for 10 min. to effect transamination. Both it and the control chromatogram are now sprayed with 0·25 per cent ninhydrin in acetone, and allowed to stand at room temperature or heated for 5 min. at 90°. The changes in colour observed under these conditions are summarized in Table 1.

Table 1. COLOURS OBTAINED WITH REPRESENTATIVE AMINES ON NINHYDRIN-TREATMENT BEFORE AND AFTER TREATMENT WITH PYRIDOXAL

Compound*	Colour formed		
	Without pyridoxal	With pyridoxal	
	5 min., 90° C.	5 min., 24° C.	5 min., 90° C.
Pyridoxamine	orange	orange	orange
α-Amino-acids and their peptides†	purple or blue-purple	orange	orange-purple
α-Substituted α-amino-acids‡	purple	orange	orange-purple
β-Amino-acids and their peptides§	purple	light yellow	purple or purple-brown
γ-Aminobutyric acid	light purple	light yellow	purple
Agmatine, ethylamine, histamine, putrescine, taurine, tryptamine and tyramine	purple or purple-grey	yellow	purple or grey
Benzylamine	purple	light yellow	orange-blue
Serine-3-phosphate and threonine-3-phosphate	purple	purple	purple

* 5 μl. of an *M*/50 solution of the test compounds were used. This is much higher than the sensitivity of the method requires.

† Amino-acids: Alanine, α-aminobutyric acid, α-alanine ethylester, aspartic acid, asparagine, arginine, citrulline, cysteic acid, cystine, diaminopimelic acid, glutamic acid, glycine, histidine, homoserine, isoleucine, leucine, lysine, methionine, ornithine, phenylalanine, phenylglycine, serine, threonine, tryptophan, tyrosine, valine. Peptides: Alanylglycylglycine, glycylalanine, alanylglycine, glycylasparagine, leucylglycine.

‡ α-Aminoisobutyric acid, α-methylserine, α-methylisoserine.

§ β-Alanine, β-aminobutyric acid, β-alanylglycine, β-alanylleucine, β-alanylhistidine.

It is evident that the sequential treatment with pyridoxal and ninhydrin provides a convenient means for distinguishing α-amino-acids (or their peptides) from β-amino-acids and other primary amines. The former transaminate with pyridoxal to yield pyridoxamine and an orange colour with ninhydrin; the latter with the one exception noted (benzylamine) do not transaminate at 90° to an extent sufficient to alter materially the colour obtained with ninhydrin. Many of the α-amino-acids develop no colour with ninhydrin within 5 min. at room temperature whereas pyridoxamine does; consequently the colour reactions exhibited by α-amino-acids on the pyridoxal-treated chromatogram under these conditions are not complicated by development of the purplish tint due to residual amino-acid that appears on heating. On the other hand, pyridoxal inhibits the rate of colour development of amines with ninhydrin, presumably because of formation of the Schiff's bases, and it is necessary to heat to obtain colour development with these compounds. It is interesting to note that α-amino-acids which lack an α-hydrogen atom (for example, α-methylalanine) and hence cannot transaminate by the mechanism postulated for unsubstituted α-amino-acids[3] nevertheless give an orange spot indicative of pyridoxamine formation. Separate investigation has shown that decarboxylation accompanied by partial transamination occurs in these instances[5]; the reaction provides a model for the enzymatic decarboxylation of amino-acids by pyridoxal phosphate proteins. Although appropriate metal ions catalyse transamination reactions of this type in aqueous solutions[2,3], their addition is not required for, and does not alter the course of, the reaction on paper under the conditions used here. Relatively little or no formation of pyridoxamine occurs with serine-3-phosphate and threonine-3-phosphate. This is to be expected since α,β-elimination reactions to yield nitrogen-free products predominate with these amino-acids, as reported elsewhere[6]. The reactions of the amino-acids with pyridoxal on paper correspond closely to those previously observed between amino-acids and keto-acids under similar conditions[7,8].

The procedure outlined here permits further refinements. By reducing the pyridoxal concentration, or by incorporating this reagent into the ninhydrin spray, it should be possible to obtain colours varying from bluish-purple to orange with the various α-amino-acids, depending upon the ease with which they undergo transamination. Examination under ultra-violet light of the pyridoxal-treated chromatogram, before ninhydrin treatment, reveals distinct differences in the fluorescent characteristics of certain of the Schiff's bases obtained. Finally, the method in reverse (pyridoxamine spray followed by ultra-violet examination or ninhydrin-treatment) can provide a means for detection of α-keto-acids on papergrams. In this application, however, the procedure has proved less sensitive than chromatography of the keto-acid 2,4-dinitrophenylhydrazones.

This work was supported in part by a grant from the U.S. Public Health Service.

Non-specific Hydroxylation of Aromatic Amino-Acids by an Insect Cuticle

DURING an examination of the amino-acid composition of the larval cuticle of the blow-fly, *Calliphora vomitoria*, it was found that phenylalanine and tyrosine were readily removed by extraction with water at 50° C. for 2 hr. Surprisingly, however, these amino-acids could not be recognized in the extract.

Instead, alanine and ninhydrin-negative diphenolic compounds were found. This observation suggested that the cuticle is capable of hydroxylating aromatic amino-acids in a manner similar to the action of the artificial system studied by Dalgliesh[1].

To explore this possibility further, larval cuticles in batches of twenty were cleaned by scraping, extracted in water, and then incubated in 0·1 per cent phenylalanine solution. After 24 hr. the solution was made slightly acid with sulphuric acid and extracted with peroxide-free ether. The ether was removed by evaporation, and the solid residue taken up in 10 per cent *iso*-propyl alcohol and examined chromatographically. Butanol–acetic acid–water (4 : 1 : 5), *m*-cresol–acetic acid–water (50 : 2 : 48), and benzene–acetic acid–water (2 : 2 : 1) were used as solvents. The chromatograms showed ninhydrin-negative silver-reducing spots indistinguishable from those produced by hydroquinone and catechol, and their identity was further established by the fact that they gave the same reactions as these compounds when tested with the following reagents: Ehrlich's reagent, ferric chloride, Roux's sucrose reagent, Pauly's reagent, and Folin and Ciocalteu's reagent.

Similar results were obtained when cuticles were incubated with tyrosine, and the cuticles were also found to be capable of forming hydroxylated products when tryptophan was used as substrate.

These observations indicate the possibility that larval cuticles may contain hydroquinone and catechol. Five hundred cuticles were therefore cleaned and extracted with hot absolute ethanol for six hours, and the extract concentrated and examined chromatographically. In accordance with expectations hydroquinone and catechol were shown to be present.

The presence of deaminated dihydroxyphenols in the larval cuticle must clearly be taken into account in studying the process of puparium formation, and in the full account of these observations which is being prepared evidence will be submitted showing that hydroquinone plays a predominant part in the tanning process by which the larval cuticle is hardened.

Identification of Edible Oils and the Detection of Oil Adulteration by Differential Infra-red Spectroscopy

A RECURRING problem in the food enforcement field is detecting the adulteration of butter and olive oil with other fats and oils. Many methods of detection have been devised, but most of them lack either sensitivity or speed.

Infra-red spectroscopy has been widely used for the detection and identification of organic materials but has not been used for the identification of oils or fats, because their spectra are similar. However, applying differential spectroscopy[1], minor differences in the spectra of fats and oils are accentuated, permitting the detection of one oil in the presence of another. Other applications of infra-red spectroscopy to the field of fats and oils are reviewed by O'Connor[2,3].

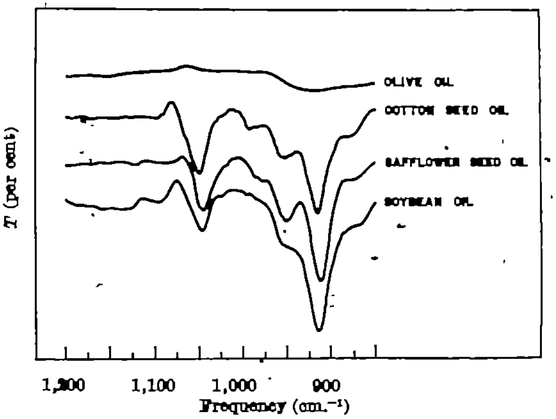

Fig. 1. Differential spectra of olive, cotton seed, safflower seed, and soybean oils with olive oil as reference

The apparatus used for this investigation was a Perkin–Elmer Model 21 double-beam infra-red spectrometer which measures the differences in absorbance between two light beams. The instrument was equipped with sodium chloride cells of 1 mm. path-length, and was operated with a fixed slit of 300 microns at a speed of 100 cm.$^{-1}$/min. over the region 1,200–900 cm.$^{-1}$.

A solution containing 10 per cent w/v of pure olive oil in carbon tetrachloride is placed in both the reference and sample cells. With the cells in place, the instrument is adjusted to read approximately 75 per cent transmission at 900 cm.$^{-1}$ with the beam trimmer. (The pen is set at this point on the chart so that deviations may be indicated from this value in either direction.) The spectrum is then recorded over the range 1,200–900 cm.$^{-1}$. Under these conditions the pen-trace obtained is essentially a straight line since there is no difference between the spectral absorption in the two beams. The sample cell is then filled with a 10 per cent w/v solution of the oil under examination while leaving the pure olive oil solution in the reference beam. The spectrum is recorded over the same range using the same

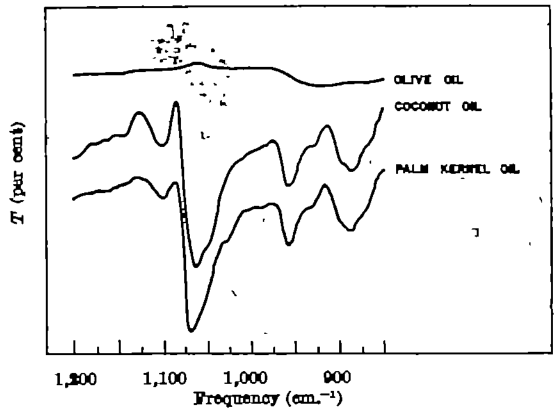

Fig. 2. Differential spectra of olive, coconut and palm kernel oils with olive oil as reference

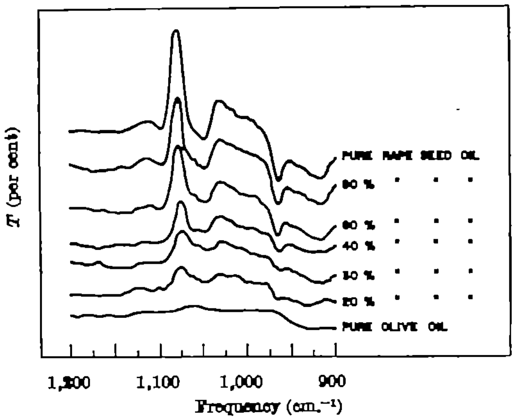

Fig. 3. Differential spectra of olive and rape seed oils and their mixtures with olive oil as reference

chart paper. Differences in the spectra of the two oils, which are not apparent by normal recording, are clearly indicated by deviations above and below the reference spectrum. These deviations are characteristic of the type of oil, and in some cases may be used for identification purposes.

Fig. 1 shows the differential spectra of olive, cotton seed, safflower seed and soybean oils relative to olive oil in the reference beam. Similarly, Fig. 2 shows the differential spectra of olive, coconut and palm kernel oils against olive oil. In both figures the percentage transmission scale has been displaced for each spectrum in order to permit the presentation of several spectra in the same figure.

The differential spectral procedure was also applied to mixtures of oils. Fig. 3 shows the differential spectra for mixtures of olive and rape seed oils relative to olive oil. As little as 20 per cent of rape seed oil may easily be detected in olive oil by this method. A similar sensitivity has been attained for the detection of several other oil mixtures.

Using this procedure, more than two hundred samples of olive oil have been examined for adulteration. Rape seed oil was detected in several samples, and its presence confirmed by isolation and characterization of the erucic acid. All olive oil samples found to be pure by the infra-red procedure were shown to be free of adulteration by all other methods tried.

The correlation between the various peaks and depressions in the differential spectra with the chemical composition of the oil has not been completed, but the peak at 1,078 cm.$^{-1}$ which is apparent in the rape seed – olive oil mixtures appears to be proportional to the erucic acid content of the rape seed oil.

This differential infra-red technique also shows promise for the detection of foreign fats in butter fat, and can be used for the rapid identification of unknown oils. A full report on this work will be published elsewhere.

Influence of Ion Exchange on Size and Shape of Chain-like Polyelectrolyte Molecules

ON conversion of the sodium salt of alginic acid (poly-*d*-manuronic acid) into the magnesium salt, a marked alteration of molecular weight and viscosity properties takes place, as shown by the figures in Table 1. The molecular weights were determined by light scattering and refractivity measurements (λ = 536 and 446 mμ, angular scattering dependence, in some tests, between 135 and 25°, 19 angles), and the viscosities were measured in Flory and Couette viscometers, the rate of shear being varied from 0·4 to 2,500 sec.$^{-1}$. In most experiments the solvent was an unbuffered aqueous solution of, respectively, 0·100 *M* sodium chloride and 0·0200 *M* magnesium chloride, *p*H about 5, but some of the viscosity tests were also made in solutions of different ionic strength and in the presence of sodium or magnesium veronal buffers, *p*H = 7·43.

Table 1

	Weight average molecular weight × 10^{-3} (25 ± 2°)	Intrinsic viscosity 100 cm.^{3} sol./gm. (25 0°)	Influence of rate of shear on viscosity at low ionic strength
Sodium alginate	110 ± 20	9·34 ± 0·09	Relatively large
Magnesium alginate (I)	1,250 ± 300	6 86 ± 0·07	Small
Magnesium alginate (II)	350 ± 100	7·80 ± 0 10	

Magnesium alginate (I) was prepared from a non-oriented sodium alginate gel by treatment with 2 *M* magnesium acetate, the alginate concentration being 0·5 gm.-equiv./l. reaction mixture. Magnesium alginate (II) was obtained by dialysing solutions of the same sodium alginate, 0·015–0·05 gm.-equiv./l., against 0·02 *M* magnesium chloride. On reconversion of (I) into sodium alginate a material of average molecular weight (96 ± 8) × 10^3 was obtained.

The results indicate that the bivalent magnesium ions combine with carboxylate groups of the alginate to form inter- and intra-molecular salt bridges, while the monovalent sodium ions are not capable of producing such links. The relative number of inter- and intra-molecular bridges must depend on: (*a*) the degree of orientation of the alginate chains at the moment of the sodium magnesium ion exchange; (*b*) the concentration conditions. In the magnesium alginates (I) and (II), both inter- and intra-molecular bonds appear to play a part: the former are made responsible for the large molecular weights, while the latter bring about a more compact configuration, which in turn gives rise to relatively small intrinsic viscosities and rate of shear dependence.

A detailed description of these experiments and molecular dimensions will be given elsewhere.

We are grateful to Prof. J. A. V. Butler who made it possible for us to use the Couette viscometer at the Chester Beatty Research Institute.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, November 18

British Occupational Hygiene Society (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.15 p.m.—Prof. T. F. Hatch (University of Pittsburgh): "Human Engineering".

British Computer Society (at the L.C.C. County Hall, London, S.E.1), at 6.15 p.m.—Mr. A. J. Barnard: "Applications of a Computer to the work of Norwich Corporation and Plans for Future Use".

Institute of Metal Finishing (at the Northampton Polytechnic, St. John Street, London, E.C.1), at 6.15 p.m.—Mr. V. F. Henley: "Production of Multi-Coloured Designs of Anodised Aluminium".

Royal Institute of Chemistry, London Section (at Erith Grammar School, Avenue Road, Erith), at 7. p.m.—"Careers in Chemistry".

Tuesday, November 19

University of London (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 1.15 p.m.—Dr. H. Kalmus: "Evolution Observed".*

Institution of Electrical Engineers, Measurement and Utilization Sections (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "The Measurement of Dynamic Characteristics of Electrical Machines", opened by Mr. J. M. Layton, Mr. V. N. Manohar and Mr. R. A. Stevens.

Plastics Institute, London and District Section (at the Wellcome Building, 183–193 Euston Road, London, N.W.1), at 6.30 p.m.—Dr. P. L. Clegg: "The Flow Properties of Polythene and their Effect on Fabrication".

Society for Visiting Scientists (at 5 Old Burlington Street, London, W.1), at 7.30 p.m.—Discussion Meeting on "Science and Furniture". Chairman: Sir Gordon Russell, C.B.E., M.C. Speakers: Mr. J. C. Pritchard, O.B.E., Dr. W. F. Floyd and Monsieur René Varin, C.B.E.

British Glaciological Society (joint meeting with the Herbertson Society, at the School of Geography, The University, Mansfield Road, Oxford), at 8.15 p.m.—Mr. J. A. Heap: "Glaciology in the Modern World".

Wednesday, November 20

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Prof. M. E. L. Mallowan: "Excavations at Nimrud, 1957".

Royal Meteorological Society (at 49 Cromwell Road, South Kensington, London, S.W.7), at 5 p.m.—Mr. H. Riehl and Mr. D. Fultz: "Jet Streams and Long Waves in a Steady Rotating-Dishpan Experiment—Structure of the Circulation"; Mr. G. H. Tucker: "Evidence of a Mean Meridional Circulation in the Atmosphere from Surface Wind Observations".

Royal Statistical Society (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.15 p.m.—Sir Harry Campion, C.B., C.B.E.: "Recent Developments in Economic Statistics" (Presidential Address).

Eugenics Society (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Symposium on "Problem Families". Speakers: Mr. Paul Cadbury, C.B.E., Mr. M. MacGregor, and Miss Catherine Wright.*

Royal Institute of Chemistry (at the Royal Society of Health, 90 Buckingham Palace Road, London, S.W.1), at 6.30 p.m.—Annual General Meeting.

Society of Chemical Industry, Corrosion Group (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Mr. W. F. Higgins: "Protection of Magnesium Alloys".

Oil and Colour Chemists' Association (at the Royal Society of Tropical Medicine and Hygiene, Manson House, 26 Portland Place, London, W.1), at 7 p.m.—Dr. F. A. Champion: "The Painting of Aluminium and its Alloys".

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 7.45 p.m.—Concert of Music and Folk Dances of India.*

Thursday, November 21

Linnean Society of London (at Burlington House, Piccadilly, London, W.1), at 4.15 p.m.—Symposium on "Water Pollution" opened by Dr. Hynes, Dr. Butcher, Mr. Pentelow, Mr. Westlake, Mr. Pettett and Major J. L. Spicer.

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Sir Eric Rideal, F.R.S., and Mr. F. H. Taylor: "On Hæmolysis and Hæmolytic Acceleration"; Mr. D. A. T. Dick and Miss Leah M. Lowenstein: "Osmotic Equilibria in Human Erythrocytes Studied by Immersion Refractometry".

Institution of Mining and Metallurgy (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—General Meeting.

University of London (at King's College, Strand, London, W.C.2), at 5.30 p.m.—Mr. C. K. Haswell: "The Development of Power in the Service of Man".*

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. J. H. Humphrey: "Antibody Metabolism".* (Eleventh of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation. Further lectures on November 26, 28 and December 3 and 5.)

University of London (in the Chemistry Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. Raymond Irwin: "The Golden Chain—a Study in the History of Libraries". (Inaugural Lecture.)*

Institution of Electrical Engineers, Education Discussion Circle (at Savoy Place, London, W.C.2), at 6 p.m.—Discussion on "High-Voltage Experiments" opened by Prof. E. Bradshaw.

Society of Chemical Industry, Road and Building Materials Group (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Mr. B. J. Gee: "Producer-Gas Fired Lime Kilns".

Institution of Mechanical Engineers, Hydraulics Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 5.45 p.m.—Discussion on "Instrumentation for the Measurement of Fluid Pressure".

Chemical Society (at Burlington House, Piccadilly, London, W.1), at 7.30 p.m.—Scientific Papers.

University of London (in the Swanley Hall, Wye College, Wye, near Ashford, Kent), at 8.15 p.m.—Mr. M. Westmacott: "Mountaineering in the Peruvian Andes".*

Friday, November 22

Royal Astronomical Society (at Burlington House, Piccadilly, London, W.1), at 4.15 p.m.—Geophysical Discussion on "Fossil Evidence for Wind Directions". Chairman: Prof. P. A. Sheppard. Speakers: Mr. R. A. Bagnold, Mr. N. D. Opdyke, Prof. S. K. Runcorn and Prof. F. W. Shotton.

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. W. H. McCrea, F.R.S.: "Physics and the Astronomical Universe".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer (preferably with a special interest in inorganic chemistry) in Chemistry—The Secretary, Birkbeck College, Malet Street, London, W.C.1 (November 23).

Lecturer (with special qualifications in physical chemistry); and an Assistant Lecturer (Grade B, with special qualifications in inorganic or organic chemistry) in the Department of Chemistry—The Clerk to the Governors, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (November 25).

Research Assistant (graduate suitably qualified for registration for the Ph.D. (Internal, London) degree) in the Department of Chemistry—The Head of the Department of Chemistry, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (November 25).

Research Fellow in the Research Department of the Institute of Education; the field of investigation will be "Science and Education"—Prof. E. A. Peel, The University, Edmund Street, Birmingham (November 25).

Junior Research Fellow in Soil Science, to carry out investigations of problems relating to soil structure—The Secretary, The University, Aberdeen (November 27).

Assistant Lecturer or Lecturer in Veterinary Preventive Medicine—The Registrar, The University, Liverpool (November 30).

University Lecturer (preferably with qualifications in applied thermodynamics) in Mechanical Engineering—The Secretary, The University, Aberdeen (November 30).

Reader in Mathematical Statistics in the Research School of Social Sciences, Australian National University—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, December 2).

Lecturer or Assistant Lecturer (graduate in metallurgy or pure science, and preferably with experience in production metallurgy) in Metallurgy—The Registrar, The University, Leeds 2 (December 9).

University Lecturer in Statistics—The Secretary of the Appointments Committee of the Faculty of Mathematics, Arts School, Bene't Street, Cambridge (December 11).

Lecturer in Psychology at the University of New England, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, December 13).

Senior Lecturer in the Department of Geophysics, University of the Witwatersrand, Johannesburg, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa, December 15).

Lecturer in Pathology at Makerere College, University College of East Africa—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (December 19).

Senior Research Fellow; Research Fellow; Junior Research Fellow; and a Research Electronics Engineer on the staff of the Nuclear Physics Research Unit, Department of Physics, University of the Witwatersrand, Johannesburg, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa, December 31).

Lecturer in Microbiology at the University of Cape Town, South Africa for duties which will include lectures and the supervision of practical classes in mycology and protozoology—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa, January 15).

Senior Fellow; and a Research Fellow in the Department of Geophysics, Research School of Physical Sciences, Australian National University—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, W.C.1 (January 17).

Chair of Theoretical Physics in the Department of Physics, University of Cape Town, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa, January 31).

Demonstrator in the Department of Geology—The Secretary of the Appointments Committee, Department of Geography, The University, Downing Place, Cambridge (January 31).

Lecturer in Physics at the University of Cape Town, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa, January 31).

Senior Lecturer or Lecturer in Animal Husbandry in the Faculty of Agriculture, Makerere College, The University College of East Africa—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (February 14).

Abstractor (with a degree in agriculture or natural science and a knowledge of languages)—The Director, Commonwealth Bureau of Pastures and Field Crops, Hurley, Berkshire.

Assistant Lecturer, Grade B (with an honours degree or equivalent and preferably with teaching and industrial or research experience), in Chemistry—The Registrar, Hatfield Technical College, Roe Green, Hatfield, Herts.

Assistant Professor (preferably with a good background in analytical, inorganic or physical chemistry) in General Chemistry—Lester Kieft, Department of Chemistry, Bucknell University, Lewisburg, Pa., U.S.A.

Chair of Mathematics, tenable at Bedford College—The Academic Registrar, University of London, Senate House, London, W.C.1.

Jeyes' Research Fellows (2) (suitably qualified graduates) in the Biology Department, for research on (a) biological, and (b) physico/chemical aspects of chemical soil sterilization—The Registrar, University College of North Staffordshire, Keele, Staffs.

Lecturer (preferably with a higher degree and research interests) in Inorganic Chemistry—The Secretary, Sir John Cass College, Jewry Street, London, E.C.3.

Scientific Officers (with a first- or second-class honours degree in physics and preferably experience in nuclear radiation measurement), to work in a Section concerned with a wide range of measurements of nuclear and allied radiations—The Senior Recruitment Officer, Atomic Weapons Research Establishment, Aldermaston, Berkshire, quoting Ref. 1613/34.

Senior Lecturer (man), to be responsible for science students training to teach mainly chemistry and physics in Technical Colleges—The Director, Training College for Technical Teachers, Queen Street South, Huddersfield.

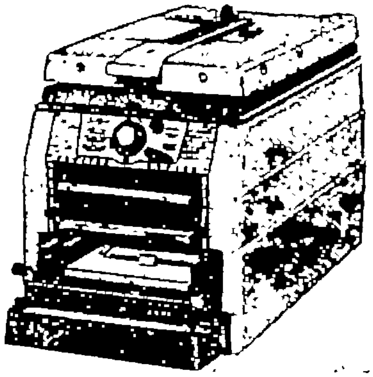
"Where σ is stress, p is density and V is particle velocity . . ."

THE LANGUAGE OF PHYSICS is full of difficulties for the transcriber. It has a profusion of symbols, italics, superior signs and inferior figures. It annexes names and descriptions from many languages. It defeats the keyboard and confuses the typist.

But it cannot defeat the 'Verifax' Copier. Being based on a photographic process, the 'Verifax' Copier will transcribe everything on the original, whether it is printed, typed, handwritten or drawn. It is speedy, too — will give you three dry copies, ready for use, in less than a minute. It is compact, self-contained, and takes up little more desk space than a typewriter. Let us send you full details.



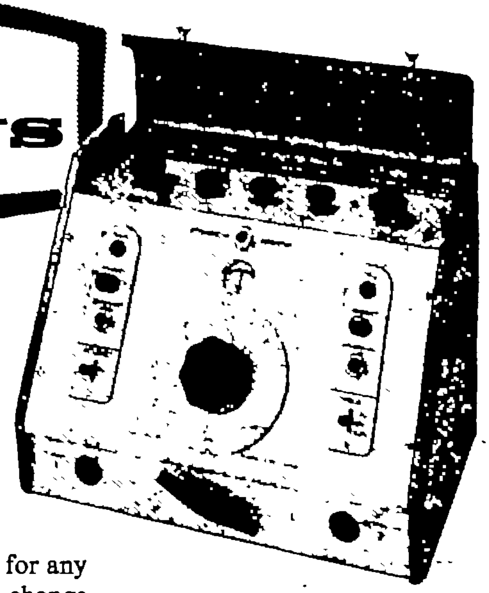
Particularly suitable for research departments and laboratories where written or printed material is often difficult to copy.

KODAK *Verifax* COPIER

Kodak Limited, Dept. 452, Kodak House, Kingsway, London, W.C.2

'Verifax' is a registered trade-mark

AUTOMATIC TITRATIONS



ARE easily carried out by the E.I.L. Automatic Titrimeter, Model 24. This instrument is fully automatic, switching itself off on reaching the pre-set end point.

Either the volumetric or the coulometric method may be used, and separate titration units for each type are available. Duplicated connections are provided on the Control unit.

The endpoint setting dial is calibrated in pH and in millivolts, and the equipment can be used for any type of chemical reaction producing a determinate change of e.m.f. The accuracy of titration is 0.05 c.c. in 50 c.c.

SCIENTIFIC AND TECHNICAL MAN-POWER IN BRITAIN

THE tenth annual report of the Advisory Council on Scientific Policy, covering the period July 1, 1956, to June 30, 1957*, again deals largely with the shortage of trained man-power in Britain which remains the chief limiting factor to scientific effort. During the year, however, the Council was also concerned with the balance and scale of the national effort in research and development in relation to national needs. The structure or organization of that effort is still under consideration, and the need for much more statistical information as to its magnitude is stressed; but the present report discusses chiefly the magnitude of the nation's research and development effort and its distribution, and questions of scientific man-power and its utilization, particularly those presented by the emigration of scientists and engineers and the Government's continued disregard of the Council's recommendations about scientific libraries.

The Advisory Council recognizes that accurate information as to the distribution of the effort in research and development in Britain is extremely difficult to obtain. The dividing lines between research, development and production are often arbitrary and indistinct, and even if adequate statistics were available, they would be liable to considerable error. Any attempt to apportion expenditure—or man-power—between teaching and research, which is inevitable in assessing the country's effort in fundamental research, is again necessarily arbitrary. Nevertheless, the Advisory Council rightly holds that, despite the uncertainties in statistics, the attempt should be made. Any figures obtained would give at least some order of magnitude to a general picture and might well indicate any gross deficiency or lack of balance.

The inquiries as to expenditure by industry on research and development on which the report on "Scientific and Engineering Man-power in Great Britain" (London: H.M.S.O., 1956) was based, and other inquiries of the universities and nationalized industries, indicate that in 1955–56 about £300 million was spent on research and development in Great Britain. Of this, £185 million (a figure which may be subject to an error of £40 million) was spent by private industry (but largely paid for by the Government), £4 million by the nationalized industries, and £5 million by the research associations. Government expenditure amounted to £65·5 million on defence research and development, and in the civil sector to £12·5 million by Government departments and £10 million by the research councils, including £1 million for the Agricultural Research Council and Medical Research Council units attached to universities. University research expenditure is estimated at £14·5 million and research expenditure by other organizations at £3·5 million, of which £2 million is on defence research.

The total expenditure on research and development in Britain thus corresponded to about 1·6 per cent of the gross national product (at market prices) for the year 1955, industry's own expenditure on research and development being about 0·8 per cent of the industrial output. These figures compare with an expenditure, estimated by the National Science Foundation for the United States as 1·5 per cent of the gross national product in 1953 and an industrial expenditure of about 1·9 per cent of net output. Since 1953, moreover, expenditure on research and development in the United States has risen more rapidly than the gross national product. Comparable figures are not available for Western European countries the economies of which are closer to that of Britain in pattern and scale, but the Advisory Council states that it understands that a number of such surveys are contemplated and that the United Kingdom is offering to assist through the European Productivity Agency.

Government expenditure on research and development during 1956–57 amounted to some £224 million (of which £177·5 million was on defence, or roughly 75 per cent of the total), and not counting the contribution from Government sources expended by the universities or the nationalized industries. Expenditure by the Atomic Energy Authority is included, both under defence research and under civil research and development, but without being distinguished. The estimates for defence research and development include some £16 million for expenditure on capital projects, sites, maintenance of buildings, and £7 million for work done on a repayment basis for private industry and other organizations. The estimates of university expenditure are based essentially on an analysis of published accounts for 1954–55, and in arriving at the figure of £9·8 million available to the universities for civil research from Government departments, including £7·5 million from the Treasury grant in aid of recurrent expenditure, it has been estimated that £4·3 million is spent on research in science and technology, £2·7 million on medical research and £0·5 million on agricultural and medical research. Since a further £2 million from Treasury grants for non-recurrent expenditure on capital works has been included, the total is again too high to give a true measure of recurrent expenditure; but, on the other hand, the exclusion of expenditure on research and development in overseas territories makes the figures included for Colonial research and development too low to give the full measure of the national effort in that field either under the Colonial Research Council or the Department of Scientific and Industrial Research.

---

* Annual Report of the Advisory Council on Scientific Policy, 1956–1957. Pp. 27. (Cmnd. 278.) (London: H.M. Stationery Office. 1957.) 1s. 4d. net.

While three-quarters of the expenditure on research and development was provided from Government sources, only about 30 per cent was actually carried out in Government or Government-controlled establishments. About 68·5 per cent of research and development was carried out by industry; but only 23 per cent was financed by industry, the rest being mainly in the form of defence contracts of various types. About 60 per cent of the total expenditure came under the heading of Government expenditure on defence research. Analysed according to the sectors in which it was carried out, Government expenditure on research and development accounted for 21·9 per cent of the total; civil research and development by the Government departments for 4·1 per cent and under the research councils for 3·3 per cent; by the nationalized industries, 1·3 per cent; by private industry, 61·7 per cent; by the research associations, 1·6 per cent; and by the universities, 4·8 per cent.

The man-power picture is similar. Of some 46,600 scientists and engineers estimated as engaged in research and development in 1955–56 in Great Britain, 4,900 were employed in the Defence departments, 1,500 on civil research in Government departments, 2,500 by the research councils, 2,500 by the Atomic Energy Authority, 1,000 in nationalized industries, 23,800 in private industry, 1,400 in the research associations, and 9,000 in the universities (assuming university teachers spend 50 per cent of their time on research), and including 5,300 graduate research students. Not far short of half were employed on defence work, either in Government establishments or in industry, although a significant proportion of the work done under defence contracts yields results of value to the development of civil industry and our export trade.

The analysis requires to be carried further and based on much fuller figures before we can say with any confidence that there is no lack of balance in our research effort and draw any sound conclusions as to its magnitude or distribution. On the figures presented here, it is no more possible than on those cited in last year's debates on the Department of Scientific and Industrial Research Bill to say that our effort in nuclear research, for example, is excessive or causing distortion. Nor, as the Advisory Council rightly observes, is it possible to lay down any proportion of the total national effort on research and development which should *a priori* be devoted to the civil sector. Determination of the actual amount which must be spent to secure that the country's defences are adequate rests on military and political considerations outside the Council's competence. Nevertheless, the figures it has collected seem to justify the considered view that the resources devoted to civil research and development have been, and still are, far too small for a country like Britain, the competitive position of which in world trade depends upon the economic development of new products and new processes, and where achievement of a rising standard of living depends mainly on success in increasing the productivity of the labour force.

The Advisory Council has for several years past been concerned with the possibility of increasing the scientific effort in the many industries where that effort is far too small, and the Department of Scientific and Industrial Research in particular is closely engaged with such problems. In the present report the Advisory Council does not discuss such problems further, but is concerned first with the transfer from defence to civil research and development which the cuts in defence should permit and with measures which might increase the effectiveness of research at the universities. It is hoped that some immediate improvement in the man-power situation will result from the absorption without delay into civil work of scientists and engineers released from defence work, and also that the major proportion of new graduates in science and engineering coming forward now and for some time to come, and suitable for research and development work, will go into civil industry. But the Council also recognizes that even with the 6 per cent increase in the output of qualified scientists and engineers in 1956 compared with 1955, and with a 20 per cent increase between 1954 and 1956 in the number of students entering the science and technology departments of universities, it must still be concerned to see that sufficient scientists become teachers to provide adequate grounding in mathematics and science for the larger number of children entering the secondary schools in 1958.

The Advisory Council was asked for advice as to the desirability of making greater use of Government defence research establishments for civil purposes. At present such work for other Government departments and private industry accounts for about 5 per cent of the work done in these establishments. The Advisory Council accepts the general position and agrees that such establishments could sometimes with advantage undertake civil work where it would otherwise be impossible to make full use of equipment, facilities or research teams. Nevertheless, the Advisory Council is undoubtedly right to urge that staff freed by the defence cuts should not in general be retained in defence establishments. It is entirely sound that civil research should be carried out so far as possible in civil establishments, and the Advisory Council is only disposed to admit the placing by firms of research contracts with defence establishments as promoting the use of more and more of our research potential in the interest of the civil sector of the economy.

The biggest and most important problem is likely to arise in industry, and the Advisory Council's fear that, in the short run, expansion in civil research and development may not be concomitant with the decrease in defence contracts is borne out by some of the disclosures in the report on industry and technical progress. The Council suggests that if the total civil research effort falls, the use of civil research and development contracts should be re-examined. Arrangements have been made as a result of recommendations in the Advisory Council's 1952–53 report for the Department of Scientific and Industrial Research to act as a central focus in all matters relating to the placing of development contracts by Government departments, to keep in touch with what is being done in other departments, to collect, evaluate and disseminate information about such projects, and to provide advice and assistance when required. So far the response has been small, but the Advisory Council is confident that the scheme should be useful.

If the Advisory Council is wise to seek to shift the balance in research effort from the Government sector to that of private industry and the universities, it rather surprisingly makes no comment on the slender efforts made by the nationalized industries. Somewhat surprisingly, too, it seems content to accept the present expenditure on scientific research in British universities as a reasonable proportion of the total efforts on research and development effort—5 per cent in 1955–56. Its figure of £14·5 million is reached after taking into account all data available through published university accounts, the research councils and the University Grants Committee, and it includes about £2 million from research contracts placed by Government with industry. The Advisory Council does not consider that this 16 per cent (compared with the 50 per cent out of 285 million dollars in American universities in 1953–54) represents any cause for alarm, although any marked increase in sponsored research would be most undesirable. Again, it disregards entirely the contribution from the colleges of technology, on which the Willis Jackson Committee rightly laid some stress, though it is here that the question of sponsored research might prove more difficult.

Some contract work is almost inevitable, and the Advisory Council goes to the root of the matter in pointing out that Government support of free scientific research in universities, through the Treasury grant, the research councils and the Royal Society, should always be at a level which permits university research to flourish without increasing resort to contract work—an observation which is equally valid in respect of research in the colleges of technology. In general, however, it accepts the proportion of the nation's scientific man-power engaged on research in the universities as reasonable, and while this view may well be open to challenge, the challenge will be the stronger if made when discussing the balance of research effort in the main fields of work, or possibly in reviewing the arrangements for co-ordination of effort into which the Advisory Council is still inquiring. In this connexion, indeed, it is pointed out that the universities will be severely taxed during the next ten years to find the staff and accommodation for the increasing load of undergraduate teaching; but that additional teaching staff in itself means additional university research, and the increased number of undergraduates should also lead to an increase in the number of postgraduate research assistants.

Meanwhile, however, the Advisory Council makes one comment of first-class importance in reference to the effectiveness of university research to which Sir George Thomson also referred trenchantly in his recent Fawley Foundation Lecture. It believes that the proportion of supporting staff to professional workers is too low, and that a substantial increase in the number of technicians employed would do much to increase the value and productivity of the research effort of the universities. Indeed, it is probable that there are few ways in which a comparatively small expenditure could do more to eliminate the waste of highly skilled man-power, and the Advisory Council might have done well to frame its conclusion in the form of a recommendation to the Lord President of the Council, or perhaps to the University Grants Committee. Left in its present form, it is unlikely to receive effective backing.

In commenting on the transfer of highly specialized man-power from defence to civil work, the Advisory Council refers to the grave danger that, unless efforts are made to assist highly qualified men to find new jobs which they will regard as satisfactory, emigration may increase, particularly to the United States and Canada, where there is a large unsatisfied demand for such men. During the year, the Council made inquiries from the universities, the Board of Trade, professional institutions and the immigration authorities in the United States and Canada as to the immigration of highly qualified scientists and engineers, and the subject is discussed in a separate section of the report. The indications are that, over the past seven years, 1950–56, about 190 postgraduate chemists and 145 postgraduate physicists left the universities to take employment or fellowships in the United States or Canada. These figures represent about 6 per cent and 10 per cent, respectively, of the average annual numbers of postgraduate chemists and physicists who left the universities during the last five of these years, and the number was greater in 1956 than in any previous year. In the same period, some 410 chemists and 130 physicists accepted postgraduate fellowships in the United States or Canada, about 40 per cent remaining there on completion of their fellowships; if the information obtained from four of the largest professional institutions is typical, about 8 per cent of the increase in membership in 1956 left the country that year. Figures of immigration into Canada and the United States indicate that the number of emigrants from the British Isles who described themselves as engineers took an upward turn in 1956 after falling between 1953 and 1955; and if inquiries about posts abroad indicate a serious intention to emigrate, there may be a big increase in the number of engineers who emigrate in 1957.

The evidence is not entirely consistent—a Gallup poll at Cambridge seemed to indicate that no more than 1 per cent were serious prospective emigrants, although three times as many would be considering emigration; the Advisory Council recognizes that its conclusions need checking by statistics collected on a more systematic basis and it has asked the Committee on Scientific Man-power to keep the situation under review. It also recognizes that to a certain extent emigration is beneficial to British interests, and if there were no current shortage, an increase in the movement would be welcomed, both in view of the growing need of the less-developed countries for technical assistance and because of the benefits to be reaped in return. As it is, the problem is to strike a balance, and the Advisory Council suggests further that factors which encourage young scientists and engineers holding fellowships or studentships in the United States or Canada not to return to Britain should, if possible, be removed; for example, if industry would arrange to set up an organization in the United States and Canada to interview graduates on behalf of United Kingdom employers the return flow might be increased. Again, it suggests that more British scientists and technologists should be encouraged to do postgraduate work in Europe, and that more publicity should be given to the fact that Department of Scientific and Industrial Research and some other fellowships can be held in Europe.

Higher salaries and better equipment and facilities for research in American universities are mentioned as the main inducements which attract young research students from United Kingdom universities; but otherwise the Advisory Council does not touch on the fiscal considerations stressed by the Chancellor of the Exchequer in his last Budget speech. If further inquiry should establish a continuing and substantial increase in the emigration of such highly trained professional men, the Advisory Council may well have to urge such considerations, among others, very strongly on the Government. It cannot leave the problem alone until, as with the failure to implement the Council's recommendations about scientific libraries, Britain's scientific and technological capacity is endangered.

In this matter of scientific libraries, the Council is again only able to report trifling progress. Although a unit has been set up by the Department of Scientific and Industrial Research to implement the planning of a National Scientific Lending Library, search is still being made for a suitable location outside London for a National Lending Library of Science and Technology. Agreement has been reached, in principle, for the transfer in due course of part of the collection of the Science Museum Library to the new National Library, but it appears that acquisition of a suitable site for erection of the National Reference Library of Science and Invention, in conjunction with a new Patent Office Library, is still under consideration. The Advisory Council repeats its warning that the needs which these libraries are intended to meet are continually growing, and that the longer action is deferred, the more difficult it will become to find adequate solutions to these problems of the dissemination and utilization of scientific information.

It is a pity that the bearing of these projects, and indeed of the conception of the Science Centre itself, both on the efficient utilization of scientific man-power and on the application of the results of research, has not been presented in such a way as to bring out the wastefulness and costliness of the Government's dilatoriness and inaction. The history of the whole project, its implications and possibilities, should make it plain where the responsibility lies and frustrate any attempt to make party political capital out of a dereliction of duty in which both political parties share. The over-riding lesson to be learned from the Advisory Council's latest report is in fact just this danger of allowing preconceived ideas or political doctrine to prevent the action to which impartial inquiry points. The wise use of the limited resources of Britain in research and development demands, indeed, accurate knowledge and sound judgment: it demands equally vision and determination, impartiality and courage.

MANAGEMENT IN INDUSTRY

Effective Industrial Management

By James L. Lundy. Pp. xviii + 588. (New York and London: The Macmillan Company, 1957.) 44s.

THIS is a remarkable book. Remarkable because, symbolically, it clearly shows why industry in the United States is so much more productive than in Britain; and because it deals with all aspects of management and nearly all in a highly competent matter. It is equally noteworthy because, unwittingly, the author has revealed the inadequacies of certain British publications which masquerade as authoritative works on some aspects of management studies.

The fundamental reason for the difference in productivity between American and British industry is brought out in the introduction to this book. In many colleges and universities in the United States the industrial engineering and management curricula include an introductory survey on management as a prerequisite for more specialized courses. This book has been prepared as a text for these introductory courses. Yet apart from the usual background material illustrating the development of modern methods of management, the book contains chapters on topics which even now are practised in comparatively few firms in Great Britain and which even so-called progressive firms are chary of introducing. These include certain accounting and budgetary controls, inspection and quality control, the latter including the use of statistics, various job evaluations, merit-rating and incentive schemes, operational research, inventory control and the means of evaluating purchasing performance. Their mere inclusion in an elementary text-book for introductory courses in management shows how much more objective is the American approach.

The second feature which makes this book so remarkable is its comprehensive nature. Sections are introduced dealing with all aspects of management including finance, sales, organization, research and development, production and maintenance, work study, materials handling, design, purchasing, production control, inspection, quality control, transport and all aspects of the personnel function.

With its American connotations the chapters dealing with the personnel function of management is of least relevance to British industry; the rest of the book could be used by any manager in a British firm wishing to improve his knowledge of particular functions or to strengthen his grasp of management as a whole. Lundy deserves high praise for the lucid way in which he has presented so many topics so authoritatively in such a short space.

Of the third reason which makes this book so remarkable little need be said. Until management is taken seriously as a subject worthy of study in graduate and postgraduate courses at universities, British text-books will continue to be written by men who are academically and intellectually inadequate. We have no comparable book to this in Britain; the need grows greater daily. T. H. Hawkins

EVERYMAN'S PARASITOLOGY

Animals Parasitic in Man

By Dr. Geoffrey Lapage. (Pelican Book No. A394.) Pp. 320+8 plates. (Harmondsworth, Mddx.: Penguin Books, Ltd., 1957.) 5*s*.

THERE is a deplorable lack of knowledge and much prejudice among the general public about the parasites afflicting mankind, and even the medical man, who is expected to treat the diseases caused by them, is not much better off, owing to the neglect of parasitology in the medical curriculum. The publishers and editors of the Pelican Medical Series have therefore performed a valuable service in producing a book on this subject written by a well-known parasitologist of wide experience and erudition. As stated in the foreword and preface, this book is intended for a wide range of readers, including not only educated laymen but also junior and senior members of the medical profession, as well as biologists in general.

Instead of a conventional systematic account of the animal parasites, the author has dealt with the subject in a comparative way, from the point of view of the gradual complication of their life-cycles and the patterns of host–parasite relations. This method of approach provides the reader with an evolutionary background to the natural history of parasitic infections.

In an introductory chapter the author defines the concept of parasitism in its various manifestations. In the next chapter a brief account is given of the main zoological subdivisions to which the animal parasites belong, followed by a discussion of different types of life-histories, hosts and modes of transmission of the infections. The following five chapters are devoted to parasites with monogenetic, digenetic and polygenetic life-cycles, comprising helminths and protozoa, the bionomics, structure and host–parasite relations of which are described in some detail. Separate chapters are allocated to malaria parasites and trypanosomes and the diseases caused by them, while in another an account is given of animals parasitic in or on the skin (fleas, lice, fly maggots and mites) and of blood-suckers, such as biting insects and ticks, as well as leeches and bats. In each case, essential anatomical structures of the parasite, its course of development and method of transmission, as well as its effect upon the host, are adequately described. Important features of this book are the illustrations and diagrams, which—with the appropriate captions—give a clear picture of the life-histories and bionomics of the parasites described in the text.

In the last two chapters Dr. Lapage considers the effect of a parasitic life upon the pathogens and the reactions of the host to infection (resistance and immunity), and winds up with a short discourse on the methods of control of infections.

The author has succeeded admirably in the task of providing an instructive and stimulating book suitable for every type of reader: to the non-scientist it opens a new and fascinating field of knowledge, while the medical man and biologist are introduced to the essentials of parasitology, and even the professional parasitologist will find it useful as a 'refresher'. Unlike some other writers of popular science books, Dr. Lapage has avoided vulgarization, for, although written in simple non-technical language, which can be understood by the non-initiated reader, the biologist can rest assured that the recognized scientific terminology and the exact zoological nomenclature are adhered to throughout the text.

Those readers whose interest has been sufficiently aroused will find at the end of the book a useful list of references for further reading. There is also a detailed subject-index of about fourteen pages.

It is to be hoped that this book will meet with the success it deserves. Last—but not least—to have produced a book of such high quality at such a low price is an achievement of which the publishers can be justly proud. C. A. Hoare

HISTO-PATHOLOGY

Histological Technique for Normal and Pathological Tissues and the Identification of Parasites

By H. M. Carleton, with the collaboration of R. A. B. Drury. Third edition. (Oxford Medical Publications.) Pp. xvi+343. (London: Oxford University Press, 1957.) 30*s*. net.

THIS is the third edition of the late H. M. Carleton's useful book on histological technique. It contains not only straight histological technique, but also many current pathological and parasitological methods. All the methods in the book have been carefully tried by either Carleton or R. A. B. Drury; the latter collaborated especially in histo-pathological and bacteriological methods, and techniques for spirochaetes. This edition contains fifty-five fewer pages than the first (1926), and yet covers the modern ground very well indeed. Carleton and Drury's book is the only work of this kind in the English language, because of the special parts of the biological field it covers. It is excellent for the zoologist, cytologist and parasitologist to have at his disposal a small volume of this kind, and there is no doubt that it will stimulate the younger workers to try techniques outside their fields. From this point of view—and it is what Carleton intended—the book should be most helpful in the coming years. For the small laboratory, for science laboratories in schools, and for people who have to work in laboratories abroad, this book is warmly recommended.

How far such books will survive in the future, with the impact of electron microscope technique, is a moot point. One supposes, however, that medical and junior biology students will always have to study, with the optical microscope, sections prettily stained by current histological methods.

The frontispiece has a photograph of Harry Carleton. No doubt we all become less beautiful with age, but to those who have other photographs of Carleton, the choice made for this book will seem unfortunate.

There is a foreword by Sir Roy Cameron which informs the reader that, "A pupil of Gustav Mann, whom he succeeded at Oxford, and of Champy, he inherited their common sense and uncanny intuition". Actually, Carleton never saw Mann, was not his pupil, and did not succeed him. Carleton was trained as a cytologist by the reviewer and succeeded the latter after he had migrated to University College, London. There seems little doubt that Sir Roy's kindly piece about "common sense and uncanny intuition" must have belonged to Carleton's period with C. Champy at Paris. J. Brontë Gatenby

TELECOMMUNICATION

Communication Engineering

By Dr. W. L. Everitt and Prof. G. E. Anner. Third edition. Pp. xi+644. (London: McGraw-Hill Publishing Company, Ltd., 1956.) 67*s*. 6*d*.

THE recognition of telecommunication as a separate and distinct branch of applied science involving fundamental principles of great generality and requiring powerful mathematical weapons for attack upon some of its problems may be said to have developed during the nineteen twenties. Prof. W. L. Everitt's text-book, when it first appeared in 1932, was one of a very small group of pioneer texts which exemplified this recognition and endeavoured to treat the subject of telecommunication as a unity. The book, which was written at a level appropriate to university undergraduate courses, was quickly accepted by teachers as a work of exceptional quality and before long had established itself as one of the standard text-books for students.

The third edition of "Communication Engineering" appears under the same title but under the joint authorship of Prof. Everitt and Prof. G. E. Anner. In the preface to the new edition the authors remark that, at the time at which the first edition was planned, it did not appear presumptuous to cover, in one volume, the major fundamental concepts in the field. Now, however, that is quite impracticable, and "it has been decided to concentrate on the area which must precede the study of all other divisions of communication, namely, the fundamentals of linear-network analysis and synthesis including the use of unilateral elements".

The book opens, as did its predecessor, with a chapter on the fundamental principles of communication networks. This introduction is excellent. The basic concepts underlying multi-channel frequency-division communication systems are introduced almost at once, and this is followed by a clear description of amplitude and angle modulation and of the relative effects of interference in the two systems. A similar treatment is given of the principles of signal sampling, pulse-modulation and time-division multiplex. Finally, there is a section dealing briefly with the quantitative measure of informatio and with the implications of the Hartley–Shanno law.

Two chapters are devoted to the transient an steady-state analysis of linear networks. These ar followed by a chapter giving a thorough treatmer of resonance and a chapter on bridge networks. Th last chapter deals with the important application of the bridge principle in communication circuit namely anti-side tone, duplex and phantom circuit two- and four-wire repeater circuits and circuits fo the stabilization of radio-frequency amplifiers. Th treatment of passive networks with lumped parameters is completed by two further chapters o iterative networks and wave filters. Transmissio lines, in the new edition, occupy a good deal mor space than in the old, there being a separate chapte on lines of low loss which includes a very satisfactor treatment of impedance charts and their application It is noteworthy that in addition to deriving th transmission line equations as the limiting case for repeated lumped network these are also establishe from the fundamental differential equations. In m opinion Prof. Everitt's application of the compensation theorem to establish the steady-state relationships for mismatched termination and reflexion is most valuable illustration of the power of circu theory, but it lacks the quality of developing physic insight. The concept of a true time delay in transmission can be first developed unambiguously for th genuinely distributed system and then interprete for the repeated lumped system satisfactorily but the reverse sequence presents some awkwar problems.

Impedance transformation receives very full an satisfactory treatment, excellent illustration bein given of the use of the Smith chart in relation t broad-band impedance transformation. One chapte is devoted to equalization and includes a fairly fu treatment of the semi-graphical method of computin the attenuation response curve which is known as th 'corner plot' method.

Two further chapters complete the main text o the book. The first of these treats linear amplifier Again the treatment is on as general a basis as practicable, figure of merit being introduced at a early-stage, design for maximally flat respons receiving considerable attention and the relations o steady-state response, transient response and ampl tude response being studied. The final chapte entitled "Electromechanical Coupling", gives a bri elementary treatment of the more important electromechanical transducers employed in telecommunication.

Comparing the new book with the old, there a inevitably losses as well as gains. Those like th present reviewer who had come to regard certai sections of the old book, as for example that o modulation and demodulation, as giving some of th clearest and most illuminating elementary treatment available, cannot but regret the disappearance of good many well-tried and familiar sections. On th other hand, the more comprehensive treatment o linear communication networks on a 'broad-ban basis is of the highest value.

As a text for students the new edition of "Communication Engineering" is a work of excellent qualit which should commend itself as did its predecessor to the good opinion of teachers of the subject.

James Greig

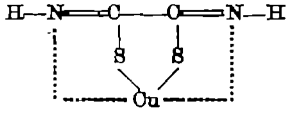
TIMBER PRESERVATION BY COPPER COMPOUNDS

By D. S. BELFORD and PROF. R. D. PRESTON, F.R.S.
Botany Department, University of Leeds
AND
C. D. COOK and E. H. NEVARD
Messrs. Hickson's Timber Impregnation Co. (G.B.), Ltd., Castleford

DURING the past year we have been making what is probably the first attempt to utilize modern physical techniques of sub-microscopic structural research to resolve some of the outstanding problems associated with the impregnation of timber by water-borne preservatives. The long-term object of the work is to determine why certain timbers are impermeable to preservatives, while others apparently of the same microscopic character can be treated with ease. In view, however, of the lack of information concerning the precise location of the ingredients comprising the preservatives within the timber, the immediate problem has concerned an investigation of the physical state and distribution of preservatives in the timber on a sub-microscopic scale. We have used the methods of polarization microscopy, X-ray diffraction analysis, electron microscopy and electron diffraction analysis. The results obtained to date seem to us to be of sufficient importance to merit immediate publication pending the preparation of a series of longer papers.

The work so far has been carried out exclusively on Douglas fir (*Pseudotsuga taxifolia*) for several reasons. Douglas fir is widely used in Great Britain for constructional purposes, but is often difficult to treat with preservatives. The heartwood is only moderately durable and the sapwood very liable to decay. Because of the lack of durability of the heartwood, long and expensive treatment schedules are frequently required, and even then the results are irregular and sometimes inadequate. A further advantage of Douglas fir as a test material is that, being a conifer, it has a relatively simple structure consisting only of two principal cell types—tracheids and ray parenchyma.

The preservative used for the main investigation was that known commercially as 'Tanalith' *C* (a mixture in water of copper sulphate, potassium dichromate and arsenic pentoxide); but in addition tests were also made with copper sulphate alone, copper sulphate/potassium dichromate mixtures, arsenic pentoxide alone, as well as copper arsenate, chromium arsenate, cobalt chloride, ferric chloride and zinc chloride. Each treatment was carried out on matched blocks measuring 2 in. × 2 in. × 1 in. Initially, blocks were treated under pressure, but the following treatment was finally adopted. The blocks were placed individually in a beaker and weighted with a lead weight, and the beaker was then placed in a desiccator under a vacuum of 27 in. of mercury for 10 min. The treatment solution was then admitted without allowing air to enter and the vacuum maintained for 10 min. longer. Air was then admitted to the desiccator and the timber allowed to soak for two hours, after which it was dried. Although the timber generally darkens on treatment, the coloration is too weak to allow determination of the distribution of the preservative in sections using the light microscope. Accordingly, various staining techniques were applied either before or after sectioning, and the most effective of these proved to be rubeanic acid (dithio-oxamide).



which under alkaline conditions forms a deep blue insoluble complex with trace amounts of copper. The microscopic appearance of the wood was then most revealing, two points in particular being very noticeable. First, in no conditions was any of the blue copper–dithio-oxamide complex observable in the cell lumina. This shows that the preservation of wood using a copper salt does not depend on the lining of the cell lumina with a copper compound. On the other hand, the middle lamella in particular was stained very deeply and the stain was noticeable throughout the whole of the cell-wall thickness. The stain was, however, patchy over any section, making it quite clear that the copper was not distributed uniformly throughout the test wood sample. The increased durability of the timber as a result of treatment with an aqueous solution of copper salt must therefore depend on the copper content of the cell walls and on the forms in which the copper is present.

Longitudinal sections stained with dithio-oxamide and examined under the polarizing microscope exhibited a spectacular dichroism. Apart from disturbances caused by the bordered pits, the sections were a deep blue colour for light vibrating in a plane parallel to tracheid length and pale yellow for light vibrating at right angles to tracheid length. Whenever, in a section, the cellulose microfibrils changed direction, the dichroism changed accordingly. These observations indicate that the copper–dithio-oxamide complex is orientated specifically with respect to the cellulose microfibrils. It must be concluded that at least a proportion of the copper in the cell wall is associated very closely with the cellulose.

This led us to examine impregnated wood in the electron microscope, using both ultra-thin sections and material ground in a blender. Ultra-thin sectioning of wood is notoriously difficult, and this is also true of preserved wood. Nevertheless, the sections we have been able to examine have shown, within the cell walls, the presence of sub-microscopic particles distributed at random (Fig. 1*b*). These particles were identical in appearance to some of the crystals which appeared when a drop of 'Tanalith' *C* solution was evaporated to dryness on a specimen carrier (Fig. 1*a*). There does appear, therefore, to be evidence that certain components of 'Tanalith' *C* are deposited at random within the cell wall.

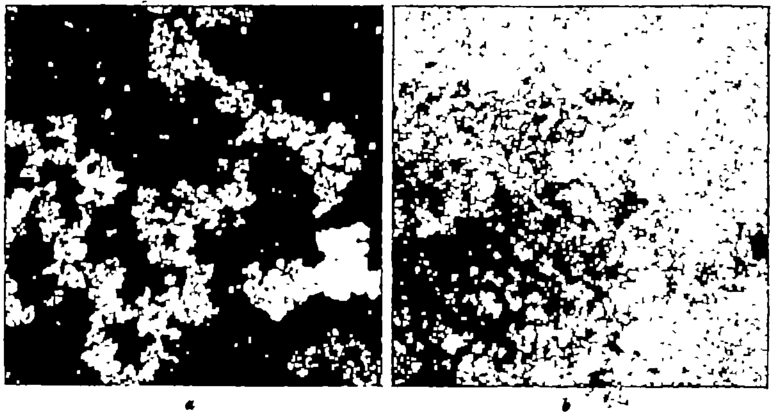


Fig. 1. (*a*) Micrograph of 'Tanalith' *C* crystals from a 0 5 per cent aqueous solution dried on to specimen support. Palladium/gold-shadowed. (× 19,800.) (*b*) Micrograph of a section of 'Tanalith' *C* impregnated *Pseudotsuga* late wood, showing crystals within the cell wall. Methacrylate not removed, unshadowed. (× 19,800)

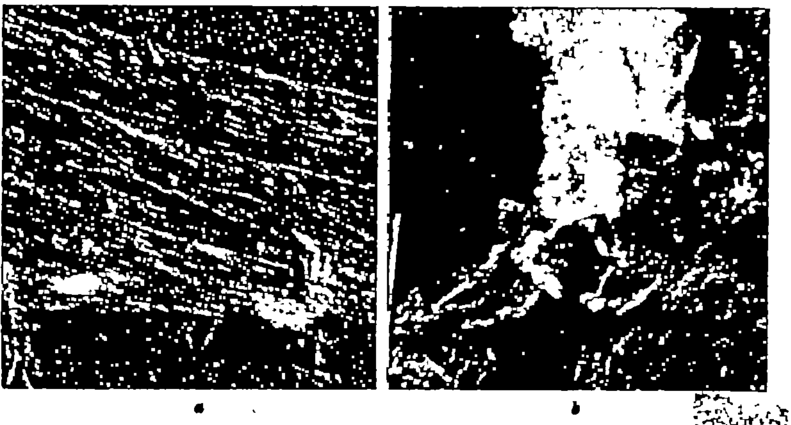

Fig. 2. (*a*) Micrograph of a particle of blended untreated *Pseudotsuga* wood. Palladium/gold-shadowed. (× 19,800.) (*b*) Micrograph of a particle of blended 'Tanalith' *C*-impregnated *Pseudotsuga* wood, showing aggregations of electron-dense preservative material. Palladium/gold-shadowed. (× 13,800)

When pieces of untreated wood, after disintegration in the blender, were examined in the electron microscope, the cellulose microfibrils appeared to be relatively free of opaque incrustations (Fig. 2*a*). The cellulose microfibrils of wood treated with 'Tanalith' *C*, however, showed heavy incrustations of some electron opaque material (Fig. 2*b*). Certain fragments of the treated wood, whether showing incrustations or not, gave remarkably sharp and characteristic electron diffraction diagrams (Figs. 3*a* and 3*b*). We have checked these diagrams against the diagrams of all the various components of 'Tanalith' *C* and, using the A.S.T.M. index of crystal spacings, against the X-ray diagrams of all known copper salts, without finding any agreement. The diagrams, however, resemble though are not identical with, the X-ray patterns of the copper–alkali–cellulose II described by Hess and Trogus[1]. Furthermore, the electron diffraction diagrams faded fairly rapidly when the intensity of the electron beam was increased, a phenomenon which is characteristic of organic rather than of inorganic compounds. In every case the electron diffraction diagram is oriented with respect to the cellulose microfibrils. It seems, therefore, probable that at least a proportion of the copper within the cell walls occurs in the form of a copper–cellulose complex. The X-ray diagram of the whole of the treated wood failed to reveal the presence of this complex owing, no doubt, to the relatively small amount of copper which is present in the wood. This failure does, however, show further that the complexing is limited to strictly localized regions of the cellulose.

It has also been observed that similar diffraction patterns to that obtained for 'Tanalith' occurred when the wood was treated with aqueous solutions of copper sulphate and copper sulphate–potassium dichromate mixtures. Since the electron diffraction work has been purely qualitative, it has not been possible to assess whether there is a quantitative difference in the copper cellulose complex between treatments with 'Tanalith' *C* and treatments with copper sulphate alone. When the wood was impregnated with chromium, cobalt, ferric and zinc salts, similar diffraction diagrams were again obtained. It must be concluded from these observations that when timber is impregnated with metallic salts of the type described, the metal component is situated within the cell wall of the timber and a proportion at least is complexed with the cellulose to form metallo-cellulose complexes.

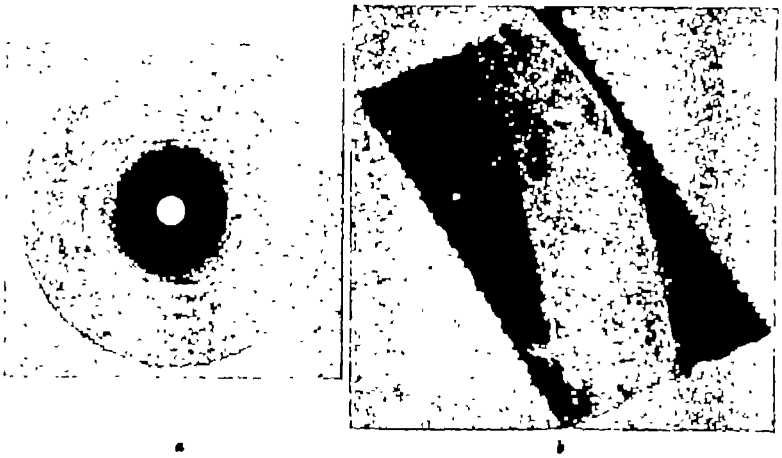

Fig. 3. (*a*) Electron diffraction diagram of the metallo-cellulose complex, given by the particle of cell-wall shown in Fig. 3*b*. The continuous rings are due to the palladium/gold-shadowing. (*b*) Micrograph of a particle of blended, 'Tanalith' *C*-impregnated *Pseudotsuga* wood, giving the electron diffraction pattern shown in Fig. 3*a*. Palladium/gold-shadowed (× 4,450)

After completing the preliminary work described in this report, our attention was directed to the work of Walton-Smith *et al.*[2] on the preservation of timber, using copper formate. These workers have concluded from indirect evidence that, after impregnating the wood with copper formate followed by autoclaving, the copper is converted to a copper–cellulose complex and that it is this complex which confers upon the wood its durability. Our own results prove conclusively the existence of the complex, and, taking their results with ours, we can be rather specific concerning the location of this copper within the cellulose microfibrils.

Cellulose microfibrils consist of a number of molecular chains of cellulose lying parallel to each other and, over certain regions of the microfibril, regularly arranged in a space lattice. It is quite impossible to conceive that aqueous solutions containing copper ions could penetrate into these crystalline regions since water itself is known not to penetrate. These regions, however, are surrounded by others in which the cellulose is paracrystalline; the cellulose chains here lie approximately parallel to each other but are not regularly spaced. Within these regions the copper ions can penetrate, and it is in these areas of the microfibrils that we would expect the copper–cellulose complex to form.

Walton-Smith *et al.*[2] have found that the maximum amount of copper fixed within the wood using their copper formate method is about 0·8 per cent by weight of copper. This copper loading corresponds very roughly to 1 copper atom per 20 glucose residues within the paracrystalline regions of the microfibrils. It is clear that if this copper were distributed uniformly within the paracrystalline regions, a uniform space lattice would not develop and no electron diffraction diagrams of the copper–cellulose complex would be possible. The fact that electron diffraction diagrams are obtained shows quite clearly that the copper is located within the paracrystalline regions of the microfibrils, and within these regions sufficient copper is incorporated to link the cellulose chains laterally into an ordered space lattice.

We conclude, therefore, that the metallic components of a copper–chrome–arsenic water-borne preservative impregnated into Douglas fir are located within the cell wall. A proportion at least of this metal complexes with the cellulose of the paracrystalline regions of the microfibrils and the resulting metal–cellulose complex is highly orientated. We are not yet certain as to any connexion with this complex of the crystalline deposits observed in the electron microscope to be distributed at random within the walls.

PHOTOSYNTHESIS

A SYMPOSIUM on photosynthesis occupied the morning session, on September 10, of Section K (Botany) during the recent Dublin meeting of the British Association. Prof. W. Stiles was in the chair.

Dr. G. E. Fogg, of University College, London, opened the symposium with a paper on "Actual and Potential Yields in Photosynthesis". He said that the total energy reaching the Earth's surface was 5 × 10^{23} calories a year; at present the most effective conversion of this to potential energy is by green plants in photosynthesis. Schroeder's estimate of the total yield of photosynthesis on Earth, particularly of the yield of forests, namely, 1·63 × 10^{10} tons of carbon per year, was probably too small. An estimate of the forest production based on the most recent information was 1·54 × 10^{10} tons per year (instead of 1·10 × 10^{10}), giving a revised total world production of 2·1 × 10^{10} (or 2·4 × 10^{10} if respiratory losses were allowed for). There is still uncertainty as to the total production in the oceans. Using the radiocarbon method, Steemann Nielsen recently found an average value for tropical and sub-tropical waters of between 0·1 and 0·2 gm. carbon/m.^{2}/day. Other workers have found somewhat higher values, suggesting a total production for the whole hydrosphere of 3·2 × 10^{10} tons per year. This is considerably less than some earlier estimates. One difficulty is to decide whether the radiocarbon method measures net or gross production: further error will arise if any of the products of photosynthesis are excreted from the plant. The value of 3·2 × 10^{10} is to be regarded as a firm lower limit and in fact may be too small by a factor of up to five.

If the radiation of utilizable wave-lengths alone is considered, then a total yearly production of 5·6 × 10^{10} tons corresponds to an efficiency of energy conversion over the Earth's surface as a whole of approximately 0·2 per cent. Under optimal conditions of low light intensity in the laboratory, efficiencies of 25 per cent and greater have been obtained. In part, the efficiency in the field is lower because the intensity of sunlight is too high for efficient conversion by the plant. To obtain higher values under natural conditions it is necessary to find new varieties or new crop plants which are capable of utilizing efficiently the natural radiation and then seek methods of using their produce. An ideal crop plant would have a complete ground-cover throughout the growing season, continuously producing new leaves and allowing a continual harvesting of leaves after they had passed their maximum activity. Alternatively, unicellular algae offer the possibility of higher yields, but these must be grown in tanks specially designed to obtain maximal utilization of light energy. In this case, sewage can be used as a source of carbon dioxide. Yields up to 34 gm. carbon/m.^{2}/day have been obtained in small-scale trials. The price of the product is likely to be five to ten times that of conventional crops, and Dr. Fogg concluded that the process is unlikely to be economically possible in the near future unless some radical simplification in technique is achieved.

Dr. C. P. Whittingham, of the Botany School, University of Cambridge, spoke next on "The Chemical Nature of Photosynthesis". He began by discussing the work of Calvin and his colleagues who, by combining the techniques of paper chromatography and tracer carbon, were able to make great advances in our knowledge of the biochemistry of photosynthesis. Two types of experiment gave information as to the intermediates between carbon dioxide and carbohydrate. First, the percentage activity of a compound as a fraction of the total radioactivity fixed was determined, and the first-formed intermediate assumed to be that which, at zero time, would extrapolate to 100 per cent. This type of experiment indicated that phosphoglyceric acid was the compound first formed from carbon dioxide. Secondly, evidence was obtained by determining the relative activity of individual carbon atoms in the labelled molecules. The first-formed phosphoglyceric acid and hexose were labelled exclusively in the third and the third and fourth carbon atoms, respectively, indicating a two-carbon precursor. In fact, the two-carbon compound postulated turned out to be a five-carbon molecule, ribulose diphosphate. In light, phosphoglyceric acid is believed to be reduced to triose and hence to carbohydrate; in addition, some triose and hexose are converted via sedoheptulose to re-form more ribulose, which then continues the reaction sequence. A continuous supply of two reagents is required to operate the cycle in the direction of net synthesis: a supply of reducing power and of adenosine triphosphate. Both must be produced as a result of the absorption of light energy.

Previous to work with carbon isotopes, a physical separation of the process of carbon reduction from that of the fixation of light energy had been achieved by Hill using chloroplasts isolated from the plant. As then prepared, isolated chloroplasts showed no reaction with carbon dioxide, but were able, in light, to reduce ferric salts, quinone and other substances. It is possible that in the plant, reoxidation of part of the reduced product via a suitable enzyme system could result in the formation of adenosine triphosphate, thus supplying both requirements of the carbon cycle. Dr. Whittingham suggested that those cytochromes which are known to occur only in photosynthetic tissues might be concerned in this phosphorylation which depends on light. Isolated chloroplasts, suitably prepared, have more recently been shown both to phosphorylate suitable acceptors in the light and to be also capable of carbon dioxide reduction. Thus any spatial separation of the photochemical and thermochemical processes in photosynthesis is not at the gross morphological level of plastid and cytoplasm.

Attempts have recently been made to study the structure of the chloroplast and relate it to its photochemical activity. The electron microscope has revealed a multi-layered structure with areas of a high degree of organization, tentatively identified with the 'grana' seen in the light microscope. Mercer and his colleagues in Australia have studied the change in structure occurring during greening of etiolated maize seedlings. In the etiolated plant the chloroplasts had an irregular granular appearance, but as greening occurred the development and organization of a layered structure were observed concomitant with the development of photosynthetic activity. The extensive interfacial area produced by a multi-layered structure offers a surface suitable for the orientation of chlorophyll molecules. This would result in a concentration of pigment within the interface, thus facilitating energy transfer both between accessory pigment molecules and between chlorophyll molecules. Tentative calculations show a permissible transfer of excitation energy from an absorbing molecule through several hundred other molecules before dissipation. Long ago, Emerson and Arnold showed that not every chlorophyll molecule, but about only one in every five hundred, was capable of producing oxygen from a brief intense light flash. This would be consistent with a unit of 500–1,000 chlorophyll molecules associated with each energy conversion centre. Such a unit is much smaller than the chloroplast or the granum and might be identified with a portion of lamellar interface. The nature of the energy conversion centre at which excitation energy is converted to chemical bond energy is still not clear. Some consider it to be an enzymic link between intermediates of the carbon path and certain individual chlorophyll molecules. Others favour the view that it is a physical structure with polar character analogous to a *p–n* junction. Excitation results in a supply of electrons to one surface and depletion from the other; the electrons and 'positive holes' then initiate respectively the carbon reduction process and oxidation of water to molecular oxygen.

The final paper was by Dr. S. R. Elsden, University of Sheffield, who spoke on "The Photosynthetic Bacteria". Photosynthesis in all three major groups, the Chlorobacteriaceae, the Thiorhodaceae and Athiorhodaceae, differs from that in the green plant in that no oxygen is produced and an additional substrate—more or less specific to the group—is required. Nevertheless, there are a number of features common to photosynthesis in bacteria and the green plant.

All three groups of bacteria contain both chlorophyll and carotenoid pigments and these are located in small spherical particles, the chromatophores. The chlorophyll of the Chlorobacteriaceae appears to be very closely related to the chlorophyll *a* of the green plant; the Thiorhodaceae and Athiorhodaceae have a different chlorophyll which is a tetrahydroporphin derivative. The action spectra for growth and for photosynthesis are similar to the *in vivo* absorption spectrum of the chlorophylls, indicating that the chlorophylls are the primary photosynthetic pigments as in green plants.

The Thiorhodaceae can use as substrate hydrogen, sulphur compounds and a wide range of organic compounds; the Athiorhodaceae can use hydrogen and organic compounds but not sulphur compounds. With organic substrates most of the substrate carbon is converted to cell substance, but in addition carbon dioxide is taken up if the substrate is more reduced than carbohydrate and given out if more oxidized. This has made it difficult to determine the amount of carbon dioxide fixation. Attempts to use carbon-14 dioxide have been complicated, due to the presence of exchange reactions. Inhibition by cyanide is greater where a substrate is metabolized with the fixation of more carbon dioxide. It appears probable that the process of carbon dioxide fixation in the bacteria is similar to that in the green plant.

Specific cytochromes have been found in the photosynthetic bacteria and are presumed to play a similar part to that of the cytochromes found associated with the chloroplast of the green plant. The bacterial cytochromes are of the *c* class with absorption maxima for the α-band between 550–555 mμ. They are not autoxidizable and differ in oxidation-reduction potential from organism to organism, varying, for example, from − 100 mV. for a compound isolated from the green bacterium *Chlorobium thiosulphatophilum* to $+ 340$ mV. for a compound from *Rhodospirillum rubrum*. Duysens and Chance and Smith have shown by studies of difference spectra that a hæm pigment is relatively oxidized in light and reduced in dark in *Rhodospirillum rubrum*. Illumination of preparations of chromatophores isolated from the bacterium is accompanied by phosphorylation of adenosine phosphate, and it is probable that this is related to the oxidation of hæm pigment observed in light. This would indicate a close similarity in the photochemical activity of chloroplasts isolated from the green plant and chromatophores isolated from the photosynthetic bacteria.

The elucidation of the reactions involving carbon dioxide using isotopes and the comparative studies of photosynthesis in bacteria and green plants emphasize that the basic biochemical pattern is essentially similar to that of the dark metabolism of other organisms, both plant and animal. The unique feature of photosynthesis lies in the mechanism whereby light energy is used to drive the reaction sequence in the direction of net synthesis. An understanding of the mechanism of energy conversion is the major challenge for future research in photosynthesis and may contribute to the technology of energy conversion just as the study of the over-all process of photosynthesis has to the technology of food production.

C. P. WHITTINGHAM

A TRIBUTE TO FREDERICK SODDY*

By PROF. F. A. PANETH, F.R.S.

Director at the Max-Planck-Institut für Chemie, Mainz

THE first International Conference on Radioisotopes in Scientific Research seems an appropriate occasion upon which to consider our debt to Frederick Soddy. The duty to clarify his picture is specially incumbent on us, as it is the tragedy of his life that members of the younger generation may know him only as the person who adopted the term 'isotope' and, perhaps, as the author of provocative statements in economics and other fields far remote from science. The number of those who knew Soddy in his creative period is dwindling.

In fact, the whole science of radioactivity owes to Soddy infinitely more than the coining of the household word which is the unifying tie of this Conference.

First, I would like to recall that the fundamental theory of radioactive disintegration was developed by Rutherford and Soddy. From experiments carried out during 1901–3 at the University of Montreal by the physicist Rutherford and the chemist Soddy, they drew the conclusion that the emission of the Becquerel-rays (as they were called in those days) was accompanied by chemical transmutations; in a vague way such a hypothesis had been considered before as one of several possibilities, but the French school in particular had favoured other explanations. Anybody who studies the original papers will easily recognize the decisive part the chemist must have played in this joint work; some of the arrangements are, from the point of view of experimental chemistry, models of a scientific investigation. Nevertheless, in later books Soddy's name sometimes no longer appears in this context: to Rutherford is attributed the sole merit—illustrating the old truth, well known to students of the history of science, that great reputations tend to absorb the smaller ones—although Rutherford himself always gave full credit to his colleague.

Their ways, however, soon parted. Soddy's name immediately appeared again in connexion with an experiment of the greatest significance: the proof that, in the process of radioactive disintegration by α-rays, helium is evolved in sufficient quantities to be identified spectroscopically. This time the team was Ramsay and Soddy: the study of such small quantities of rare gases is so difficult that in those days Ramsay's laboratory in London was the only place where the necessary experience was available, but the radioactive technique—then quite new to Ramsay—was clearly Soddy's contribution. Anybody who knows from Ramsay's later publications on radioactive transmutation, after Soddy had left, how incapable he was of taking the precautions necessary in this field will credit Soddy with the clean and convincing conduct of experiments in which he later proved himself so much more adept than Ramsay.

So far, Soddy's name had been linked with those of senior and already very famous investigators. He came fully into his own during the ten-year tenure of a lectureship in physical chemistry at the University of Glasgow, where he devoted himself to radiochemistry proper, that is, to the study of the chemical behaviour of the radioactive substances. Such work had been going on in many laboratories, but the published results were frequently erroneous and no attempt had been made at a comprehensive survey. By far the clearest presentation of the new subject was given by Soddy in 1911, in a small volume called "The Chemistry of the Radioelements". Here, for the first time, the phenomenon of the chemical inseparability of those substances which to-day we call isotopic was stressed as something fundamentally new and important. More than that, a connexion was indicated between the position that a radioelement occupies in the disintegration series and in the periodic table; the first part of the important 'radioactive displacement law' is already contained in this book, namely, the rule that emission of an α-particle means shifting down by two places in the periodic table. The second part of the law, namely, that emission of a β-particle leads to the production of an element one place higher in the table, was pronounced three years later, almost simultaneously, by Fajans and Soddy; the experimental basis for this statement had in the meantime been safely laid, largely through the systematic efforts of Soddy's laboratory. In the course of various researches the inseparability of some radioelements from other elements had independently been found by Svedberg, by Boltwood, by Hahn and others, but it is Soddy's outstanding merit to have undertaken a special investigation in order to clarify this mysterious phenomenon; here he was ably helped by a Scottish student with the name of A. Fleck, now Sir Alexander Fleck, chairman of Imperial Chemical Industries, Ltd. Their well-planned analytical work contributed decisively to the recognition of the validity of the displacement law and thereby to the understanding of the physical cause of isotopy. It was fitting that Soddy should christen this phenomenon, and that, in 1921, he should be awarded a Nobel Prize.

---

* Address delivered in Paris on September 9 at the inaugural session of the International Conference on Radioisotopes in Scientific Research.

After these brilliant successes in his scientific efforts—I have not time to mention other excellent papers by Soddy—everybody would have expected him to become the leader of a strong British school of radiochemistry, in a position perhaps similar to that of Rutherford on the side of physics. Soddy's books ("The Interpretation of Radium" and others) were eagerly read; they showed didactic and literary qualities of the highest order and seemed to add to his qualifications for a successful teaching career. But nothing of this sort happened. True, after a few years at Aberdeen, Soddy was called to Oxford as professor of inorganic and physical chemistry, but little scientific work emerged from his laboratory there, no school of radiochemistry was formed, and in 1936 he gave up his chair and retired into private life. How is this surprising eclipse of Soddy as a scientific worker to be explained? To help us understand it, something must be said about his character.

Science was never the only concern in Soddy's life. He had a deep interest in social questions, and whenever he suspected that injustice was being done to a certain group, or that something was wrong in the social structure, he fought it in the most uncompromising way. I had an opportunity to see this side of his nature as early as 1913 when I had the privilege of learning the then current methods of gas microanalysis under his guidance in Glasgow. Scottish Sundays would have left me rather lonely if Soddy had not introduced me to the hospitable house of his parents-in-law, Dr. and Mrs. Beilby. Incidentally, I read recently in the *Proceedings of the Chemical Society* that on that house a tablet is to be fixed, recalling that there, about 1912, the name 'isotope' was invented. This date is certainly too early; in the many discussions to which I had the pleasure of listening in the first half of 1913, this word was never used. According to Soddy's own story, it was a little later supplied to him by a school teacher, a lady to whom he had explained that the substances to be named occupied "the same place" in the periodic table. (The term made its first public appearance in Soddy's letter to *Nature* of December 4, 1913, p. 399.) It is very unfortunate that in recent years this clear scientific meaning has been obscured by the indiscriminate use of the word 'isotope' for any radioactive substance. If no relation to another substance occupying the same place is involved, the designation 'radioelement' or 'radionuclide' ought to be used. One substance in isolation can no more claim to be an isotope than an only child can be a brother.

I remember very clearly having heard Soddy's heated arguments, in Dr. Beilby's house at 11 University Gardens, in favour of home rule for Ireland and votes for women, the two main political topics of those days. Later he took a deep interest in political economy; to the theory of money he devoted several publications in which he expressed very radical views. Objections from acknowledged experts in this field he used to brush aside with the remark that chemical experts did not accept his views on isotopes either when he first pronounced them. There was, however, the difference that in chemistry he could present such convincing facts that resistance was overcome within a few years. In economics he met with no such success, and he became more and more embittered about this failure.

Nearer home, he tried to introduce reforms into the structure of the University of Oxford; he considered some aspects of the college system, as, for example, the independent teaching of physical chemistry in several small and poorly equipped college laboratories, as outmoded. He was a declared admirer of some features of the German university system. However, he was not good at waiting or satisfied with slow progress, but was always inclined to suspect unpardonable indolence or even ill-will. After he had left Oxford some developments went in the direction desired by him, just as votes were given to women and independence to Ireland. But Soddy did not wait. Never satisfied by a compromise, he manœuvred himself more and more into the position of an opponent and critic without influence; finally he resigned, and Britain lost the hope many had certainly cherished that this great man and his pupils would establish a permanent school of radiochemistry.

After his retirement, Soddy had little contact with colleagues and followed the further development of the science he had helped so much to launch with growing distrust. He resented especially the dominant role physics assumed in radioactive research. Apart from the general trend—physics has invaded other branches of chemistry as well—it was Soddy's own premature retirement which accelerated this shifting of the centre of gravity. He had been the only man in Great Britain who could to a certain extent have kept the balance. Instead he was, in his later years, inclined to believe in dark scheming on the part of physicists who did not want to acknowledge the merits of chemists. But anybody who ever had the opportunity of knowing the generous character of Rutherford and his readiness to admire and enjoy good scientific work, wherever it was done, will be quite unable to accept Soddy's occasional bitter remarks. It is most regrettable that these unfounded grievances of an old and disgruntled Soddy have found their way into recent books.

The reasons for Soddy's tragic scientific isolation in later years are to be found in his own personality. He was gifted in many, perhaps too many, ways. He was such a good writer of English prose that it was all too easy for him to give his polemical essays the sting he wished. Once, when he had solved a problem of stereometry, it amused him to publish it in verse. An occasional excursion into the history of chemistry instigated him to the best vindication known to me of the strong claims of William Higgins, as opposed to those of John Dalton, to be the originator of the chemical atomic theory. His special gift for technical constructions made him for long periods exchange the laboratory for the workshop. There are many other examples which could be quoted to illustrate the richness and variety of his talents.

Rutherford once said in a lecture that he was naturally in favour of simple explanations in physics, being a simple person himself. Now, Frederick Soddy was not a simple person. He was a very complex personality, not easy to approach, living a rather solitary life—especially after the early death of his charming and devoted wife—but he was a great idealist, always ready to fight against what he deemed morally wrong, without any consideration of his own personal interests. Very kind and helpful to young and struggling people, he was suspicious of nearly everyone in authority and power. If he had lived, on September 2, 1957, he would have completed his eightieth year. It is fitting, at a conference to discuss the scientific applications of isotopes, to remember the man who was the first to see the general theoretical importance of what had been until then scattered observations. Let us honour the memory of a brilliant intellect, an experimenter second to none among the founders of radiochemistry, and an uncompromising champion of his ideals.

OPERATIONAL RESEARCH

It is just about twenty years since the expression 'operational research' was coined to describe the activities of the Air Ministry research section studying the operational problems of radar. There was rapid progress during the first decade, mainly—and quite naturally—in military applications. The three British Armed Services all had groups in England, and there were many overseas sections. In the United States and Canada development was also rapid, and a tripartite operational research conference on defence matters was held shortly after the War; similar conferences have since been held at regular intervals, and have been extended in the military sphere to include nations of the British Commonwealth and the North Atlantic Treaty Organization.

Although work of the type now termed operational research has been carried out in industry for the best part of a hundred years, it is only since 1947 that there has been any formal description of this science. An Operational Research Society was founded in the United Kingdom in 1947—initially as a club with members drawn from personnel of the various military groups who had returned to civilian life. An American Society was formed in 1953 and a year or so later came the (American) Institute of Management Science. Societies or groups have since been formed in most of the major Western European countries, and also in India and Japan.

With this widespread interest, it is understandable that suggestions for an international meeting this year met with a ready response. Indeed, this highly successful conference (sponsored by the Operational Research Societies of Britain and America and the Institute of Management Science) for experienced workers in both the military and civil fields was over-subscribed from the start. The Conference was held at Oxford during September 2–6, and the two hundred and fifty members present represented twenty-one different nations, and it was felt that similar conferences should now be held at regular intervals.

At the inaugural meeting delegates were welcomed by Sir William Slater (president of the Operational Research Society). The eminent speakers who followed him avoided any attempt at formal definition of operational research, but spoke with great authority on its basic principles and growing importance in industry, in defence and in the economy of nations. The first four business sessions were devoted to the presentation of papers on methodology and applications, and the final session to development (that is, to the extent of growth of operational research) in the main countries represented. During the week, one session was spent in panel meetings, at which were discussed special aspects of operational research, for example, education and training, or its relation to management. There were a formal dinner and reception on the first night and also informal meetings during the week; these latter were prosecuted so vigorously that it is doubtful if any delegate got his or her full ration of sleep during the conference. After leaving Oxford, parties visited various British operational research centres. The proceedings of the conference are to be published at the end of the year and can be obtained from the *Operational Research Quarterly* (11 Park Lane, London, W.1).

The largest delegations were from Britain and the United States, and these accounted for twenty-four of the twenty-eight main papers. The conference brought out differences in the approach of these countries to operational research. Judging by the papers presented, interest in the United States is greater in development of mathematical techniques (seven papers) than in applications (three papers), though the methodological papers were usually based on real situations involving decision-making. This mathematical interest seems to stem from universities and research organizations. In the United States much operational research is conducted on a consulting basis by university departments, and this no doubt stimulates academic research. In the United Kingdom, however, interest is in applications (six papers) rather than methods (three papers). It is lamentable that so few British universities show any real interest in operational research. There are many individual workers known by their publications, but some of these are not members of the Operational Research Society and so were not eligible to attend this conference.

If papers are to be judged both by reading and by the interest aroused, then there were outstanding contributions in each session. On the morning of September 3, Mr. H. K. Weiss, of Northrop Aircraft, Inc., presented a paper on "Lanchester-type Models of Warfare". F. W. Lanchester's differential equations are well known from his classical work, "Aircraft in Warfare: The Dawn of the Fourth Arm" (Constable, London, 1916). In Weiss's paper historical data were used to establish the reasonableness of the Lanchester assumptions and then to expand the theory to take into account the movement of forces. It then deals with small combat forces, weapons of greatest effectiveness, and combat between heterogeneous forces. This work all leads to development of optimum tactics between heterogeneous forces. In the discussion it was acknowledged that the simplifying assumptions and unknown values of the relative effectiveness of weapons (killing-rate) cause serious difficulties. It is doubtful, for example, whether the effectiveness of a force is equal to (numerical strength) × (weapon effectiveness), for this assumes that a man who can and should shoot will in fact do so. Another complication is over-hitting: a casualty may be due to more than one hit, each of which is sufficient to incapacitate. For most weapons, however, the probability of hitting with a single shot (or even burst) is very low, and so overhitting is not initially important. In the case of a small force faced by much larger forces and in process of total elimination, overhitting may become substantial but it will not affect the outcome.

One other paper in this session should be of interest to the British public. It was a description by Messrs. J. Stringer (Central Electricity Authority) and K. B. Haley (University of Birmingham) of work in hand to reduce the cost of transport of coal to power stations to a minimum. The use of linear programming showed how some saving in cost of transport might be achieved. The effect of the loss of this business on another nationalized concern was not discussed. This paper also contained an account of an interesting mechanical analogue computer for solving linear programmes.

The afternoon session on September 3 was even more mathematical than that in the morning. The papers by Mr. T. C. Koopmans (Cowles Foundation for Research in Economics) on water-storage policy, and by Dr. R. M. Oliver (Broadview Research, Inc.) on control of production and inventories both contained much of mathematical interest. Comment on both, however, referred to the assumptions made in the mathematical model rather than to the mathematics itself. Mr. Koopmans's paper is of interest to those who heard the papers presented at a recent Royal Statistical Society meeting on queues.

Dr. J. H. Engel (Operations Evaluations Group, United States Navy) aroused more general interest with his paper, "Use of Clustering in Mineralogical and Other Surveys". His presentation, too, was much to be commended for its clarity and precision. In any search the first run will produce some spurious results and some misses. Further rapid runs will produce similar effects but will tend to confirm genuine signals. Such confirmed signals will then be the basis for more detailed examinations of areas in which prizes may be found. New fast searches are cheap, and detailed searches are expensive. It is likely that there is an optimum balance between effort on fast searches and detailed examinations giving maximum result per unit of expenditure. The paper read was confined to a special case in which the number of prizes in the area is known. A hypothetical numerical example given as an appendix to the paper illustrates the salient points. An (n,s)-clustering technique implies n coverings by fast search and a cluster of s contacts as the minimum required to justify detailed ground search. As in many other operational research studies, the answer is sensitive to the criterion. Applications of this theory do require accurate knowledge of equipment performance and costs, which are both matters of some difficulty.

The first session devoted to applications of operational research produced two papers of great general interest. All sufferers from traffic jams in Britain must be grateful for work on traffic flow. Mr. J. G. Wardrop (Road Research Laboratory) gave a paper on the "Traffic Capacity of Weaving Sections of Roundabouts". This described experimental work and its validation by observation of actual traffic conditions. The experiments were made at Northolt Airport during 1955–56, and some of the experiments were presented in film form. The main conclusion was that, in good conditions, about 800 mixed vehicles per hour per ten feet of weaving width can pass through a roundabout of normal design. Cycles, darkness and wet weather all reduce flow. Police control, however, appears to expedite matters. Much smaller flows may be encountered in some circumstances, as when two main streams meet and both turn right. Interference from adjacent roundabouts would also cause reduction. If this work is used as a guide to roundabout design much benefit should result. This type of analysis could be extended to show when roundabouts should be abandoned in favour of fly-overs, clover-leaf junctions and so on.

The other paper of particular public interest in this session was that by Messrs. J. C. R. Clapham and H. D. Dunn (National Coal Board) on communications in collieries. This attracted headlines in the daily press. In brief, underground communication in collieries was found to be inadequate for safety warnings and the cost of satisfactory improvement, on a national scale, is estimated at £5,000,000. Amortized over a reasonable period, this looks like only a few pence per ton on the price of coal—a very small premium for the safety of the men involved.

The second session on applications of operational research contained one paper that produced a long stream of commentators. This was on the "Level of Protection afforded by Stocks", by Messrs. John Harling and M. J. Bramson, of ORbit, Ltd. Stock control is a management function particularly susceptible to mathematical study and has, at one time or another, attracted the attention of many operational research workers. In the simplest terms, the object of this paper is to show the level of protection against run out of various levels of stock when the supply and demand functions to and from the stock are known. In this case delivery times were normally distributed, whereas demand from a production line was Poissonian. Cost of running out, that is to say, of stopping the production line, was not readily calculable. This paper represents an advance on previous published work in that it takes into account vagaries of delivery. Most stock control assumes constant lead time from order to delivery—and indeed delivery at fixed times is not unusual. However, circumstances can arise when vagaries of delivery are the main contribution to size of stock for a particular level of production.

The last paper of the session was by Mr. J. K. W. Slater (National Institute of Agricultural Engineering) on "The Collection of Data on the use of Machinery on Farms". This could well prove to be one of the main foundations of a study of how British farm productivity can be raised. It shows the dimensions of the problem clearly. For example, the average size of farm in England and Wales is only about 100 acres. More than 20 per cent of farms are less than 5 acres, though many of these very small farms must be exceptional in equipment and intensity of operation. Any idea of heavy investment on small farms (say, 100 acres) is likely to be ruled out on economic grounds, particularly in hill regions. Is it too much to hope that more thought will be devoted to understanding the problems of these farmers ?

Looking back after a week or so, this conference seems particularly satisfactory for the international unity achieved. By the end of the week national delegations had fused most successfully and happily with one another. The feeling of common aims towards progress transcends everything else.

A RETROSPECT*

By Dr. ANDREW D. BOOTH
Birkbeck College, University of London

IT is now more than ten years since general-purpose digital computers became a subject of everyday discussion among scientists, and it is appropriate to look at the field to see if their early promise has been fulfilled. There is no need to discuss the structure of these machines, which are familiar to any research worker who has to use numerical processes in order to obtain his results or to predict from his theories; it suffices to say that the computer consists of five units, namely, arithmetical, control, storage, input and output.

The progress of the machines themselves over the past decade is not without interest. All the more elegant designs are derived from the classical work of the late John von Neumann[1], and it is unfortunate that he was promoted to the higher spheres of scientific administration before the Princeton machine was in a state in which he could use it extensively. Von Neumann, in common with all the other pioneers in the design of computers, under-estimated the difficulty of producing a reliable store of large capacity, and so the devices, which should have been operating in 1948, did not start to come into use until the early 1950's.

Four of the earliest machines to operate were built in England, namely, ACE, APERC, EDSAC, and MUEC[2]. All were taken up commercially, but it is sad to observe that technological virtuosity has allowed the Americans, in this as in so many other things, to overtake the British. The blame for this can be laid at the door of the manufacturers of electronic components: in 1947, I was forced to obtain miniature electronic valves from the United States; only in the past few years have reliable semi-conductor diodes been available in Britain, and the junction transistor is still far behind those available in the United States. Rectangular hysteresis-loop magnetic materials are but recently in quantity production, and it is perhaps symbolic that one large manufacturer assured me in 1950 that such devices were theoretically impossible, notwithstanding the fact that several American specimens were under test in his laboratory.

Coming now to the applications to which computers have been put, the field can be divided into four parts, comprising commercial, engineering, scientific and non-numerical uses.

Of the first class of applications little need be said. It is of comparatively recent origin, probably because such functions as wages calculation and tax estimation must be performed accurately and to a rigid time-schedule. No interest is attached to calculations of this type, which are trivial in concept and mathematics. More interesting, however, are some applications of computers to the planning of buying[3] and manufacturing strategy in business. Unfortunately, in its general aspect, this class of problem requires a storage capacity which is greater than that currently available, so that although small-scale test analyses have been carried out, no large-scale planning is in operation.

In engineering a number of interesting applications have been made, including the design of a proton synchrotron[4], non-linear control systems[5], power distribution network performance[6], power transformer design[7], the optimization of train schedules[8], and the analysis of frameworks[9]. The power-transformer design programme operates as follows. It is assumed that the machine is supplied with purchasers' specifications and with an initial estimate of the core area for the desired transformer. The machine calculates the number of turns on the low-voltage winding from the well-known formula: $N = k_1V/k_sABf$, where k_1 is a scaling constant, V is the voltage applied to the winding, k_s is the core space factor, A is the assumed core area, B is the assumed working flux density, and f is the operating frequency.

In general, N will not be a whole number, so that the machine has to take the nearest integer to it and re-calculate the flux density. On the basis of this integer approximation to N, the number of turns on the high-voltage winding can be evaluated by using the known transformation ratio specified by the customer.

Once these basic quantities are known, the next step is the calculation, from the known conductor sizes, of the window dimensions of the laminations; this is followed by an estimation of the weight of active iron, W, in the core.

At this point the first cycle of the design process is complete and the next stage is to estimate the excellence (or otherwise) of the result. The criteria are (1) iron loss, derived from the formula: $P = W(a_1B + a_2B^2 + a_3B^3 + a_4B^4)$, where $a_1 \ldots a_4$ are known loss coefficients; (2) load loss, Q, derived from currents and winding sizes and lengths; and (3) reactance, R. The quantities P, Q and R are then compared with the values which they require to have in order to meet the specification, and if necessary the core area, A, assumed initially, is modified by means of the formula:

$$\Delta A = A(\alpha \Delta P/P_d + \beta \Delta Q/Q_d + \gamma \Delta R/R_d)$$

Here α, β and γ are weighting constants, chosen as a result of experience to ensure optimum convergence. P_d, A_d and R_d are the customer's specified values of P, Q and R, and $\Delta P = P - P_d$, $\Delta Q = Q - Q_d$, $\Delta R = R - R_d$.

As soon as satisfactory values for the loss functions have been obtained, a final set of residual characteristics is evaluated and from this, if necessary, modifications are made to such preset parameters as the core material and the winding type and layout.

---

* Substance of a lecture delivered to Section G (Engineering) of the British Association in Dublin on September 10.

Finally, the machine calculates the arrangement of windings and core, costs, size of tank and so on, ending with an overall check to ensure that no mistakes have crept in. It is interesting to note that about three cycles of refinement are usually required to bring the losses within ± 2 per cent of those specified, and that the whole process can be completed in about four seconds on a medium-speed computer.

Space does not permit a description of the electric-traction programme, which is of considerable interest since it involves operations with discontinuous quantities, such as the sudden imposition of speed restrictions and the change of motor connexions with increase of speed. The value of this type of investigation is shown, however, by the fact that it indicated how, by optimum running, the energy consumption on the 40-mile run from Liverpool Street to Shenfield and back could be reduced by 40 per cent with a corresponding rise of only 14½ per cent in running time.

A half-way house between engineering and pure science is meteorology. Here, the methods of mathematical weather prediction pioneered by Brunt[10] are about to become practicably useful because the latest high-speed computers will enable the calculations to be performed sufficiently ahead of real time to qualify as predictions rather than verifications.

New scientific applications of digital computing machines appear daily and range from the study of stellar evolution to the binding energies of molecules, and from the design of optical systems to the analysis of speech. Since a mere catalogue would be uninteresting, a single example, from the field most familiar to me, will be considered in rather more detail. It is of topical interest because the recent determination of the structure of vitamin B_{12} by Dorothy Crowfoot Hodgkin[11] is a landmark in the analysis of molecular structure by X-rays and would have been impossible without an automatic digital computer.

In X-ray crystallography the basic data are a set of observed 'structure factor amplitudes', $|F_0(h,k,l)|$, which are simply related to the intensities of the X-ray reflexions which are obtained during diffraction measurements on single crystals. The Miller indices (h,k,l) are simple whole numbers.

It was shown by the Braggs that crystals could be considered to be built up of a large number of elementary building blocks—or unit cells—each of which is an identical copy of the others. Under these conditions the structure can be considered to be periodic, so that a Fourier expansion should be possible for the expression of variations in electron density from cell to cell. It can be shown[12] that, if the unit cell is assumed to have axial dimensions (a,b,c) and if (x,y,z) are the co-ordinates of any point inside that cell, then the density of electrons $\rho(x,y,z)$ is given by the triple Fourier series :

$$\rho(x,y,z) = \frac{1}{V}\sum\sum\sum_{h,k,l\,=\,-\infty}^{+\infty} |F_0(h,k,l)| \cos\left\{2\pi\left(\frac{hx}{a}+\frac{ky}{b}+\frac{lz}{c}\right)-\alpha_{h,k,l}\right\} \qquad (1)$$

In this expression V is the volume of the unit cell and $\alpha_{h,k,l}$ is a phase angle which cannot, in general, be determined experimentally. If $\alpha_{h,k,l}$ were determinable from experiment a direct calculation of $\rho(x,y,z)$ could be made since the $|F_0(h,k,l)|$ are known; the calculations, though tedious, would then be well within the range of human computers. In practice, however, an indirect approach must be adopted.

It may be shown that :

$$F^2(h,k,l) = A^2 + B^2$$

$$\text{where } A = \sum_{r=1}^{N} f_r \cos 2\pi\left(\frac{hx_r}{a}+\frac{ky_r}{b}+\frac{lz_r}{c}\right)$$

$$B = \sum_{r=1}^{N} f_r \sin 2\pi\left(\frac{hx_r}{a}+\frac{ky_r}{b}+\frac{lz_r}{c}\right)$$

$$\text{and} \qquad \tan\alpha_{h,k,l} = B/A$$

Here f_r is an atomic scattering factor, which is known from wave mechanical considerations, and (x_r,y_r,z_r) are the co-ordinates of the centre of the rth atom of the N which make up the structure. Thus, if approximate co-ordinates are known, an approximate value of $\alpha_{h,k,l}$ can be calculated and it can be shown that the substitution of this in (1) with the experimentally determined $|F_0(h,k,l)|$, and the subsequent location of maxima in electron density, lead to an improved set of (x_r,y_r,z_r). Repetitions of the process lead to convergence to very accurate atomic co-ordinates.

The whole process may be exhibited in cyclic form : (1) rough approximations of (x_r,y_r,z_r) ; (2) compute $\alpha_{h,k,l}$; (3) locate maxima in $\rho(xyz)$ using $|F_0(h,k,l)|$ and $\alpha_{h,k,l}$; (4) compute $|F_0(h,k,l)|$ using maxima found in (3) ; (5) calculate discriminating function ; (6a) if unacceptable repeat from (1) using the co-ordinates found in (3), (b) if acceptable print out co-ordinates and stop.

The only step which requires explanation is (5). One discriminating function is :

$$R = \sum_{h,k,l} \big||F_0(h,k,l)| - |F_c(h,k,l)|\big| / \sum |F_0(h,k,l)|$$

which can be shown to decrease to a value less than 0·20 as the process converges to the solution required.

The operations described are all ideally suited to a computing machine and it is only necessary to mention that the time for processing a complete structure of moderate complexity (twenty distinct atoms, say) has been reduced from three years to as many weeks. In fact the actual computing time is now far shorter than the time required to obtain the experimental results and to do the preliminary and incidental 'thinking'. The latter is important since, despite popular utterances to the contrary, the computer is not yet within sight of replacing the scientist.

Finally, a brief mention of the non-numerical applications of computing machines. These include the playing of games, the composition of music and poetry, and the translation of languages. At least one musical 'composition' by a computer which I have heard appeared to me preferable to the effusions of certain distinguished modern composers, but the poems leave much to be desired. Language translation has now reached the state of practicability, and awaits only the funds to construct *ad hoc* machines for it to be useful[13].

The playing of games on computing machines is interesting both for amusement and for the light which it throws on the problem of intelligent thought.

Nim and 'noughts and crosses'[14] can, of course, be played perfectly by a computer since they fall into the class of determined games; a satisfactory game of draughts appears now to be possible[15] but chess is still beyond the capacity of existing machines. Intelligent thought by machines poses a question which is largely one of definition. During a conversation between myself and R. W. Hamming the following was suggested: if a machine is set to play a simple game such as 'noughts and crosses' against a human being, it is exhibiting at least some of the characteristics of intelligence if, knowing only the size of the square and its own 'move' (that is to say, O or X), it can deduce from the results of several games the required configuration for a win, and play accordingly. Deduction by exhaustion, or playing all possible games, is not considered to be a valid solution. No programme of this type has yet been written.

IMPERIAL CHEMICAL INDUSTRIES, LTD.: PHARMACEUTICALS DIVISION

NEW RESEARCH LABORATORIES

By Dr. J. YULE BOGUE

THE new pharmaceutical research laboratories of Imperial Chemical Industries, Ltd., at Alderley Park, Macclesfield, Cheshire, were formally opened by Lord Waverley on October 1, just twenty-one years after the Company's first entry into the pharmaceutical field. These laboratories represent the culmination of an expanding endeavour which, from the beginning, placed great faith in the possibilities of inventive research in the fields of applied organic chemistry and experimental biology. The discovery through the past years of such important drugs as 'Sulphamezathine', 'Paludrine', 'Antrycide', 'Mysoline' and, more recently, 'Fluothane' and 'Helmox', justifies the early faith in the potentialities of research of this nature. The development has meant the gradual addition of different scientific disciplines to create the balanced research organization which now exists in its new quarters.

Alderley Park extends to some 350 acres, of which the laboratories occupy only a small part, leaving plenty of land for farm animals—an essential feature in the study of diseases which afflict domestic animals. The landscape is attractive, with the woodlands which surround the park ensuring privacy. The main block of buildings enjoys a superb view over Radnor Mere, where many wild birds find sanctuary.

A novel feature, which has influenced the design of the experimental animal houses, is a rat- and mouse-breeding unit designed to produce specific pathogen-free animals. For many years, research both in Great Britain and elsewhere has been severely hampered by the common infections inevitably found in commercial stocks of laboratory animals. The animals, delivered by Caesarian section with sterile precautions and artificially reared to weaning under strictly aseptic conditions, are free from their natural infections. These animals can be maintained in the disease-free state and produce disease-free offspring provided they are protected from contact with outside sources of infection. Everything which enters or leaves the breeding unit has to pass through a routine of decontamination or sterilization. Staff pass from changing and decontamination rooms, through a disinfectant trough and air locks fitted with ultra-violet and electrical insecticidal dispensers. The entry of equipment and the issue of animals and processed feeding stuffs takes place through double-entry autoclaves, designed so as to prevent both ends being opened at the same time, thereby maintaining an aseptic 'lock' between the unit and the outside.

The breeding rooms have no windows and no natural ventilation. The treated air is changed ten times an hour without recirculation. The scale of operation, 500,000 animals a year, presented several novel problems. The manhandling of 45 tons of drinking water and bottles a week was avoided by an automatic watering system. Flushing of the racks is also automatic.

In the experimental animal houses the natural pathogens of mice and rats are kept out by means of vermin-proof barriers at strategic points. Each animal cell opens on to a verandah screened to keep out birds. The verandah access allows air dilution to reduce the risk of cross-infection to a minimum. Separate ventilation and independent temperature control of each animal cell are other features.

In the infectious diseases animal house, staff and attendants must pass through clothes-changing routines in the decontamination locks. Colour coding also plays a part. On the virus floor, cell doors painted in various colours indicate animals infected with separate diseases. Inside, all movable equipment is given the same colour, while operators wear coloured overalls. The colours must never be mixed. In diseases dangerous to man, the principle adopted is that of containment. The infected animals are housed in ventilated cupboards located on each side of a ventilated manipulation hood fitted with glove ports.

The non-infectious animal house serves physiology, pharmacology, parasitology and pathology. In addition to housing the pathogen-free rats and mice, the standard cells have been adapted to serve as insectaria, snail room, chick rooms and so on.

The biological laboratories are arranged in suites of three rooms, of which the two outer, one a mirror image of the other, flank a central area devoted to a study space and utility area. Fexibility is the keyword of their design. The laboratory furniture, instead of being fixed, can be moved to suit the individual needs of the worker. Welded steel table frames carry stainless steel, hardwood or plastic tops. Flexibility is maintained by bringing the services into the laboratory in repetitive units which carry electricity, gas, vacuum, air, water, drainage and, where required, steam. The outlets are grouped in units at 5-ft. intervals on each lateral wall. In addition, there are two floor outlets in the centre line of the laboratory which are readily tapped through optionally removable service pedestals. Cylinder gas outlets are provided on one wall, and the cylinders are housed in cupboards in the corridor to eliminate trundling them into the laboratories.

The central utility area may house sterile cubicles with bacteriologically filtered air, centrifuge and ventilated hoods, smoking and varnishing units, electrostatically screened rooms, dark rooms, etc. The window side of the central unit provides office or study facilities for both laboratories. The windows of the biological laboratories are double. The outer window can be opened for cleaning while the inner portion is a single sheet of plate glass permanently fixed. The space between is provided with a heating coil and a remote-controlled venetian blind.

Each floor contains a series of constant-temperature rooms providing temperatures ranging from − 70° C. to blood heat.

The chemical laboratories set fewer problems than the biological ones. The basic design is similar to that of the standard synthetic laboratories in the Dyestuffs Division, namely, two laboratories each accommodating four chemists, with office space between. In addition, there is provision for a number of special services and techniques. Physical chemistry and biochemistry, with their high degree of instrumentation, both required special accommodation. There are also specially designed laboratories for micro-analytical work, radiochemical investigations and the handling of highly toxic chemicals or gases. A large-scale laboratory is available for making large batches of intermediates or for the preparation of promising compounds for clinical trial. The area is flame-proof and it is here that the preliminary work on sealing-up can be carried out.

Centrally placed among the laboratory blocks are the wash-up, media kitchen and stores. The unit receives dirty and contaminated glassware for sterilization, washing, storage and re-issue. The layout is entirely subordinated to the flow of materials handled. Every effort has been made to reduce drudgery to a minimum through mechanical aids.

The total graduate staff accommodated in the new laboratories is approximately a hundred, of whom more than half are chemists (organic, physical, pharmaceutical and biological). The other scientific disciplines include bacteriology, virology, mycology, protozoology and helminthology. There are also units for pharmacology, physiology and pathology which cover the work on parasitic diseases and infections, the diseases of organic dysfunction and the pharmaceutical aspects of surgery such as anaesthetics. In addition to the graduate staff there is a staff of assistants and technicians and a general labour force. The overall total of employees on the site is about four hundred and fifty.

The entire work of the laboratories is concerned with the invention and discovery of new drugs and preparations for use in human and animal medicine. The broad scope of the research is indicated by the different scientific disciplines mentioned above. Administratively, the staff is divided into two groups, chemical and biological, each of which is in turn divided into a number of sections with defined responsibilities in a particular field. As a matter of practical day-to-day working there is a natural and non-formal division into flexible teams of scientists who are all collaborating on a common problem. This may be illustrated, by way of example, by the pattern of research on a particular bacterial disease. The natural team combination will emerge from: (1) Members of the chemical group whose duty it is to synthesize new compounds for evaluation. (2) Their opposite numbers in the biological group who are charged with the task of reproducing the disease in an experimental animal and providing an accurate assay procedure for the new chemicals which come along. The routine assay is, of course, only as good as the research behind it. (3) Biochemists who must, by studies of the mode of action, generate ideas upon which chemists engaged in synthesis can build. Later, as active drugs begin to emerge, pharmacology and pathology come into the picture, and also the pharmaceutical chemists who must present the potential new drugs in a form which is likely to be acceptable to the practising doctor or veterinarian.

The particular targets of research are generally decided by a combination of economic and technical factors. An industrial research laboratory must pay its way, and the products of successful researches must carry the burden of paying for the effort which does not produce its own monetary return. Research targets vary in their degree of feasibility or in the time which may be expected to elapse before useful results accrue. The work in progress at Alderley Park, therefore, has both long-term and short-term objectives. In the long-term category are studies on the chemotherapy of cancer and viruses. No quick answer can be expected in these fields which are closely related, as both involve the study of the intimate processes of cell division and the multiplication *in vivo* of macromolecular species. Knowledge gained in this kind of work is of value not only in a direct sense, but also for its bearing on the biochemistry of micro-organisms generally. Some of the research projects in chemotherapy may become progressively more difficult as knowledge advances. This apparent paradox arises because the discovery of a drug for the treatment of a particular disease automatically alters the objective. The requirement now is for a drug with improved properties, generally fairly precisely defined. For example, although it is not difficult to synthesize new chemical compounds with antimalarial activity, it is by no means easy to make one which is better than such drugs as 'Paludrine' or 'Chloroquin'. There are already many effective antibacterial drugs, and the problem now is not so much to find a new antibacterial, as to find one which has specific properties overcoming the particular disadvantages or limitations of those which are already available to the doctor. It is not difficult to synthesize anæsthetics, but the recent invention of 'Fluothane' was the result of a deliberate search for a volatile anæsthetic having in particular the property of non-inflammability.

The projects under study at Alderley Park are divided broadly into infectious or parasitic and non-infectious diseases. The former includes diseases caused by viruses, bacteria, fungi, protozoa and metazoa. The non-infectious diseases include those of the nervous system (such as epilepsy), hypertension rheumatism and allergic phenomena (for example, hay-fever and asthma). This broad coverage, supported by first-class laboratory facilities and an enthusiastic staff, should pave the way for continuing advances in the chemotherapeutic treatment of disease.

THE ACCIDENT AT WINDSCALE

THE accident at the United Kingdom Atomic Energy Authority's Windscale No. 1 Pile on October 10 has rightly been taken very seriously by both the Government and the Authority. A Committee of Inquiry was set up by the Authority to investigate the cause of the accident and the measures taken to deal with it and its consequences. The White Paper dealing with the accident which has now been published* contains a memorandum by the Prime Minister together with six annexes. Instead of the original report on the cause of the accident which, in the national interest, is not being published, the first annex comprises a less technical and more qualitative account of the sequence of events.

One feature of a graphite-moderated reactor is that a considerable amount of energy is stored in the graphite due to atomic displacement caused by neutron bombardment. This is known as Wigner energy, and the phenomenon had been observed before the Windscale reactors were built. The energy can be 'released' by raising the temperature of the graphite, or it may release itself spontaneously. In either case, it is transformed into thermal energy and heats the graphite. The White Paper implies that this 'Wigner release' phenomenon was unknown at the time of construction of the Windscale reactors. A spontaneous release occurred in No. 1 Pile in 1952, without harmful effects, and since that time eight controlled releases have been carried out in the pile. To achieve the release, a small amount of nuclear heat is applied, with greatly reduced flow of coolant so as to maintain the graphite at a constant temperature but higher than normal. The operation demands careful control of the nuclear heating-level, based upon observations of the temperatures within the pile.

The Committee of Inquiry was satisfied that the thermocouples in the pile, while adequate for normal operation, were neither sufficient nor correctly placed for the Wigner release operation, nor was the power-level meter accurate enough at the lower powers being used. It appears, moreover, that insufficient instructions had been given to the operators to enable them to deal reliably with the conditions arising. In previous Wigner releases, two nuclear heating operations had proved necessary to obtain complete release. In the opinion of the Committee, the second heating was, on this occasion, applied before it was necessary, and too much of it was applied too quickly. Some cartridges were ruptured, most probably cartridges containing fuel. The further rise in temperature as Wigner energy was released caused the exposed uranium, and eventually the graphite, to burn. It appears that some two days elapsed between the occurrence of the rupture and its detection, during which time the fire spread. After several unsuccessful attempts to extinguish it by careful air control, water was successfully used.

The Committee found that the steps taken to deal with the accident, once it had been discovered, were prompt and efficient, and displayed great devotion to duty on the part of all concerned.

Annex 2 contains the report of the Committee on the measures taken to deal with the consequences of the accident, and concerns actions taken to protect the workers and the public. A report by an independent committee to the Medical Research Council is included as Annex 3, and these two annexes should be considered together.

When an out-of-door air sample showed an activity of upwards of ten times the normal level, precautionary measures were taken to protect the workers on the plant.

These included frequent sampling over the site, orders to the workers to remain indoors and to wear face masks, and an inspection of canteen food. Examination of the total-body radiation and thyroid absorption showed that some workers received doses greater than the recognized limit for continuous operation, and they will, therefore, be removed from radioactive work for a period. Strontium and cæsium absorption appear to have been insignificant. These conclusions are endorsed by the Medical Research Council Committee.

Dealing with the measures taken to protect the public, the Medical Research Council Committee agreed that the health physics manager correctly assessed that the main problem might arise from ingestion of contaminated food. It directs attention to the delay between recognition of a possible radioactive hazard to the surrounding countryside, and the institution of extensive and rapid milk sampling. It appears that thirty-four hours elapsed between the recognition of this possible hazard and the receipt of the first milk analyses, and some seven hours between the receipt of the first seriously contaminated milk and the decision to prevent deliveries. It is not stated at what stage a milk analysis was ordered, nor how long such an operation takes.

It appears that it had not been anticipated that iodine vapour would escape from the filter in preference to particulate fission products, and that information was not available to deal with this situation.

---

* Atomic Energy Office. Accident at Windscale No. 1 Pile on October 10, 1957. (Cmnd. 302) Pp. 26. (London: H.M. Stationery Office, 1957.) 1s. 3d. net.

The Medical Research Council Committee concludes that, despite these shortcomings, the protection measures were essentially right and, once brought into play, were applied decisively, and were adequate. It is convinced that it is in the highest degree unlikely that any harm has been done to anybody.

The chairman of the Atomic Energy Authority has accepted full responsibility for the accident, and at his request further inquiries are in hand to undertake a technical evaluation of information arising from the accident, and to review organization problems concerned with reactor operation.

A short, but convincing, note by the Authority gives several reasons why this accident could not happen with the Calder Hall or the new Electricity Authority reactors.

Much experience and information have been gained from the accident, without, so far as can be judged, any ill effects on humanity. We are fortunate in that the cause and history of the accident have almost certainly been traced, and we can be especially thankful for those much-criticized excrescences at the top of the ventilation stacks, the radioactivity filters.

W. MURGATROYD

OBITUARIES

Dr. Gerty T. Cori

DR. GERTY T. CORI, who died at St. Louis, Mo., on October 26, was a most distinguished biochemist. In 1947, Prof. Carl F. Cori, her husband, and she shared with Prof. B. A. Houssay, of Argentina, the Nobel Prize for Medicine and Physiology.

Gerty Cori was born in Prague, Czechoslovakia, graduating in medicine from the German University in that city in 1920. In the year she graduated she married a fellow medical student, Carl Cori, by whom she later had one son. In 1922, Carl and Gerty Cori moved to the United States, becoming American citizens in 1928. Until 1931 they worked at the State Institute for the Study of Malignant Diseases at Buffalo, N.Y., and in 1931 they moved to St. Louis, where ultimately they both held professorships of biochemistry in the School of Medicine of Washington University.

Their principal researches have been in the field of carbohydrate metabolism, with particular reference to the mechanism of breakdown and building up of glycogen and the influence of hormones on the processes. In their early researches at Buffalo they discovered the 'Cori cycle', whereby lactic acid produced in mammalian muscle is converted to liver glycogen and thence can go via blood sugar to muscle glycogen and so back again to lactic acid. Their characterization of phosphorylase and their identification of the then unknown glucose-1-phosphate as the product of the action of the enzyme on glycogen under suitable conditions were of outstanding importance in the elucidation of pathways whereby glycogen is broken down and built up in muscle and liver. This discovery led to the first *in vitro* production of glycogen, which took place in their laboratory. Before this could be done, they characterized a branching enzyme (amylo-1 : 4-1 : 6-transglucosidase) in muscle which converts some 1 : 4 links of the amylose formed from glucose-1-phosphate, under the influence of phosphorylase, into 1 : 6 linkages, and thus produces a branched polysaccharide—in this instance glycogen—from a straight-chain one, namely amylose. In conjunction with her pupils during the past few years, Gerty Cori has, despite a rapidly growing illness, developed an enzymic method for assessing the molecular architecture of glycogen. Using such methods, she has differentiated several types of glycogen-storage disease according to differences in the enzymes and abnormalities of the structure of the stored glycogen.

The researches of Gerty Cori and her colleagues concerning the influence of insulin on the enzyme hexokinase are still a matter for discussion, but undoubtedly they have given rise to much fruitful investigation regarding the fundamental action of insulin all over the world.

Gerty Cori was a charming hostess as well as an outstanding scientist, being a woman of wide general culture and interests. A brave woman, outstanding as a scientist among scientists, she has left a permanent record of herself in numerous laboratories, not only in publications but also in the wide influence she exerted on research in the difficult field of carbohydrate metabolism.

F. G. YOUNG

Prof. J. A. S. Ritson, O.B.E.

JOHN ANTHONY SYDNEY RITSON, emeritus professor of mining in the University of London, died on October 16 at the age of seventy. He was born at Pelton, Co. Durham, on August 18, 1887, and was educated at Uppingham and the University of Durham.

As a Rugby player he was capped several times for England between 1910 and 1913 and never in later life lost his love for the game which so appealed to the 'Geordie' side of his temperament. In the First World War his crisp and firm appraisal of men and situations won him the command of the 12th Royal Scots, a regiment he led with dash and distinction from 1916 until 1919. His battle honours included the D.S.O. and bar, the M.C. and four 'mentions'. After a post-war period as H.M. Inspector of Mines, during which he served successively in Scotland, Yorkshire and South Wales, he was appointed to the chair of mining in the University of Leeds in 1923.

In 1935 he was made O.B.E., and in the following year took over the chair of mining at the Royal School of Mines (one of the three associated Colleges which form the Imperial College of Science and Technology, London). Here his love of manly sports, his directness of approach and the whole-hearted way in which he embraced the cause of his students won him a host of friends. His long memory for names and faces was a valuable asset in this connexion, since metal miners go out from the Royal School of Mines all over the world and international social contacts are important. In addition to his academic activities, he did valuable work on O.E.E.C., where he helped to generate post-war interests in the development and treatment of low-grade ore deposits. Part of the fruits of his work, in which he took an important role, was the institution of the first degree course in the world in mineral dressing, at the Imperial College.

He took a serious operation in his stride in 1950. After he retired in 1952 he continued with a busy consulting practice in addition to his work with the Institution of Mining and Metallurgy and the Institution of Mining Engineers, in each of which he had been president. During the Second World War he did much work for the Ministry of Mines, but was never too busy to find time to see an old student. Other bodies which he served included the Geological Survey of Great Britain, the Coal Commission and the Natural Resources Commission. He was, until his death, the Crown mineral agent.

In addition, his consulting practice took him to many foreign countries and Dominions. We who worked under him learned to value his small human weaknesses not less than his qualities of leadership. He leaves a widow and two sons.

E. J. Pryor

NEWS and VIEWS

Royal Medals of the Royal Society

H.M. The Queen has been graciously pleased to approve recommendations made by the Council of the Royal Society for the award of the two Royal Medals for the current year as follows: Prof. W. V. D. Hodge, Lowndean professor of astronomy and geometry in the University of Cambridge, for his distinguished work on algebraic geometry; Prof. F. G. Gregory, professor of plant physiology at the Imperial College of Science and Technology, London, for his distinguished studies in plant physiology.

The New Scientist

The first anniversary issue of *The New Scientist* appeared on November 21. As H.R.H. Prince Philip says in a congratulatory letter, its birth could not have been more opportune. The accident at the Windscale factory, nuclear power and space travel have further stimulated the layman's interest in the activities and achievements of scientists. *The New Scientist*, as especially shown in its articles on the artificial Earth satellites, is admirably suited to satisfy their curiosity. It is one of the few realistic attempts to bridge the gulf between the scientists and non-scientists. Besides Prince Philip's letter, this issue, which marks the beginning of the journal's second year (vol. 3, No. 53), includes articles on "The Present Golden Age", by Sir Charles Darwin; "X-Ray Analysis", by Sir Lawrence Bragg; "Submarine Oil Tankers", by Nigel Calder; "Progress of Quick Freezing", by Dr. J. Hawthorn; and "Ragworms and Caviar", by Dr. R. P. Dales; there is also a Christmas book section. We offer *The New Scientist* our congratulations and best wishes, and feel sure that there will be many more anniversary issues.

500,000th Leitz Microscope: Dr. Paul A. Weiss

Prof. Paul A. Weiss, head of the laboratory of developmental biology of the Rockefeller Institute, received the 500,000th microscope made by the firm of Ernst Leitz at a brief ceremony in his laboratory. The presentation of the microscope to Dr. Weiss is in the tradition of special recognition given by the Leitz organization to famous scientists for their fundamental contributions to the knowledge of living structures and their development and pathology. He is the first American to be so honoured. Robert Koch, discoverer of the tubercle bacillus, received the 100,000th Leitz microscope in 1907; Paul Ehrlich, pioneer in chemotherapy, the 150,00th in 1912; Martin Heidenhain, the histologist, the 200,000th in 1921; Ludwig Aschoff, the pathologist, the 300,000th in 1930; and Gerhard Domagk, Nobel prizeman for his work for chemotherapy, the 400,000th in 1949. Dr. Weiss, whose biological researches have covered a wide field, is known for his work on the analysis of the development and growth of living structures.

Royal Aircraft Establishment Appointments:

Mr. R. W. Pye

Mr. R. W. Pye has been promoted deputy chief scientific officer as head of the Trials Department of the Royal Aircraft Establishment. Mr. Pye graduated in mathematics at Cambridge in 1933 and joined the Royal Aircraft Establishment in 1936, when he worked on problems of airborne gunnery and the aerodynamics of winged torpedoes. During the War he was responsible in the London Headquarters for a range of armament research. At the beginning of 1947 he went to Australia in the team led by Lieut.-General Evetts to initiate the setting-up of the rocket range at Woomera. For the past eighteen months of his stay in Australia he was acting chief superintendent of the Long Range Weapons Establishment (now Weapons Research Establishment) at Salisbury and made important contributions to the planning and installation of the range facilities. Since his return to England in mid-1950, Mr. Pye has been intimately concerned with the extension of the guided weapon ranges in the United Kingdom and the introduction of new and advanced trials instrumentation techniques.

Mr. P. A. Hufton

Mr. P. A. Hufton has been appointed to the new post of head of the Bedford Divisions, Aerodynamics Department. In this post, which carries the rank of deputy chief scientific officer, he will take charge of the aerodynamic flight testing and wind tunnel testing at the Royal Aircraft Establishment, Bedford. Mr. Hufton took his M.Sc. at the University of Manchester in 1934 and then joined the staff of the Royal Aircraft Establishment where he worked throughout the period 1934–46 on various aerodynamic research problems, specializing in research on aircraft in flight. In 1946 he moved to the A. & A.E.E., Boscombe Down, as superintendent of performance and in 1953 returned to the Royal Aircraft Establishment to take charge of the Supersonic Division, Aerodynamics Department, a post which he has held until his present appointment. He rapidly became expert in the expanding field of hypersonic aerodynamics, and under his leadership a strong research team was built up. During this period he was promoted to deputy chief scientific officer and acted as head of the Aerodynamics Department throughout 1956 while Mr. L. F. Nicholson was at the Imperial Defence College.

Dr. D. Küchemann

Dr. Dietrich Küchemann has been promoted to the rank of deputy chief scientific officer and appointed head of the Supersonics Division of the Aerodynamics Department at the Royal Aircraft Establishment. Dr. Kuchemann studied under Prandtl at Göttingen where he obtained his doctor's degree in 1936. Remaining in Gottingen for the next ten years he worked at the Aerodynamische Versuchsanstalt under Prof. Betz. During this period he became an acknowledged expert on propulsion aerodynamics and much of his understanding and new thought on these problems was crystallized in the book "Aerodynamics of Propulsion" published in 1953, in which he collaborated with Dr. Weber. In 1946 he came to England and has since worked in the Aerodynamics Department of the Royal Aircraft Establishment where his personal researches were acknowledged in 1954 by his appointment as a senior principal scientific officer on individual merit. While at the Royal Aircraft Establishment Dr. Küchemann has made major contributions to the methods of design of swept wings and the junction of such wings with bodies and nacelles, particularly at transonic speeds. More recently he has worked on problems of wing stalling and flow separations and has been mainly responsible for the important work leading towards an understanding of the vortex type flow around slender wings.

Linnean Society of London: Centenary Celebrations, 1958

The Linnean Society of London is arranging to celebrate in 1958 the 200th anniversary of the publication of the tenth edition of the "Systema Naturae" of Linnaeus, and the centenary of the joint communication made to the Society by Darwin and Wallace on evolution by natural selection. A memorial tablet will be unveiled on July 1 in the rooms of the Society commemorating the reading of the Darwin–Wallace communication. This will be followed by a dinner of the Society. A special meeting of the Society will be held in the Memorial Hall of the Royal Geographical Society, Kensington Gore, on July 15, at which two papers will be read on the work of Linnaeus by Dr. A. Tindell Hopwood and Dr. A. J. Cain. These will be followed by a presentation of Darwin–Wallace Silver Medals to a number of British and foreign zoologists and botanists. A joint conversazione with the Royal Society and the Geological Society will be held at Burlington House on the evening of July 15, at which Darwiniana and Wallaciana will be exhibited. A Darwin–Wallace memorial number of the *Journals of Botany* and *Zoology* is to be published containing the text of Dr. Julian Huxley's Darwin–Wallace Lecture which will be delivered in the Royal Albert Hall at the opening session of the International Congress of Zoology on July 16, together with some fifteen original contributions from distinguished botanists and zoologists working in the field of evolution. Bronze replicas of the Silver Darwin–Wallace Medals (in case) will also be available for purchase.

The Convergatron

At a meeting of the American Nuclear Society, on October 29, Dr. Lyle B. Borst, chairman of the Department of Physics, College of Engineering, New York University, described a new design for nuclear power plants. Dr. Borst envisaged a subcritical reactor controlled by a small neutron source and amplified by a 'convergatron'. This is a neutron amplifier which magnifies the flow of neutrons in a manner analogous to that of the thermionic valve and the transistor. A series of convergatrons would amplify neutrons from a weak source to a large power reactor, and yet the power plant itself would shut off upon the removal of the source. Because all parts are subcritical, there is no danger of losing control of the chain reaction.

The convergatron consists of three sections—one containing the pure neutron moderator such as plain water or graphite, one containing unenriched uranium-238, and a thermal neutron barrier such as cadmium. Fast neutrons from the fission of uranium in the fuel zone penetrate the cadmium barrier. They are slowed by the moderator to become thermal neutrons that activate the next fuel zone. The fast neutrons starting in the reverse direction are slowed by the moderator until they can no longer penetrate the cadmium. Each fuel zone receives neutrons from the preceding stage. Therefore each succeeding stage can operate at a higher power while still depending upon the preceding stage for its excitation. With several stages, the convergatron, acting as a power source through heat transfer, should be able to generate enough power to make the system practicable in many areas of the world.

Nuclear Power Stations and Public Health Hazards

Several questions about nuclear power stations were dealt with in the House of Commons on November 11 by Mr. D. L. M. Renton, who repeated that if public confidence were shaken at all by what happened at Windscale (see this issue of *Nature*, p. 1093), so far as Calder Hall and the Electricity Authority's nuclear power stations are concerned, confidence should be completely restored by the White Paper and the Prime Minister's statement. As regards the suggestion of an independent inspectorate, the Atomic Energy Authority has prepared safety regulations for Broadwell power station and a permanent safety staff is already drawing up a formal safety code of procedure for both the design and the operation of nuclear reactors. The suggestion of a public monitoring system would receive consideration. A public inquiry will be held into the proposal to build a nuclear power station within the Snowdonia National Park; but in reply to the suggestion of a full inquiry into the whole question of the siting of nuclear power stations instead of dealing with them individually, Mr. Renton thought that individual inquiries as required were the best way of dealing with the matter.

Afterwards, on November 12, replying to a question whether he would consider setting up a special department within the Factory Inspectorate to select and train inspectors for the nuclear power stations, the Parliamentary Secretary to the Minister of Labour, Mr. L. R. Carr, said that this is not considered necessary. Four inspectors in the Chemical and Engineering Branch and twenty-one in the districts have already been trained, and fifty more are to be trained under a programme covering protection against radiation hazards in industry generally, including nuclear power stations. Two inspectors in the Chemical and Engineering Branch have also received training in the design, maintenance and operation of reactors.

Progress in the Commercial Use of Atomic Energy

The Paymaster-General, Mr. R. Maudling, replying to a question on November 11 in the House of

Commons about progress in the development of a package nuclear reactor for export purposes, said that recent studies have suggested that the Calder Hall type of reactor should be capable of modification to produce electricity at a competitive price from small stations of about 20–30 megawatts capacity. Other reactor systems that might be suitable for generating electricity in smaller power stations are being investigated, and two British firms have marketing rights for small power reactors of American design. British manufacturers have received a number of inquiries and are actively exploring possible markets for the types they can offer. Research is proceeding into many types of reactors; Mr. Maudling added that he understood that small reactors for civil use are not yet operating in the United States and that there is no proof of their reliability or economy.

Further questioned as to controlled thermonuclear fission, Mr. Maudling said that the experimental apparatus at Harwell known as ZETA is now operating, and discharges through heavy hydrogen gas have yielded very high temperatures. Experiments are proceeding to identify the source of the accompanying neutron emission, which probably arises from thermonuclear reactions but may be due to other complex nuclear processes. Many major problems remain to be solved before the practical application of thermonuclear reactions could be considered, and although research and development in this field are being given the highest priority, the work must be expected to remain in the research stage for some years.

Responsibility for Atomic Energy Developments

In reply to a question in the House of Commons on November 12 as to whether, in view of the fact that responsibility for nuclear energy matters involves much detailed study of highly technical problems, he would consider transferring that responsibility from himself to a senior Minister in the House of Commons, the Prime Minister said that he considered that the existing arrangement is the most suitable at the present time. There are disadvantages, but when the various uses of nuclear energy are so much in the field that the Prime Minister of the day is bound to have them under his control, there are advantages and the system works fairly well; in the detailed work, he said, he is being greatly helped by the Paymaster-General.

Instrumentation of British 'Skylark' Rockets

A 'Skylark' high-altitude research rocket, fired in darkness at the Woomera rocket range on November 13, reached a height of 83 miles. It was the fourth of six proving rockets scheduled to be fired before the beginning of a joint programme of upper atmosphere research by the Royal Society and the Royal Aircraft Establishment. The first three firings having shown the performance of the rocket vehicle and its 'Raven' solid-propellant motor to be satisfactory, attention has been turned to trials of rocket-borne and ground equipment. 'Skylark No. 4', in addition to routine instrumentation, such as timing gear, telemetry sender, power supplies and Doppler transponder and microwave beacon used for tracking purposes to give velocity and position, carried equipment for four separate high-altitude measurements. First, eighteen grenades were ejected from the rocket at 3-sec. intervals at altitudes above 100,000 ft. On the ground microphones recorded the time of arrival of the sound waves, ballistic cameras recorded the positions in space of the flashes and a detector recorded the instant of each flash. The experiment, which is being made by University College, London, aims at measuring atmospheric temperatures and high-altitude wind velocities. Secondly, fourteen cartridges of 'window' (strips of fine metal foil) were released explosively in two clouds at different heights above 100,000 ft. and followed by tracking radars. The experiment, devised by the Imperial College of Science and Technology, London, is designed to measure winds at altitudes up to 50 miles. Thirdly, a section of the rocket nose was insulated from the remainder of the body to make a condenser of fixed capacity forming part of a 5 Mc./s. oscillatory circuit for measuring ionospheric electron densities, the results being telemetered to the ground. Devised by the University of Birmingham, this ingenious device will be more effective in later rockets which will penetrate farther into the ionosphere. Finally, three Pirani pressure gauges were carried in the rocket cone, one measuring ram pressure in the very tip of the nose, the other two measuring cone-wall pressures. These measurements, being made by the Royal Aircraft Establishment, enable the undisturbed ambient pressure at various altitudes to be determined.

British Computer Society: Glasgow Branch

At a meeting, held on November 11 in the Chartered Accountants Hall, Glasgow, to inaugurate the Glasgow Branch of the British Computer Society, a committee was appointed, initially for the period until April 1958. Mr. K. D. Henderson was elected convener and honorary secretary and the following were elected members of the Committee: Dr. D. C. Gilles, Mr. W. B. Mackay, Prof. D. C. Pack, Mr. T. B. Simpson and Mr. J. J. B. Young. The committee is arranging a series of lectures by people experienced in the application of electronic computers, the first of which will be given in December. In due course, study groups will be formed to consider various aspects of the application of computers to commercial, engineering and scientific work. Inquiries can be addressed to Mr. K. D. Henderson, 89 Wellington Street, Glasgow, C.2.

Information and Control

Information theory has grown so rapidly and has found applications in so many fields that the new journal, *Information and Control* (New York: Academic Press), can play a valuable part in centralizing research results. The editors are L. Brillouin (New York), C. Cherry (London) and P. Elias (Cambridge, Mass.), and there is a strong international supporting editorial board. The journal will publish work on the theories of communication, computers and automatic control, but it will also accept papers offering experimental evidence or theoretical results bearing on information theory, from related fields. In the first number, Brillouin's editorial is essentially a comment on Born's form of Occam's razor: "concepts which refer to distinctions beyond possible experience have no physical meaning and ought to be eliminated". Of the eight other items, special reference may perhaps be made to the paper by G. A. Miller and E. A. Friedman, in which, following a suggestion due to Shannon, the authors discuss various experiments in reconstructing mutilated texts.

Journal of Applied Bacteriology

THE *Journal of Applied Bacteriology* is normally published bi-annually, issues appearing in June and December. In 1957 three numbers will be published, the third appearing in December. This extra number of the *Journal* will contain the papers read at a special symposium of the Society for Applied Bacteriology held in July last. The subject of the symposium was "Bacterial Spores". Orders for the special issue (35*s.*) and new orders for the *Journal* (35*s.* per issue) should be sent to Mr. A. H. Walters, Honorary Publications Manager, Society for Applied Bacteriology, Milton-Deosan Research Laboratory, 64 Wimpole Street, London, W.1.

Grant to the Macaulay Institute for Soil Research

THE Rockefeller Foundation has made a grant of up to 9,500 dollars to the Macaulay Institute for Soil Research for the development of spectrochemical methods of analysis. This grant will be used for purchasing a British-made 11-channel direct reading attachment to a medium quartz spectrograph. This equipment, which enables analyses of chosen elements to be carried out automatically in an electric discharge, will allow the Department of Spectrochemistry to develop its investigations of the role of trace elements in soil–plant relationships and other biological problems.

Oversea Service Division, Colonial Office

THE following appointments have recently been made in the Oversea Service Division, Colonial Office: P. W. A. Davies (agricultural officer, Kenya), agricultural officer, Basutoland; G. Gamble (provincial agricultural officer, Kenya), assistant director of agriculture (Field), Kenya; E. C. M. Green (agricultural officer, Kenya), provincial agricultural officer, Kenya; R. J. Spooner (agricultural officer, Kenya), provincial agricultural officer, Kenya; R. J. Dewar (deputy conservator of forests, Nyasaland), deputy chief conservator of forests, Nyasaland; R. G. M. Willan (conservator of forests, Nyasaland), chief conservator of forests, Nyasaland; R. M. C. Williams (scientific officer, East Africa High Commission), senior scientific officer, East Africa High Commission; G. Froyd (veterinary officer, Kenya), veterinary research officer, Kenya; M. I. Ashrif, agronomist, Sierra Leone; T. M. Denoon, temporary livestock superintendent, Department of Veterinary Research, Federation of Nigeria; R. Hewson, agronomist, British Guiana; L. B. Palmer, agronomist, British Guiana; J. M. Taylor, development officer, pig industry, Jamaica; J. B. Robertson, fisheries officer, Tanganyika; C. W. Holloway, assistant conservator of forests, Kenya; M. G. Allderidge, assistant geologist, British Guiana; L. L. Fernandez, assistant geologist, British Guiana; P. Rix, geologist, Kenya; D. J. L. Casley, statistician, East Africa High Commission; R. G. Erskine, temporary veterinary research officer, Federation of Nigeria; T. M. Leach, chief veterinary officer, Northern Nigeria; B. J. Hills, metallurgist, Tanganyika; D. W. Parry, cartographer, Kenya.

Announcements

DR. GERHARD HERZBERG, director, Division of Pure Physics, National Research Council of Canada, has been elected an Honorary Fellow of the National Academy of Sciences, India.

MR. PHILIP SHERIDAN HOPKINS, professor of aviation and head of the Department of Aviation at Norwich University, Vermont, has been appointed director of the Smithsonian Institution's National Air Museum.

AT a recent meeting of the Board of the British Nuclear Energy Conference, the Institute of Fuel was admitted to membership. The purpose of the British Nuclear Energy Conference is to co-ordinate the activities of the constituent members in the field of nuclear energy; meetings are held and a journal is to be published.

THE Company of Glass Sellers offers scholarships in glass technology, tenable at the University of Sheffield. The scholarship examination consists of papers in chemistry, physics and mathematics. Entry forms (which must be returned by February 1) and further information can be obtained from The Registrar, University of Sheffield, Sheffield, 10.

THE Nutritional Biochemicals Corporation, of Cleveland, Ohio, has issued a new catalogue of research 'biochemicals' (October 1957). There are a few new items, including decarboxylases for the natural forms of the amino-acids arginine, aspartic acid, histidine, lysine and tyrosine. Biochemists will note wistfully that 1 gm. of coenzyme A (75 per cent) still costs 600 dollars, though there are some price reductions.

PROF. C. E. H. BAWN will deliver the fourth lecture of the Plastics Institute for young people on "The Progress of Plastics" in the William Beveridge Memorial Hall, Senate House, University of London, W.C.1, at 2.30 p.m., on January 2, 1958. Admittance will be by ticket only, obtainable from the Secretary to Council, Plastics Institute, 6 Mandeville Place, London, W.1.

THE annual meeting of the Science Masters' Association will be held in the University of Leeds during December 31–January 3. Further information can be obtained from the annual meeting secretary, W. H. Dowland, 93 Westbourne Road, West Hartlepool, Co. Durham.

THE 124th meeting of the American Association for the Advancement of Science will be held in Indianapolis during December 26–30, with headquarters in the Claypool Hotel. In addition to the eighteen sections of the Association, some seventy affiliated and associated societies will also meet. Further information can be obtained from Sidney S. Negus, Medical College of Virginia, Richmond, Virginia.

A THREE-DAY meeting of the Society of Glass Technology is to be held at Elmfield, Northumberland Road, Sheffield 10, during November 26–28. The programme includes delivery of the presidential address on "Forty Years beside the Glass Industry" by Mr. C. E. Ramsden (on November 26) and a symposium on "Radioisotopes and Glass" (on November 27). Further details may be obtained from the Society of Glass Technology, Thornton, Hallam Gate Road, Sheffield 10.

ERRATUM. In *Nature* of August 10, p. 296, the legend to Fig. 1 of the communication on "Photoperiodicity and Wool Growth in Romney Rams and Wethers" by Dr. A. B. Wildman should read: "Weight of clean wool conditioned to 67° F., 65 per cent relative humidity from tattooed squares".

EDUCATION AND THE UNDER-DEVELOPED TERRITORIES

SIR SYDNEY CAINE'S paper, "Education for Development", read on September 9 before Section L (Education) at the British Association meeting in Dublin, was in the vein of Prof. P. M. S. Blackett's presidential address. Although, like Prof. Blackett, Sir Sydney was concerned largely with the under-developed countries, much of what he said about the part which education has to play in the business of development bore closely on economic or industrial development anywhere, whether in the developed or the under-developed countries. As Sir Sydney pointed out, the real difference between such countries lies in the magnitude of current incomes and current capital equipment. Broadly, the under-developed countries are the poorer countries of the world and the developed are the richer, and though there may be no precisely agreed definition as to the meaning of richer or poorer, there is rarely uncertainty as to the category to which particular countries belong.

If, further, we remember that at the bottom of the process of development is the creation of wealth, and that this in turn depends on the application to a country's basic national resources of human skills and labour, assisted by capital, in turn the product of human effort, it is understandable how largely education is the common factor and the common problem. Without human skill and labour, natural resources are indeed useless, and of capital Sir Sydney remarked again that it depends on human endeavour and human abstinence to bring it into existence. The spread of knowledge and skill is fundamental to the whole creation of wealth.

Sir Sydney passed briefly over the question of technical knowledge, without deprecating it, emphasizing that merely technical knowledge is by no means enough. It must be supported by advancing fundamental scientific knowledge, as well as by the habit of mind, apt to be overlooked in the West, which accepts and applies technology, combining theoretical knowledge from books and laboratory experiments with the readiness to engage in hard and dirty labour. Again, the technologist needs also the support of more general education in two senses. Besides the creation of more wealth, full and healthy social and economic development involves raising the level of social organization and economic capacity, and this can only follow as the level of education is raised. Secondly, economic developments do not occur in isolation; and the production of more wealth brings new problems of distribution and utilization, the solution of which requires men and women trained in economics and social science as well as in natural science and technology.

Often, however, the problem of economic improvement is fundamentally one of sociology, not technology. The would-be developer repeatedly encounters situations in which sociological obstacles prevent the adoption of a major technological change which would substantially improve economic output, and Sir Sydney cited as an example the production of rice in Ceylon. This could be increased substantially by major new technical developments of irrigation and opening up unused land, but much more substantially by the adoption by existing rice cultivators of better methods already proved elsewhere. The latter means would not have involved the considerable capital investment necessary for irrigation and land development, but propaganda and persuasion of a complex type, because the existing technique of growing rice is bound up with the whole way of life in villages, and affects family relations, inheritance and even religion, thus representing a long task for the sociologist as much as for the agricultural technician.

This illustrates the second broad aspect of the need for general education which Sir Sydney Caine emphasized. It is not sufficient for the directors or operators of development to be trained in matters other than technology: the general public with whom they deal also must be sufficiently well and broadly educated. In agriculture, as in all industrial or other advanced technological operations, a sufficient level of general education is essential; and in most under-developed countries the shortage of technicians and skilled craftsmen is the real obstacle to rapid economic development. Technology is not enough. Technicians and technologists must be educated in the social as well as in the natural sciences, and the mass of the population as well as the technical élite require general education.

Reviewing next the problems of education in the under-developed countries, Sir Sydney pointed out that only highly developed countries can afford general education in its modern form, and in starting from scratch in the under-developed countries the cost of technical education can be appalling. Moreover, the diversity of language constitutes a complication which can be a most serious obstacle, particularly as higher education is bound to make great use of languages foreign to the mass of the people, while mass education is necessarily conducted in the vernacular. The supply of text-books and periodicals is another great difficulty, especially at the university and postgraduate level; and the whole problem is often further aggravated by the emotional aspects of language. Sir Sydney did not hesitate to condemn the waste of time and effort, at a time when rapid progress in education is so urgent, caused by the multi-lingual education due to racial or national prejudice. Even without this, it is difficult indeed, with the great shortage of highly trained men and women, to induce enough of them to enter the higher levels of the teaching profession, and especially in those countries emerging to national status from Colonial dependence.

All this raises serious threats to the quality of education. In spite of the acute shortage of qualified local citizens for university or technical teaching, for example, emotionalism sometimes prevents effective use being made of outside assistance. Sometimes, too, it is assumed that if the right things are done, real incomes will rise and real wealth grow unprecedentedly quickly; and there is real danger of sacrificing quality to quantity and of so overloading the teachers that they become ineffective. Sir Sydney referred particularly to the danger of lowering standards of admission to universities. According to a recent report from the University of Indonesia, of the 2,000 registered students in the Faculty of Engineering for the year in question, 1,300 were in the first year, a dozen or so in the fifth or final year and only one graduated.

The considerations noted by Sir Sydney imply that by its very nature the task of education for development must fall in the main upon the under-developed countries themselves, and in this connexion he stressed the importance of the 30,000 overseas students in the United Kingdom, the great majority of whom come from under-developed countries, while a high proportion of these are privately financed. Nevertheless, the developed countries have a most important part to play, particularly at the level of university and technical training, but their own specialized man-power difficulties set strict limits to what they can do; and Sir Sydney commented that the London School of Economics has every year to reject a high percentage of applications from abroad for higher degree studies because it has reached the limit of the numbers which its teaching staff can effectively supervise. The resources to be shared with the less advanced countries are not solely finances but above all highly trained men and women; and this is already being done by numerous agencies. Besides the great help given by British universities, through their organization as well as by offering places to overseas students, more than £29 million has been contributed during the decade 1946–56 by the British taxpayer to overseas students and education through the British Council and Colonial Development and Welfare Funds.

As the fruit of these and earlier efforts, there are now in British Colonies or former Colonial dependencies four universities, five university colleges and various other institutes of higher education. The Colombo Plan, which is essentially a collective name for various loosely co-ordinated pieces of mutual assistance by one Commonwealth country to another, has brought to numerous individuals in the under-developed areas opportunities of study overseas and grants of assistance to educational institutions. Commonwealth countries are also helping in ways quite outside the Colombo Plan, while many countries have received considerable aid to education under American foreign aid programmes. There is also the substantial help given by the Rockefeller Foundation and other private foundations, particularly for the initiation of new projects; and on the international plane much is being done through the Technical Assistance Board of the United Nations, through the United Nations Educational, Scientific and Cultural Organization and in specifically technical fields by the other specialized agencies such as the Food and Agriculture Organization and the World Health Organization.

Both the finance and technical personnel required for all this come in the main from the developed countries, and in this connexion Sir Sydney urged the importance of doing everything possible to ensure that British people who undertake a period of service abroad do not thereby damage their prospects for appointments in Britain. Something more could also be done to encourage the exchange of books and periodicals and the movements of scientists and other learned men. This is still liable to be hindered by political considerations even in non-Communist countries, and Sir Sydney fears that there is a danger of a system of exclusion of books and periodicals arising in non-Communist under-developed areas. Every effort should be made to assist people from under-developed countries to attend meetings of learned societies and to ensure that the problems of these countries receive attention at such meetings; Sir Sydney also suggested that the production in a single language appropriate to a particular area of summaries of scientific publications in diverse languages would be a very fruitful piece of international co-operation.

Such projects can scarcely become effective, however, unless the less-developed countries refrain from accentuating difficulties by exaggerating political, linguistic and psychological obstacles. If, however, the developed countries use to the full their opportunities for initiative in sharing their educational resources along such lines as Sir Sydney Caine indicates, that in itself would encourage the growth of mutual tolerance and goodwill. There would, nevertheless, appear to be a wide field in which professional societies could support what the universities and many educational institutions are already doing, not only to encourage the growth of such an atmosphere of goodwill, but also, and no less important, to assist the wisest and most effective use of the most precious of all resources, in developed and under-developed countries alike—that of trained men and women.

BIOLOGICAL RHYTHMS

At the sixth conference of the Society for Biological Rhythms, held on the Semmering, near Vienna, during August 26–28, thirty-six papers were presented by members and guests from eleven countries. They were welcomed by Dr. E. Dissmann (Klagenfurt), the local secretary.

The main theme of the opening session organized by Prof. A. Jores (Hamburg) was "Time in Biology", which was covered by six invited speakers. H. Laurell (Halmsted) critically discussed ancient and modern ideas of time, and contrasted its physical, physiological and psychological aspects; he also reviewed methods of measuring time. J. Aschoff (Heidelberg) elaborated the idea of time-cues or clues (*Zeitgeber*), namely, those periodical factors, external to a rhythmic system, which can be shown experimentally to control its phase. He demonstrated that in constant conditions of temperature and illumination and in the absence of noise or mechanical disturbance, 24-hr. patterns in the motor activity of vertebrates persist but gradually fall out of step, thus indicating that all external time-cues have been successfully eliminated. By reintroducing these potential cues one at a time their relative efficacy can be assessed. H. Kalmus (University College, London) observed that all life is accompanied by an incessant redistribution of material in space and time, and thus defined the investigation of biological rhythms as a study of the synchronization of mechanisms of transport. The appearance of any biological material at the 'right' time and at the 'right' site can be interpreted as a homœostatic arrangement brought about by the remote causes of selection, but must also be explained by the operation of physiological cues at any particular time. The opportunist nature of selection and the complexities of biological organization frequently produce non-optimal time adaptations and limited adaptability.

Dissociation of time-cues and internally established rhythms, such as those brought about by night work or air travel, may thus cause serious disturbances. Sir Nigel Ball (London) stressed the advantages, for bio-rhythmic studies, of plants over animals, in so far as the former lack the complications of a central nervous system. Using infra-red photographs he showed the extension growth of oat coleoptiles to be governed by a rhythm of approximately 24 hr. duration; this he could induce by transferring seedlings from light to darkness, and he could retard it by lack of oxygen. The rhythm persisted even after the removal of the tip of the coleoptile. In a more general way, Sir Nigel discussed the establishment and synchronization of rhythms in single elements and aggregates, and contended that the functional significance of the endogenous rhythms widely found in plants still remains obscure. F. Halberg (Minneapolis) surveyed many examples of physiological functions dependent upon time, and E. von Stockert (Rostock) gave a lively account of disturbances in the time sense and time consciousness of psychotic patients.

The six speakers at the opening session then formed a panel for a joint discussion of "Time in Biology", together with speakers from the floor. Also discussed was a lecture by J. Wilder (New York) concerning the relevance of that author's law of initial values for the interpretation of certain apparently rhythmic biological phenomena. J. Ješić (Sarajevo) claimed that, in the growth and decay of biological systems, cycles are best described by parabolas, and indicated some practical uses for such a concept.

The shorter papers of the later sessions were loosely grouped according to subject-matter or method. The 24-hr. periodicity of division in normal and malignant cells was discussed by F. Halberg, E. Halberg and J. J. Bittner (Minneapolis), and the implications for bioassay of daily fluctuations by F. Vering (Vienna). Daily fluctuations of bodily functions and their clinical importance were discussed by J. Blume (Düsseldorf), who exemplified the mathematical problems by analysing some of Kleitman's temperature curves during and after regimens in artificial light with periods of twenty-one and twenty-eight hours; W. Menzel (Hamburg) demonstrated variations in the interdependence in health and disease of the 24-hr. rhythm of rectal temperature, urine volume and concentration of chloride, urea and creatinine.

Ch. Kris (Cambridge, Mass.) presented results showing correlations between numerous performance tests and physiological measurements in respect of diurnal and menstrual rhythms, and described an objective measure of physiological age derived from her measurements. The biological age of man was also discussed by M. B. J. Nadel (Herzlia, Israel), and H. U. Ziolko (Berlin), who described disturbed day/night rhythms of vegetative functions in neurotic patients, and tried to explain some of their peculiar experiences during sleep as consequences of disturbed synchronization. S. Gifford (Boston) considered the developments of the pattern of sleep and wakefulness in infants from the point of view of a psychoanalyst, and T. H. Hellbrügge (Munich) treated the subject from the point of view of the physiologist. M. B. Ischlondsky (New York) dealt with the harm which may be caused by stimulation during 'inhibitory phases' of the human central nervous system, a factor which he holds responsible for many of the contemporary psychosomatic disorders. A. Topitz (Vienna) described one particular disturbance of rhythm, namely, that resulting from air travel in an eastern or western direction. After the Vienna Philharmonic Society's air journey to Tokyo it took its members about four days to become fully adapted to Tokyo local time. He reported similar experiences from several European athletes at the Melbourne Olympic Games.

Applying a principle first introduced by Möllerström to the insulin therapy of diabetes, H. G. Dennemark (Berlin) described clinical experiments demonstrating the importance for therapy of the hour of day at which various drugs and their combinations are administered in the treatment of hypertension.

L. Stark (Newhaven) considered nervous disorders such as tremor, ataxia or clonus as manifestations of inefficient servo-mechanisms. He gave a description of the working reflex to light of the pupil of the eye in terms of an automatic control device, and showed that certain pathological reactions he found in disseminated sclerosis could be understood by making simple assumptions concerning some parameters of an information loop. H. Drischel (Greifswald) described experiments in which he asked people to synchronize pairs of regular sequences of light flashes, acoustic clicks and taps on the finger tip. Transfer from the periodicity perceived with one sense to another was reasonably accurate within 5–15 hertz, but systematic errors occurred in certain transformations at specific frequencies.

The relation between respiratory, cardiac and vasomotor rhythms was discussed by several speakers: H. P. Koepfchen and K. Thurau (Göttingen) demonstrated curves indicating that the rhythms of vasomotor tonus and of respiration in the rabbit and dog are co-ordinated centrally at a frequency 1 : 1; but showed that other simple proportions of the rhythms occur in exceptional cases. K. Golenhofen (Berlin, Litchterfelde) showed that an analogous situation exists in man by comparing graphs of the rhythmic activity of the peripheral and central blood circulation, and H. Jordan (Bad Elster) demonstrated the presence in periodograms derived from human electrocardiograms of three rhythms, of 12, 28 and 60 sec. average duration, which he considered to be superimposed on the ordinary heart-rhythm.

Other statistical contributions included a paper by K. Freudenberg (Berlin), who presented an extensive collection of data on mortality disproving the belief in the biological importance of every seventh, fourteenth, twenty-first, etc., year of human life, and a paper by W. Otto (Falkensee) on annual fluctuations in birth weight. The possible importance of seasonal climatic factors, in particular of cold fronts, on asthma attacks and mental symptoms was discussed by S. W. Tromp (Leyden), who also expressed the hope that meteorological measurements during the current International Geophysical Year might profitably be correlated with detailed clinical observations.

Some fascinating glimpses into the homœostatic mechanics of rhythms were provided by G. C. Stephens (Minneapolis). Applying temperature changes to previously established light-controlled rhythms, as had been originally done by Kalmus, he analysed the 24-hr. movements of the melanophore pigment in the fiddler crab, *Uca pugnax*. Within the temperature-range 6–26° C., a 24-hr. melanophore periodicity persisted in permanent darkness. The phases of induced rhythms could, however, be shifted by sudden changes in temperature provided these exceeded certain threshold values. Delays caused by extreme cooling persisted in darkness and were additive. Individual crabs in which melanophore rhythms of different phase had been induced kept them side by side when transferred to the same darkened aquarium. In spite of this independence of phase it was observed that the amplitude of the melanophore changes was increased by the presence of other fiddler crabs of the same or another species.

Among the papers circulated but not read, that by K. Hoffman (Wilhelmshaven) dealt with the influence of temperature and pretreatment on the 24-hr. motor activity of lizards; Y. Ondo's (Tottori, Japan) with the responses of shore sowbugs to the periodic movement of waves; E. Szirmay's (Budapest) described some uses of the comparative study of muscle rhythms, and L. S. Copelman's (Bucharest) dealt with some of the philosophical aspects of biological time.

The International Society for the Investigation of Biological Rhythms, to give it its original name, has now been in existence for twenty years, and at its six conferences a considerable part of the field has been surveyed. More recently the elaboration of general methods for the investigation of bio-rhythms and the formulation of a unifying theory have been attempted.

It is hoped that the full text of the papers will shortly be published. The Society has been invited by Dr. A. Caniggia (Siena) to hold its seventh conference in 1960 in Italy. Inquiries concerning the proceedings, membership and other matters should be addressed to Dr. A. Sollberger, Department of Anatomy, Karolinska Institutet, Stockholm.

H. KALMUS

FLAMMABILITY OF TEXTILES

IN the past few years an increasing amount of publicity has been given to accidents resulting from the burning of clothing, and in the United States legislation has been introduced to prohibit the sale of certain very inflammable types of fabric. In the United Kingdom various safety committees have been set up, and a valuable report on the flammability of apparel fabrics in relation to domestic burning accidents has been published by the British Standards Institution*. It was not surprising, therefore, that the one-day conference, organized by the Textile Institute and dealing with the flammability of textiles, attracted a great deal of attention, for this was probably the first time that members of the textile industry, of the distributory trades and of the public were able to meet and discuss together the many aspects of the problem. The conference was held at the laboratories of the Rayon Research Association in Manchester on October 15, and was opened by the president of the Textile Institute, Sir Ernest W. Goodale.

It was evident from the substance of the four papers which formed the basis of the Conference that the seriousness of the high inflammability of certain textiles is widely appreciated and that the textile industry is anxious to overcome this hazard. Progress in dealing with the problem has in the past been hindered by lack of precise information, and perhaps the most important feature of the conference was the dissemination of reliable data to replace the lore which is often associated with anything that has to do with fire.

Mr. D. I. Lawson, of the Joint Fire Research Organization, summarized valuable data on the incidence of burning accidents, and his paper emphasized several unexpected observations. Of particular seriousness to the textile industry was the statement that burns involving clothing had the highest mortality-rate of any kind of burn, and that four out of five of the total accidents reported occurred in the home. This is in spite of repeated warnings of the danger from unguarded fires. It was indeed surprising to learn that only half the parents of young children questioned in an investigation had a fireguard. Mr. J. S. Ingham, of Messrs. Marks and Spencer, Ltd., who dealt with the economic aspects of fireproofing and with the possibility of being able to sell fire-proofed garments, also stressed the dangers associated with flared-out dresses and particularly with children's nightdresses made from winceyette.

All the speakers and many members of the conference agreed on the need for a publicity campaign to encourage the use of fireguards in homes where there are young children, and to popularize close-fitting night wear. Mrs. Jean Mann, M.P., speaking from the floor, suggested that the provision of fireguards should be made a condition of house letting.

The other solution, with which the textile and chemical industries are more directly concerned, is, of course, the provision of safe fabrics. It is difficult to define a 'safe' fabric, for the textile industry and the public must be in agreement about this. One of the first problems, therefore, is to devise a test for inflammability which has some relation to the practical hazards usually met with. Several of the suggested methods were discussed in detail by Mr. F. Ward, of Courtaulds, Ltd. Mr. Lawson thought that it would be unnecessarily stringent to define as safe only those fabrics which would not ignite when exposed to a radiant source of energy similar to that emitted from the surface of open fires. Measurement of the vertical speed of flame propagation was generally regarded as being more satisfactory because this gives the length of time available to extinguish the flame or to discard a burning garment. Apparatus for measuring this was described and the term 'flame resistance rating', defined as the time for flame to be propagated 100 in. vertically, was used for expressing the results obtained. Dr. T. H. Morton, of Courtaulds, Ltd., provided a great deal of useful information on how the flame resistance rating is affected by the composition, construction and weight of the fabric, and by the use of special processes, including some of the modern fireproofing finishes. There are many finishes which will reduce flammability, but for general acceptance other characteristics such as permanence of the proof and the feel of the cloth have also to be considered. There was general agreement that any proof used for children's nightdresses should give flame resistance throughout the life of the garment, that is, the effect should not be removed by as many as fifty washes.

Clearly one of the most difficult tasks is to define a safe value for the flame resistance rating. Mr.

---

* British Standards Institution: *PD 2777* (1957).

Lawson suggested that a safe level should be well away from the level associated with the recent run of burning accidents, but not so high as to eliminate more types of fabric and flame retardant treatments than necessary. It was recommended that fabrics with a durable flame resistance rating of greater than 150 should be warranted as flameproof and identified as such. Most of the manufacturers of durable flame proofs are confident of being able to meet this standard, and many useful unproofed fabrics would be regarded as being safe.

The discussion by members of the conference was particularly stimulating, and included contributions from Dr. J. B. Bull, who has been intimately concerned with surveys made by the Burns Unit of the Medical Research Council, and from Mrs. Jean Mann, M.P., Mrs. F. P. A. McLaughlin, M.P., and Mr. Hervey Rhodes, M.P., all of whom are well known for their interest in the problems of safety and textiles.

The general conclusion from the conference was a unanimous agreement on the need for an intensified safety campaign at national level and for providing safe fabrics. Although many of the fabrics at present regarded as dangerous can be made safe by treatment with reagents such as tetra*kis*hydroxymethyl phosphonium chloride, antimony oxide, and mixtures of antimony and titanium oxides, it was recognized that a need still exists for cheaper durable treatments. Members of the conference, particularly the chemists and textile finishers, left greatly encouraged, knowing that the difficult problems with which they have to deal are sufficiently important to demand maximum effort and imagination.

C. S. Whewell

THE ROCKEFELLER FOUNDATION

In the Rockefeller Foundation annual report, 1956, the President's review, reprinted with a summary of the Appropriations Account and Principal Fund and a list of appropriations made in 1956, notes that for the year the appropriations totalled 30,075,305 dollars, the largest for any one year since the Foundation was established in 1913. Of this total, 5,963,605 dollars were for the humanities, 5,501,100 dollars for biological and medical research, 4,877,400 dollars for agriculture, 4,290,605 dollars for medical education and public health and 3,290,260 dollars for social sciences. For the fellowship programme, under which 458 individuals from 47 countries held fellowships in 1956, 2,025,000 dollars were appropriated.

In his review Dean Rusk stresses three features of the year's activities. First, noting that nineteen of the present eighty-one member States of the United Nations, with a population of more than 650 millions, have emerged as fully independent nations since the Second World War, he emphasizes that the officers and trustees of the Foundation believe that peace and orderly economic growth in the world during the next twenty-five years will be decisively influenced by what happens in these independent nations of Africa, the Middle East and Asia. Peace and stability will gain enormously if they establish constitutional systems with friendly and easy exchange with the rest of the world, increasingly productive economies, and educational systems which can train leaders in adequate numbers and educate their citizens for the responsibilities of their new societies. To enable the Foundation's expenditure on Latin America, Asia, the Middle East and Africa to be sharply increased without a large reduction of expenditure in the United States and Europe, the Trustees have decided to draw on capital funds for several years. During 1956 some 6 million dollars were allocated to the expanded programme, over and above the normal allocations to these areas from income.

Secondly, the President reviews at some length the Foundation's responsibilities in the nuclear age, commencing with its grant in 1940 toward the construction of a 184-in. cyclotron at the University of California, Berkeley. The report suggests that there are three main directions in which the resources of the Foundation can be usefully applied, taking into account the very large sums available from government and industry. The first is the public health aspects of nuclear energy, broadly conceived and for study of the effects of radiation on man. For the formulation of questions upon which further research is urgently needed the Foundation has already made grants to the National Academy of Sciences totalling 275,000 dollars. The second is in the Foundation's traditional support of basic scientific research with the main emphasis upon the living processes. Here, the nine grants for research in genetics made during the year totalled 991,000 dollars, the largest, 350,000 dollars, being to the University of Indiana, while 260,000 dollars went to the University of Copenhagen, 61,000 dollars to the National Centre for Scientific Research, Paris, 50,000 dollars to the Institute for Human Genetics, Upsala, and 24,000 dollars to the London Hospital Medical School. A third type of study for which Foundation support is planned, on a selective basis, is that of the economic, legal and political problems of the nuclear age, with special reference to the increasingly complex issues of international relations, with which nuclear energy is now inextricably bound up. About a dozen grants have been made to young professors in universities throughout the United States studying a wide range of contemporary political problems. The Foundation also hopes to assist a few mature scholars to embark on, or to complete, significant research in this field, to encourage institutes to undertake objective studies of international political problems, to stimulate the growth of organized knowledge and theories of foreign policy, including the techniques and principles involved in its conduct.

The third aspect of the year's activities emphasized by Dean Rusk is the assistance given to Hungarian scientists, scholars and students. To this refugee problem the Foundation in late 1956 and early 1957 devoted more than 1,200,000 dollars, almost 700,000 dollars of which went to the institutions in Austria which bore the brunt.

In the field of medical education and public health considerable attention was paid to professional education, grants for which included 367,400 dollars to the Christian Medical College, Vellore; 299,750 dollars to King George's Medical College, Lucknow; 273,300 dollars to Seth Gordhandas Sunderdas Medical College, Bombay; 570,000 dollars to the University of the Andes, Bogotá; 215,000 dollars to the Recife Medical School, Brazil; 290,000 dollars to the School of Medicine, Keio University, Tokyo; and 100,000 dollars to the Department of Child Health, University of Ankara. A grant of 163,280 dollars was made to provide four years support for studies of population dynamics in Indian villages jointly by Harvard

University and the Christian Medical College, Ludhiana, while one of 250,000 dollars to the Massachusetts Institute of Technology, for medical and biological research, was for the construction of a 1,000 kilowatt nuclear reactor at Boston, which would project a beam of nuclear rays into a therapy room underneath.

Some rather substantial grants of a general character made in 1956 were for the library at the international zoological station, Naples; for biological research at Amherst; for research in the natural sciences at the University of Mexico; and for biology, experimental medicine and surgery at Copenhagen. The largest of three grants for investigation of ways of meeting the nutritional requirements of children, especially during the critical years after weaning, was to the National Research Council and is being administered in close co-operation with the global programme of the United Nations Children's Fund. About 1,250,000 dollars were appropriated for field studies of viruses and basic research in virology. This included aid to collaborating groups.

In 1956 a further co-operative agricultural programme was started at the Indian Agricultural Research Institute, New Delhi, the first interests of which will be to improve the corn, wheat and other cereal crops and broad questions of advanced agricultural training and research. Under the Mexican co-operative programme, more than 400 young Mexicans and some 85 other young scientists from Latin America and the United States have received training. During 1956, 204 individuals from 30 countries received fellowships, scholarships or other study and travel grants in agriculture. Besides its participation in various types of international exchange in this field, such as the conference of 50 leading pathologists from Latin America, the United States and Canada on cereal rusts, the Foundation made numerous grants to institutions. These included 300,000 dollars to the College of Agriculture, University of Chile; 250,000 dollars to the College of Agriculture, University of the Philippines; and 200,000 dollars to the School of Agriculture, Universidade Rural de Minas Gerais, Brazil. A three-year grant of 153,600 dollars was made to the Harvard Graduate School of Public Administration to assist a seminar offering advanced training in new methods of water conservation and management.

In the social sciences, a grant of 98,400 dollars to the Computer Centre, Massachusetts Institute of Technology, was for further exploration of the uses of an advanced high-speed digital computer in solving theoretical and applied problems in the social sciences. A grant of 150,000 dollars to Vanderbilt University was for its Institute of Research and Training in the Social Sciences; of 114,000 dollars to Tulane University of Louisiana, for Latin American, legal and social studies; of 96,000 dollars to Stanford University, for its Food Research Institute; and of 50,000 dollars to the International Bank for Reconstruction and Development for its Economic Development Institute. The largest grant for international understanding in the United States in 1956 was one of 205,000 dollars over six years to the Harvard University Centre for Middle Eastern Studies, while 140,000 dollars went to the Federated Theological Faculty of the University of Chicago for inter-religious studies. The American University of Beirut received 216,000 dollars in continued support of its Arab studies programme.

ONTARIO RESEARCH FOUNDATION

REPORT FOR 1956

THE annual report of the Ontario Research Foundation for 1956* includes, besides the report of the director of research, Dr. H. B. Speakman, the financial statement and lists of papers published during 1956, with details of professional and technical staff, advisory committees, scholarships and post-graduate grants in science, 1956–57. In the Department of Biochemistry, where work for the tanning industry increased, progress was made in a group project on the production of sole leather with increased resistance to wear. The oils and fats laboratory has been investigating the production of a spread for use on Army biscuits, manufactured if possible from Canadian raw materials. It has also been studying the autoxidation of methyl isolinoleate, linoleate and oleate, using the Warburg respirometer, and the separation by gas chromatography of the volatile substances produced during the deterioration in flavour of fats and oils. A study of the fermentation of cheese whey was completed.

In the Department of Chemistry progress was made both in the development of methods for separating and determining different constituents of waste sulphite liquor and in evaluating the lignin components as sources of tanning agents and dispersing agents. Work also continued on the production of organic polymers, and the Foundation is supporting the design and construction of an atmospheric X-ray spectrometer incorporating an electron gun. Application of improved techniques developed for the analysis of condensed phosphates in fundamental studies of phosphate glasses, solutions and crystalline compounds led to the conclusion that there is a remarkable similarity in the dependence of the molecular-weight distribution of the glassy phases on their cation to phosphorus ratio.

Studies of the mechanism of fatigue failure of metals advanced considerably, and it was shown that a strong magnetic field affects the fatigue strength of ferritic metals. Basic research in the X-ray laboratory was concerned mainly with X-ray spectrographic studies, and more time was given to an investigation of the initial stages of oxidation on a metal surface.

In the work on parasitic nematodes, a minute nematode, *Aproctella stoddardi*, was recovered from a ruffed grouse, and is believed to account for one of the microfilariae previously described as occurring in this bird. Low dosages of 'Daraprim' comparable to those effective against human malaria did not prevent infection from *Leucocytozoon simondi* developing in ducks, and particular attention was also paid to the relation between the time of infection and the prevalence of blood-sucking insects known to feed on ducks.

Work was commenced on the composition of the sand fraction from glacial tills and comparable water-laid sands, while studies continued on the relation between variety and yield of soybeans. In textile research, the Sigma Unevenness Tester, previously developed, was used in a survey of worsted yarns produced in Canada, and to a limited extent in the United States and Europe.

CARDIOTONIC ACTIVITY OF THE POTATO-ROOT EELWORM HATCHING FACTOR

By Dr. C. ELLENBY and A. B. GILBERT

Department of Zoology, King's College (University of Durham), Newcastle upon Tyne

FOR many years it has been known that hatching of the potato root eelworm, *Heterodera rostochiensis* Wollenweber, takes place in response to a specific stimulus given off by the roots of the potato plant[1]: this 'hatching factor' is contained in the so-called potato-root diffusate. Attempts to isolate it have been made in Cambridge[2] and, more recently, in Groningen[3]; but although a good deal is known of its constitution, its exact nature is still unknown. The mechanism of its action is even more mysterious. Attempts to isolate the factor are severely handicapped by assay difficulties, for the only method is the hatching trial which, in its most commonly used form, is of three weeks duration[4]. It seemed highly desirable to attempt to find some preparation other than the eelworm which responds to the hatching factor; not only might this throw some light on the hatching mechanism itself, but it might also be of direct use as an assay method. The purpose of this article is to announce some initial success in both these directions.

It has already been shown that the hatching factor, eclepic acid[5], is probably a lactone acid of molecular weight about 300, containing an unsaturated lactone ring, a carboxyl group and two OH groups[6]. It seemed to us not unreasonable to assume that the activity might be associated with the lactone ring: it is well known that the lactones, particularly the unsaturated forms, include some of the most biologically active substances[7], and, in particular, that the cardiac glycosides, digitoxin, ouabain, etc., are among them. Moreover, it has already been shown that some, though not all, of the actions of cardiac glycosides[8–11] can be reproduced on the frog heart by simple unsaturated lactones. We have now found that the isolated frog heart responds to the hatching factor.

In general, the techniques used have been those of Giarman[8]. In some trials, the heart has been continuously perfused via the sinus, using the cannula he describes; more frequently, and in order to conserve our small supply of active substances, we have, like him, used a Straub preparation, cannulating the ventricle via the truncus. After perfusion in a Ringer solution, a hypodynamic state is induced by perfusion with a low-calcium Ringer solution; perfusion with a cardiotonic substance in low-calcium Ringer solution leads to a recovery. Fig. 1 shows the typical response to a series of dilutions of a concentrated preparation of the hatching factor.

Table 1 RELATIVE HATCHING STRENGTH AND CARDIOTONIC ACTIVITY

Preparation	Optimum hatching conc. (mgm./100 ml.)	Relative activity; hatching	Minimal cardiotonic conc. (mgm./100 ml.)	Relative activity; cardiotonic
G. 1	0·8	5·0	3	6·0
G 2	2·5	1·6	5	3·6
Cambridge 'standard solid'	4·0	1·0	18	1·0

Almost all our work has been carried out with either of two concentrated preparations. One, 'standard solid'[2], was kindly given us by Sir Alexander Todd some years ago. For the other preparation, *G*.1, we are indebted to Dr. G. J. Janzen, of Groningen. With either preparation, the response varies with dilution, within certain limits; a more severe test, however, is the comparison of the two. The activities have been compared by the minimal concentration required to produce a detectable effect: the standard has its limitations, but the overwhelming necessity to conserve material has imposed this upon us. In the event, the comparisons have shown good agreement. The minimal concentration for the Dutch preparation is consistently 3 mgm./100 ml.; with the Cambridge standard solid, it is about six times greater. Since the recommended optimum hatching concentrations for these two preparations are 0·8 mgm./100 ml. and 4 mgm./100 ml., the agreement of the hatching and cardiotonic assessment is remarkable. The results are summarized in Table 1.

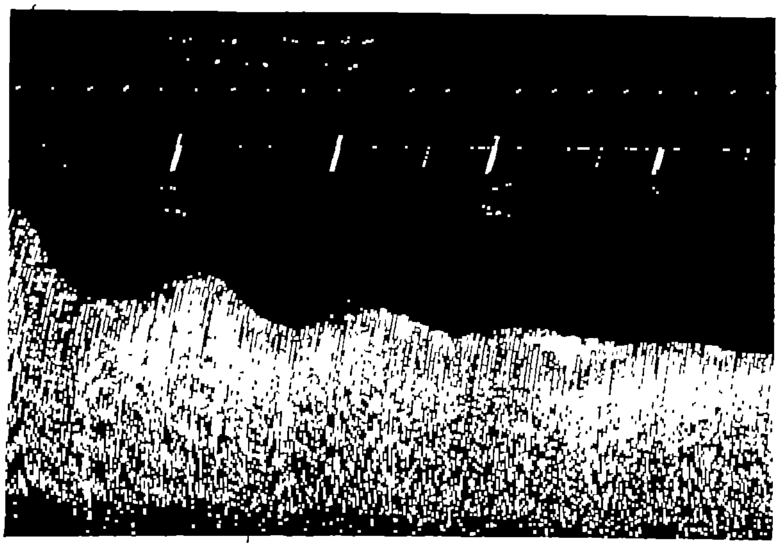

Fig. 1. Cardiotonic effect of hatching factor. Tracing begins with frog heart being perfused with Ringer, followed by low-calcium Ringer solution (single signal). Triple signals, from left to right, 64, 32, 16, 8 mgm. Cambridge 'standard solid' per 100 ml. low-calcium Ringer solution. Time signal, 30 sec. Straub preparation

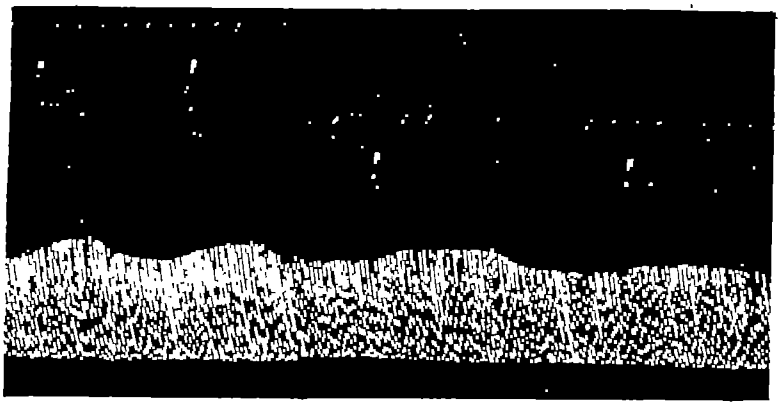

Fig. 2. 'Synergism' (see ref. 9) of hatching factor and strophanthin-*g*. Tracing begins with frog heart being perfused with low-calcium Ringer solution. First triple signal from left, 4 mgm. *G*.2 + 10 μgm. stroph.-*g*/100 ml. low-calcium Ringer solution: subsequent triple signals, respectively, 4, 4 and 3 mgm. *G*.2, all per 100 ml. low-calcium Ringer solution without strophanthin-*g*. Each stimulus is followed by low-calcium Ringer solution (single signal). Earlier tests in this same run had shown no response of the heart to any of these concentrations of *G*.2 or of 10 μgm. strophanthin-*g*. Time signal, 20 sec. Straub preparation

Very recently, however, we have carried out tests with two further Groningen preparations, *G*.2 and *G*.3; with these agreement has not been so good. As shown in Table 1, *G*.2 has a higher cardiotonic activity than its hatching assessment would suggest; nevertheless, it falls in its correct relative position. *G*.3 was the weakest preparation we have tested, its optimum hatching concentration being 5 mgm./100 ml.; and a sufficient quantity for tests with only ten hearts was available. In the event, the first run gave a reasonable agreement with the hatching assay, the minimal concentration being 54 mgm./100 ml.; however, no positive response was obtained with any of the other hearts. We have no explanation to offer for this; but we have evidence that this preparation may be unstable.

As an assay method for the hatching factor, perfusion of the frog heart has many limitations. The fact that it is far less sensitive than the eelworm is of little importance, for solutions of root diffusate are readily concentrated[12]. But the frog heart must be treated with ionic respect, and solutions obtained from potted potato plants will be quite unsuitable for perfusion; however, it has already been shown that it is not impossible to overcome this difficulty[3]; moreover, the Cambridge preparation has been assayed successfully in the present work, and this was obtained as a result of the first step in the attempt to isolate the factor, namely, absorption on charcoal and subsequent evaporation[2]. A more serious difficulty is the fact that the heart assay is unspecific—clearly the final arbiter of hatching activity must be the eelworm. Nevertheless, we are confident that, used with discretion, assay by perfusion of the hypotonic frog heart may be of use in attempts to isolate the factor.

Considering that we are dealing with preparations which are far from pure, the activity of the stronger ones compares very favourably with the more active simple lactones[9]. Moreover, as shown in Fig. 2, the minimal concentration can be halved by perfusion together with, or subsequent to, perfusion with a subminimal concentration of strophanthin-*g* (ouabain). A response at half the minimal concentration has also been obtained by perfusing the heart with the hatching factor plus a sub-minimal concentration of hydrogen peroxide. The 'synergism' with strophanthin-*g* and potentiation with peroxide are of particular importance, for they indicate that the responses obtained are indeed identical with those given by the pure lactones[9]. Moreover, it has been found that hydrogen peroxide also 'potentiates' hatching: addition of only 5 μgm. of peroxide per 100 ml. of a very dilute solution of hatching factor led to a doubling of larval emergence. Peroxide alone was without effect. Since many more larvae emerged in identical drops of more concentrated hatching solutions alone, there can have been no shortage of oxygen as such which the peroxide made good.

The increased cardiac and hatching activity produced by the addition of traces of hydrogen peroxide to solutions of hatching factor strongly suggests that there are close similarities in the mechanisms involved.

The physiological activity of cardiac glycosides has recently attracted considerable attention, since certain of them have been shown to influence sodium–potassium transport in erythrocytes[13], frog skin (Johnson, V. K., personal communication) and isolated rabbit auricles (Weatherall, M., and Rayner, B., personal communication). Digitoxin has been shown to give rise to a peroxide in solution, and it has been demonstrated that, in this form, it may influence phosphorylation[14]. Simpler lactones may also have these actions: in fact, it was shown some years ago that they may behave as peroxides[11], and, more recently, it has been shown that certain of them may influence ion transport[15]. In the present work it has been demonstrated that the hatching factor has some of the properties of the cardiac glycosides and simpler lactones: if it should be shown that it influences the same fundamental physiological processes, not only will our understanding of the hatching mechanism be deepened, but also techniques of greater sensitivity and convenience may be available for its detection. These possibilities are being explored.

We are indebted to Prof. A. D. Hobson for his support, and wish also to thank Sir Alexander Todd, of Cambridge, and Dr. G. J. Janzen, of Groningen, for their interest and co-operation. The work was made possible by a grant from the Nuffield Foundation, to which we wish to express our thanks.

AMINO-ACID COMPOSITION OF THE SIX HISTONES OF CALF THYMOCYTES

By Dr. H. J. CRUFT, J. HINDLEY, Dr. C. M. MAURITZEN* and Dr. E. STEDMAN

Department of Biochemistry, University of Edinburgh

EARLIER work[1] from this laboratory established that the histones present in the cell nuclei of many species and tissues are composite in character, all of them containing a main and one or more subsidiary histones. The former, which constituted the major component, was characterized by a relatively small solubility in aqueous alcohol and a high arginine content; its general amino-acid composition was, indeed, typical of the traditional histones of the older literature. The subsidiary histones were more soluble, and, with one exception, were distinguished from the main component by their low content of arginine. Despite their deficiency in this amino-acid, they nevertheless exhibited strong basic properties. By examining an extensively fractionated specimen of a subsidiary histone from the thymocytes of the calf it was ascertained that, for this particular histone, these strong basic properties were due to a very high content of lysine. It was also characterized by a high content of alanine and proline and by the absence of phenylalanine, tyrosine and histidine[2]. The indication that it contained a minute amount of methionine is now known to have been incorrect, for this amino-acid could not have survived the conditions under which the chromatogram in which it was detected was prepared.

The existence of subsidiary histones rich in lysine and alanine in the thymus gland of the calf has since been confirmed by several groups of workers[3-7]. In the meantime, the results of our electrophoretic and ultracentrifugal studies of various histones had convinced us that all the subsidiary histones hitherto examined were actually mixtures of closely related proteins which had so far defied all attempts at complete separation. Such studies[8] had in fact shown that the total histone from the thymus gland of the calf and the liver of the ox consisted of six components which were designated α_1, α_2, α_3, β, $1 \cdot 6\ S$ and $0 \cdot 8\ S$ γ-histones. Of these, the first three replace the α-histone and the last two the γ-histone of our earlier nomenclature[8]. Such changes were rendered necessary by the discovery that the original α- and γ-components could be resolved into five histones. The three α's differed in their electrophoretic mobilities, while the two γ's possessed nearly identical electrophoretic mobilities although they differed in their sedimentation constants.

The physical characterization of these various components rendered possible attempts at their separation. The first step in this direction was the preparation from the total histones of the thymus gland of the calf of the crude α-fraction which, despite its name, actually comprised the three α-histones and the $0 \cdot 8\ S$ γ-histone. The further stages of fractionation presented, however, many difficulties. For various reasons, both ion exchange and adsorption (alumina) chromatography failed to achieve the desired results. Using the former method with the resin '*IRC-50*' (generously given by the Rohm and Haas Co., Philadelphia) according to the procedure of Crampton, Moore and Stein[9], two fractions *A* and *B*, corresponding with their results, were obtained. But when fraction *A* was examined electrophoretically it was found to consist of a mixture of α_1- and α_2-histones. In their recent work[10], Crampton, Stein and Moore have also been led, on other evidence, to suspect the homogeneity of their preparations.

Much greater success in the separation of the α-fraction has been achieved by zone electrophoresis. Using a medium of starch with veronal buffers at *p*H 8·5 and of ionic strength 0·18 a substantial separation of the above α-fraction into the four components has been effected. In the procedure adopted, the influence on the results of the tailing observed during the electrophoresis of histones on paper or in a starch medium, which is caused by the binding of the positively charged histones to the negatively charged surfaces of the medium, was largely swamped by using high concentrations of the α-fraction. A current of 40 m.amp. was passed through the starch in the trough, which had a cross-sectional area of 17·6 cm.^{2}. The trough was immersed in ice-cold water and kept in a cold room at 2° C. Electrophoresis was carried out for 80 hr., a time suggested by pilot experiments. A print on filter paper was then taken from the surface of the starch block. After staining, this indicated the presence of four bands. Four sections corresponding with the positions of these bands were then cut from the starch block and extracted separately with 0·1 *N* sulphuric acid. The extracts were then neutralized with sodium hydroxide and lyophilized. Of the four products so obtained, the one with the smallest mobility ($0 \cdot 8\ S$ γ) was submitted to a second run. The product was electrophoretically homogeneous, but when examined by sedimentation was found to be contaminated with the $1 \cdot 6\ S$ γ-histone. This was accordingly removed by preparative ultracentrifugation in 20 per cent aqueous alcohol at *p*H 9·0 and the $0 \cdot 8\ S$ γ-histone sulphate precipitated from the acidified mother liquors with excess of alcohol. The product now sedimented as a monodisperse substance at *p*H 8·5 with a sedimentation coefficient of $0 \cdot 83 \times 10^{-13}$. The quantities of the remaining three fractions available were unfortunately too small for further purification by zone electrophoresis. The four products were therefore dissolved separately in small volumes of water and dialysed in 'Cellophane' sacs successively against water and 0·1 *N* sulphuric acid. The sulphates were then precipitated by addition of 12 vol. acetone.

When examined in the Tiselius apparatus the fastest three fractions were found to possess mobilities corresponding with α_1-, α_2- and α_3-histones, although evidence of the presence of small amounts of the adjacent components was observed in each of them. It was calculated, for example, from the pattern of the α_1-component that the impurity amounted to

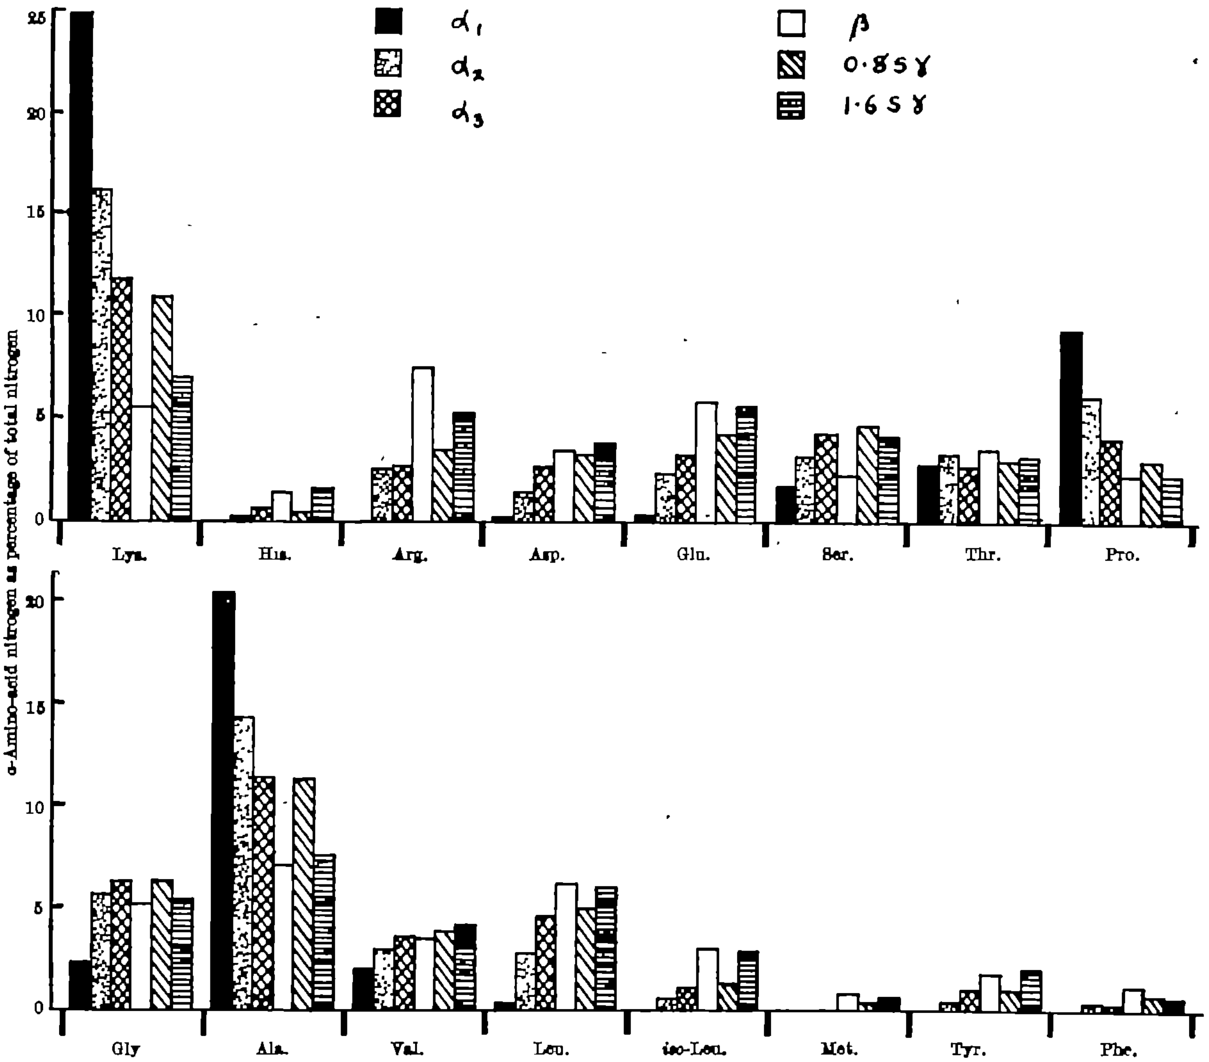

Fig 1. The amino-acid composition of the six histones from calf thymus glands expressed as α-amino-acid nitrogen as a percentage of the total nitrogen. The more usual figures of amino-acid nitrogen as a percentage of the total nitrogen can be obtained by multiplying the values for lysine, histidine and arginine by 2, 3 and 4 respectively

10–15 per cent of α_2. Sedimentation coefficients were also determined in the Spinco ultracentrifuge. The values obtained were: α_1-histone, $0 \cdot 45 \times 10^{-13}$; α_2-, α_3- and 0·8 *S* γ-histones, $0 \cdot 8 \times 10^{-13}$. Since the diffusion coefficient of the crude α-fraction is about 8×10^{-7}, this suggests molecular weights for the α_2-, α_3- and 0·8 *S* γ-histones of the order of 10,000, and of about half that figure for the α_1-histone. Of the four preparations, the α_3-histone proved to be the most heavily contaminated with impurity, for the sedimentation experiments revealed that this contained about 30 per cent of β-histone. The presence of β-histone in this component and of the 1·6 *S* γ-component in the original 0·8 *S* γ-histone despite their preparation from material containing no detectable amounts of these histones was doubtless due to the large losses during dialysis of the α- and 0·8 *S* γ-fractions. This, combined with the electrophoresis, resulted in the concentration of the negligible proportions of β- and 1·6 *S* γ-histones in the original α-fraction into readily detectable amounts in the above preparations.

The four preparations described above were obtained in insufficient amount for further purification. They were, however, all analysed for amino-acid composition. The results are presented graphically in Fig. 1, in which have also been included the figures obtained in unpublished work for pure β- and 1·6 *S* γ-histones. In calculating the results of the analyses of the α_3-histone, we have corrected the values for the presence of 30 per cent of β-histone.

Attention should be directed to the fact that the ordinates in Fig. 1 represent amounts of α-amino nitrogen expressed as a percentage of the total nitrogen. This unusual method of recording the amino-acid composition of proteins has been adopted in this case because it enables a direct comparison to be made between the number of cationic groups present in the various histones. Moreover, the figures are proportional to the number of moles of amino-acid per mole of protein.

Consideration of the above results will show that they provide a complete confirmation of the previous work which has been carried out in this laboratory on the composite nature of the histones obtained from the thymocyte of the calf. In particular, they confirm: (1) the presence of the six components shown to be present by physicochemical methods[9]; (2) the strongly basic properties of all of them[9]; and (3) the presence of high quantities of lysine, alanine and proline[5] in many of the subsidiary histones. In addition to this, however, they serve to correlate the electrophoretic mobilities of the histones with their amino-acid composition. Thus, the number of cationic groups per 100 gm. of protein nitrogen present in the six compounds, arranged in order of mobility, are: $\alpha_1 = 24 \cdot 7$; $\alpha_2 = 18 \cdot 6$; $\alpha_3 = 15 \cdot 1$; $\beta = 14 \cdot 3$; $0 \cdot 8\ S\ \gamma = 14 \cdot 2$; $1 \cdot 6\ S\ \gamma = 13 \cdot 9$. It should be added that the two γ-components possess almost identical mobilities, and that, while the β exhibits a greater mobility than the 1·6 *S* γ-histone despite their containing virtually identical numbers of cationic groups, this apparent slight discrepancy is explained by the greater number of free carboxyls present in the latter[5].

All the components resemble one another in being devoid of tryptophan, cysteine and cystine; the α's are, however, distinguished from the others by the absence of methionine. Of the six histones, α_1 is the simplest, containing only the seven amino-acids lysine, alanine, proline, serine, threonine, glycine and valine. If one excludes simple peptides from the comparison, α_1-histone is probably unique among known proteins in containing no arginine. α_2 differs qualitatively from α_1 in containing the four additional amino-acids arginine, leucine, glutamic and aspartic acids. The remaining components possess more complex compositions than do α_1 and α_2.

The conclusive demonstration in this and former communications from this laboratory of the composite nature of the histone present in the thymus gland of the calf clearly renders obsolete the many analyses of this protein recorded in the literature[11], for it is evident that the preparations to which these refer must have been unknown mixtures of two or more of the above components.

EFFECTS OF SARCOMYCIN ON THE METABOLISM OF EHRLICH ASCITES CARCINOMA CELLS

By I. J. BICKIS, DR. E. H. CREASER, PROF. J. H. QUASTEL, F.R.S., and DR. P. G. SCHOLEFIELD

McGill–Montreal General Hospital Research Institute, 3619 University Street, Montreal

UMEZAWA *et al.*[1] have found that an antibiotic, sarcomycin, produced from *Streptomyces erythrochromogenes*, shows anti-tumour activity against Yoshida rat sarcoma and Ehrlich carcinoma in mice. Hooper *et al.*[2] have shown that the chief active constituent of sarcomycin is 2-methylene-3-oxo*cyclo*pentane-carboxylic acid, the hydrogenated form of which (2-methyl-3-oxo*cyclo*pentane-carboxylic acid) lacks antibacterial activity but is highly active against Ehrlich ascites tumour. Clinical trials by Magill *et al.*[3] have indicated that sarcomycin is without appreciable therapeutic value in disseminated cancer, although Ishiyama[4] reported some favourable effects. In view of the definite activity of sarcomycin against Ehrlich ascites carcinoma, we have investigated the effects of sarcomycin on the metabolism of this tumour, using a preparation generously provided by Bristol Laboratories, Inc., Syracuse, N.Y.

Our investigations have involved a study of the effects of sarcomycin on the rate of respiration and of anaerobic glycolysis of Ehrlich ascites carcinoma cells, on the uptake of glycine-1-^{14}C into the tumour cells, on the incorporation of radioactivity from glycine-1-^{14}C into the tumour proteins and on the incorporation of phosphorus-32 (from radioactive phosphate) into the adenosine mono-, di- and triphosphates, ribonucleic acid and deoxyribonucleic acid of the tumour.

All studies were carried out *in vitro* with washed Ehrlich ascites carcinoma cells obtained from Swiss white mice after intraperitoneal injection. Ascitic fluid was withdrawn with a hypodermic syringe after six days, and the cells were separated by centrifuging at room temperature and washed three or four times with 8–10 volumes of cold isotonic saline to remove blood elements and soluble ascitic constituents.

The conventional Warburg manometric apparatus was used for estimating respiratory and glycolytic rates and for the incubations in which the uptake and incorporation of glycine-^{14}C or phosphorus-32 were studied. The Ringer media used were those described by Umbreit *et al.*[5]. Aerobic experiments were carried out by incubation at 37° in an atmosphere of air or oxygen, potassium hydroxide being placed in the centre wells of the manometer flasks for absorption of carbon dioxide; anaerobic experiments were carried out in an atmosphere of 93 per cent nitrogen and 7 per cent carbon dioxide.

For estimation of glycine uptake and incorporation by the ascites cells, glycine was tipped from the side tube of the manometer vessel (after gassing and thermal equilibrium) so that the final concentration in the total volume of 3 ml. in the manometer flask was 2 m*M* and contained glycine-1-^{14}C to give an activity of 10^5 counts per min. (0·67 μc.). After incubation, the manometer vessels were placed in crushed ice, their contents (cells and medium) were homogenized in a Teflon pestle-homogenizer, precipitated with trichloracetic acid (final concentration 13 per cent) and further homogenized. The precipitates were extracted three times with 6 per cent trichloracetic acid (first extraction carried out for 15 min. at 90° C. to remove nucleic acids), once with ethanol, once with ethanol–ether (3 : 1) at 60° C. for 10 min., once with ether, and finally the residual proteins were suspended in chloroform–ether (4 : 1), plated on aluminium disks and counted. Uptake of glycine-1-^{14}C into Ehrlich ascites carcinoma cells was estimated after incubation of the washed cells for 30 min. at 37° C. in the appropriate media. The contents of the manometer vessels were transferred to centrifuge tubes kept in crushed ice and centrifuged for 1 min. The packed ascites cells were resuspended in 5 ml. ice-cold 0·1 *M* glycine (non-radioactive) and centrifuged for 1 min. The cells were then resuspended in 2 ml. 95 per cent ethanol, kept at room temperature for 2 hr. and centrifuged. An aliquot (0·5 ml.) of the supernatant solution was plated and counted. From this count the concentration of free glycine in the ascites cells was calculated.

For estimation of phosphorus-32 incorporation into Ehrlich ascites carcinoma cells, the washed cells were packed by centrifuging and suspended in a total of eight times their own volume of Ringer solution containing no added buffer. 1·0 ml. of the suspension was used per vessel for incubation with radioactive phosphate. The final incubation medium (3 ml.) contained Ringer solution[5], 0·01 *M* phosphate buffer *p*H 7·4 with or without glucose or sarcomycin. The side arm contained approximately 0·1 mc. phosphorus-32 as carrier-free phosphate which was tipped in after the 10-min. period allowed for attainment of thermal equilibrium. At the end of a 30-min. incubation period in air at 37° C., the contents of the vessel were removed with a Pasteur pipette and added to 5 ml. of a Ringer solution containing no buffer. The ascites cells were separated by centrifuging, the supernatant was discarded and the cells washed with a further 8 ml. of buffer-free Ringer solution. They were then resuspended in 1 ml. water, precipitated with 6 ml. 95 per cent ethanol and allowed to stand for 30 min. to ensure complete precipitation. After centrifuging, the supernatant was decanted and subjected to chromatography and autoradiography as described by Bolton *et al.*[6]. In this way the activities of the adenosine mono-, di- and tri-phosphates were assessed.

The alcohol-insoluble residue was washed with two lots of 5 ml. 5 per cent trichloracetic acid, made up to 2 ml. with *N* potassium hydroxide, incubated for 18 hr. at 37° C., and an aliquot plated and counted[7]. This gave a value for the combined deoxyribo- and ribo-nucleic acids and phosphoprotein fractions. To the remaining solution was added 6 ml. *N* hydrochloric acid to precipitate the deoxyribonucleic acid fraction, and the material was maintained at 0° C. for 90 min. The deoxyribonucleic acid was removed by centrifuging and washed with two further portions of 8 ml. *N* hydrochloric acid. The washed deoxyribonucleic acid fraction was suspended in 0·5 ml. water, and 0·2-ml. aliquots were plated and counted.

Sarcomycin, at concentrations up to 200 µgm./ml., has little or no effect on the rate of oxygen consumption of Ehrlich ascites carcinoma cells either in the presence or absence of glucose. Some typical results are given in Table 1. Nor does sarcomycin at such concentrations affect the rate of anaerobic glycolysis. When the concentration of sarcomycin is increased, however, to 600 µgm./ml., relatively large inhibitions of the rates of respiration and glycolysis take place. For example, at 670 µgm./ml. sarcomycin brings about 63 per cent inhibition of the rate of oxygen uptake of Ehrlich ascites carcinoma cells in absence of glucose, and 51 per cent inhibition in presence of glucose; the rate of anaerobic glycolysis is inhibited 33 per cent. Such inhibitive effects of sarcomycin at 670 µgm./ml. are not seen on the respiratory or glycolytic rates of chick embryo (four days old) or on rat spleen slices.

Table 1. EFFECTS OF SARCOMYCIN ON METABOLISM OF EHRLICH ASCITES CARCINOMA CELLS AND ON INCORPORATION OF GLYCINE-1-^{14}C INTO THE TUMOUR PROTEINS

Incubation of washed Ehrlich ascites carcinoma cells was carried out aerobically in the conventional Warburg manometric apparatus for 30 min. at 37°. The Ringer solution, in which the tumour cells were suspended, contained 2 m*M* glycine in which glycine-1-^{14}C, having an activity of 10^5 counts per min. per vessel, was present

	No sarcomycin added	Sarcomycin added (200 µgm./ml.)
Q_{O_2} (no glucose added)	13·6	10·8
Q_{O_2} (in presence of 0·02 *M* glucose)	7·8	6 8
Glycine-1-^{14}C incorporated into tumour proteins (no glucose added)	86 counts/ min./ mgm. protein	26 counts/ min./ mgm. protein
Glycine-1-^{14}C uptake into the tumour cells (no glucose added)	11,100 counts/ min./ vessel	8,500 counts/ min./ vessel
Glycine-1-^{14}C incorporated into tumour proteins (in presence of 0·02 *M* glucose)	96 counts/ min./ mgm. protein	34 counts/ min./ mgm. protein
Glycine-1-^{14}C uptake into the tumour cells (in presence of 0·02 *M* glucose)	10,000 counts/ min./ vessel	8,700 counts/ min./ vessel

Sarcomycin, at 200 µgm./ml., brings about marked diminutions in the rates of incorporation of glycine into the tumour proteins, typical findings being shown in Table 1. Moreover, it will bring about, at this concentration, an inhibition of the rate of anaerobic incorporation of glycine, in the presence of glucose, amounting to 64 per cent, a value which may be compared with that of 80 per cent brought by sarcomycin on the rate of aerobic incorporation of glycine in the absence of glucose. Higher concentrations of sarcomycin (for example, 670 µgm./ml.) bring about more than 90 per cent inhibition of the rates of incorporation of glycine into Ehrlich ascites tumour protein both under aerobic conditions (in presence or absence of glucose) or anaerobic conditions (in presence of glucose). Incorporation of glycine into the proteins of chick embryo (four days old) or rat spleen slices is also affected by the high concentration of sarcomycin (670 µgm./ml.); but the inhibitions, which may be of the order of 70 per cent, are not so great as those found with Ehrlich ascites tumour cells. The rate of uptake of free glycine into the Ehrlich ascites cells is but little affected by sarcomycin at 200 µgm./ml., as shown in values given in Table 1. It is evident that the marked inhibitions of the rates of glycine incorporation into the tumour proteins by sarcomycin, at 200 µgm./ml., are not due to an interference with the rate of transport of the amino-acid into the tumour cells. Moreover, it is clear that sarcomycin exceeds in potency, so far as inhibition of glycine incorporation into Ehrlich ascites tumour proteins is concerned, the series of compounds having antitumour activities investigated by LePage and Greenlees[8]. Roberts *et al.*[9] have suggested that sarcomycin might effect its antitumour activity by interference with an aspect of glutamine metabolism. We have not found, however, any reversing action of L-glutamine on the inhibition by sarcomycin of the incorporation of glycine-1-^{14}C into Ehrlich ascites carcinoma proteins.

It is now known that incorporation of amino-acid into protein requires the participation of adenosine triphosphate[10], the stimulating effect of adenosine phosphates on the incorporation of amino-acid into proteins in cell-free liver extracts having been established[11]. Rabinovitz *et al.*[12] have demonstrated that incorporation of amino-acid into the proteins of Ehrlich ascites carcinoma cells takes place aerobically and anaerobically in presence of glucose. Dinitrophenol (5×10^{-4} *M*) inhibits aerobic incorporation of amino-acids and at the same time stimulates oxygen consumption; but it has little effect on glycolysis-linked incorporation. Thus the dinitrophenol does not inhibit the incorporative mechanism directly, but it depletes the necessary energy supply[12], presumably adenosine triphosphate.

In view of these facts and the demonstration that sarcomycin inhibits the incorporation of glycine into the protein of ascites carcinoma cells, investigations were carried out to discover the effect of sarcomycin on the incorporation of phosphorus-32 into the adenosine phosphates and into the ribo- and deoxyribo-nucleic acid fractions. It is already known[13] that compounds having antitumour activities can affect the incorporation of phosphorus-32 into the nucleic acids of mouse tumours.

Our results, given in Table 2, show that the presence of glucose markedly increases the incorporation of phosphorus-32 into adenosine di- and tri-phosphate and ribonucleic acid in Ehrlich ascites carcinoma cells incubated aerobically for 30 min. at 37°; little enhancing effect is seen with adenosine monophosphate or deoxyribonucleic acid. They also show that sarcomycin (200 μgm./ml.) greatly reduces the incorporation of phosphorus-32 into adenosine di- and tri-phosphate and the ribonucleic acid fraction in the absence of glucose, the inhibitions amounting to about 50 per cent. Finally, they show that, in the presence of glucose, sarcomycin suppresses the incorporation of phosphorus-32 into adenosine mono-, di- and tri-phosphate and the ribonucleic and deoxyribonucleic acid fractions, the inhibitions amounting to about 70 per cent except in the case of the last fraction. This suppression of incorporation of phosphorus-32 is not due to an inhibition of the rate of transport of phosphate into the ascites cells. In the experiment described in Table 2, phosphorus-32 uptake into the ascites cells amounted to 134,000 counts per min. and in the presence of sarcomycin (200 μgm./ml.) the uptake amounted to 112,000 counts per min. The results point, therefore, to an interference by sarcomycin with the reactions of the adenylic acid system and could be explained either by an inhibition of the rate of formation of adenosine triphosphate or by an increased rate of breakdown of that substance. The inhibitions are of the right order to account for the suppression of incorporation of glycine-1-^{14}C by sarcomycin if this incorporation is dependent on the rate of phosphate turnover in the adenine nucleotides and nucleic acids. This conclusion is supported by the fact that anaerobic incorporation of amino-acids into ascites proteins takes place to a marked extent only in the presence of glucose[12] and by the observation (Creaser, E. H., and Scholefield, P. G., unpublished work) that incorporation of phosphorus-32 anaerobically into the adenine nucleotides and nucleic acids in Ehrlich ascites carcinoma cells is very greatly increased (more than twenty-fold with adenosine di- and tri-phosphate) by the presence of glucose.

Table 2. EFFECTS OF SARCOMYCIN ON INCORPORATION OF PHOSPHORUS-32 INTO ADENOSINE PHOSPHATES, RIBONUCLEIC ACID AND DEOXYRIBONUCLEIC ACID OF EHRLICH ASCITES CARCINOMA CELLS

Incubation of 0·125 ml. packed washed Ehrlich ascites carcinoma cells in 3 ml. isotonic Ringer solution was carried out aerobically for 30 min. at 37° C. in the conventional Warburg manometric apparatus. The Ringer solution contained 34·3 μmoles radioactive phosphate equivalent to 12×10^6 counts per min. of phosphorus-32

Additions to suspension of Ehrlich ascites tumour cells	Incorporation of ^{32}P (counts per min. $\times 10^3$) into:				
	AMP	ADP	ATP	RNA fraction	DNA fraction
Nil	2·25	16·9	7·60	4·7	0·98
Glucose 0·02 *M*	2·86	32·4	26·0	10·3	1·27
Sarcomycin 200 μgm./ml.	3·25	7·0	3·27	2·4	0·60
Glucose, 0·02 *M* plus sarcomycin, 200 μgm./ml.	1·4	13·5	9·9	3·2	0·75

The mechanism by which sarcomycin effects its disturbance of the reactions of the adenylic acid systems is still obscure. Although the disturbance resembles the 'uncoupling' action of dinitrophenol, the behaviour of sarcomycin differs markedly from that of the latter. The most obvious differences are: (1) lack of stimulation of the rate of oxygen consumption of ascites cells which is a characteristic feature of dinitrophenol activity, (2) marked inhibition of glycine-1-^{14}C incorporation anaerobically in presence of glucose, in contrast to the feeble (or lack of) inhibition exercised by dinitrophenol under the same conditions (ref. 12, and Bickis, I. J., and Quastel, J. H., unpublished work).

We are indebted to the Rockefeller Foundation, the National Cancer Institute of Canada and the Cancer Research Society for grants which made this work possible. We are also grateful to Lederle Laboratories Division (American Cyanamid Company) for an initial supply of mice bearing the Ehrlich ascites carcinoma which was used in this work.

Combined Light and Velocity Measurements of the Variable Star 12 Lacertae

During the summer and autumn of 1956, fifteen observatories co-operated in securing brightness and radial velocity measurements of the variable star 12 Lacertae. The variable belongs to the group of Beta Canis Majoris stars, consisting of about a dozen known members, which vary in light and radial velocity. Stars of this group have spectral types *B*2, *B*3, and luminosity classification II–IV, and their periods range between 0·15d. and 0·25d. The amplitudes of the light curves are small, of the order of some tenths of a magnitude. The light and radial-velocity curves are often not quite regular, showing that they are the result of several components. Thus the star 12 (*DD*) Lacertae has a principal period of 4h. 38m. and a secondary period of 4h. 44m., while recently a third component of 3h. 45m. has been found, and a fourth one of 3·9h. has been suggested. The periods occur in the variation of both the light and the radial velocity. The presence of components with closely similar periods and amplitudes of the same order produces the beat phenomenon, characteristic of a number of stars of the Beta Canis Majoris group. The occurrence of this relatively large number of components produces the observed complexity of the light and velocity curves.

The derivation of these components from scattered observations obtained at a single site is difficult, because of the small amplitude of the light curve and the complexity of its character. Too much information is lost during the time when the star is not under observation.

Accordingly, a plan was undertaken to obtain more information about 12 Lacertae, a typical member of the group, by combining observations made at sites distributed around the world at northern latitudes between 30° and 60°. Although regular observations were arranged for the period July–December 1956, the main effort was to observe the star continuously during the fourteen days between August 28 and September 12. A smaller number of observatories participated in increased observing activity between September 27 and October 12.

This campaign was successful on the whole, although we did not succeed in keeping the star under continuous observation during one complete fortnight, mainly because of the facts that, of the three Asiatic observatories which had intended to co-operate, those at Naini Tal (India) and Nanking (China) could not join the campaign because of continuous bad weather and of instrumental difficulties, and owing to bad weather Tokyo Observatory was able to make a good series of observations on one night only and secured some scattered observations during three other nights. The observations were finally made at fifteen observatories, including seven in Europe, seven in America and one in Asia. The distribution of the observing time is given in Table 1.

Table 1

	Aug. 28–Sept. 12	Sept. 27–Oct. 12	Outside these periods	Total
Photoelectric brightness observations	296·4 hr	128·3 hr.	139·9 hr.	564·6 hr.
Radial velocity observations	143·0 hr.	—	10·5 hr.	153·5 hr.
				718·1 hr.

The number of observations and their density in time are such that our campaign may certainly be called successful. That fairly continuous observation of the star was possible at least during part of the period is shown by Fig. 1, giving the resulting light-curve in the Julian day intervals 2,435,720·3–2,435,721·8 and 2,435,722·2–2,435,723·8.

In order to plot the various observations to the same scale of magnitudes, the relative zero-point corrections of the different magnitude scales were determined by comparing all overlapping parts of the light-curves. In this way a system of twenty-five equations with twelve unknowns was obtained, and solved by the method of least squares. The scales of the various sets of observations appear not to differ by more than some hundredths of a magnitude. The magnitude scale of the accompanying figures is that used at the Simeis Observatory (Crimea, U.S.S.R.). The figures clearly show the semi-regular shape of the light curves and demonstrate how difficult it would have been to infer such irregularities from observations at one site taken during 0·3-day periods at intervals of one or more days.

The further reduction of the observations, including the colours and the radial velocities, will be carried out by one of us (C. de Jager) and will be published elsewhere.

We are grateful to Prof. O. Struve (Berkeley, U.S.A.) and also to Prof. B. V. Kukarkin (Moscow, U.S.S.R.), president of the Commission for Variable Stars of the International Astronomical Union, for their stimulating advice and support in preparing this campaign.

Nuclear Magnetic Resonance Studies of Boron Trifluoride Complex Formation

HIGH-resolution nuclear magnetic resonance spectroscopy affords a uniquely penetrating method of studying co-ordinate complex formation between boron trifluoride and electron donor substances. The examples investigated so far comprise oxygen compounds (water, alcohols, ethers and ketones), but the method promises wide application. Details of a typical experiment follow. Fluorine magnetic resonance (at a frequency of 34·2 Mc./s.) is observed in a quantitatively prepared liquid mixture of two donor substances (as, say, methanol and ethanol) with boron trifluoride, the latter in quantity insufficient to saturate both donors. The temperature is controlled during a given measurement, the usable range extending from somewhat above room temperature to about − 100° C. At sufficiently low temperatures two relatively narrow resonance peaks are seen, separated in the case cited by some 70 c./s. These correspond to the co-ordination complexes of the respective donors. Measurement of the peak areas (assumed to be proportional to the volume concentrations) in mixtures of various composition indicates that reversible equilibrium is established between the two donors and their respective complexes. The mass law constant may thus be measured. The values at a series of different temperatures yield the corresponding enthalpy and standard entropy changes for the interconversion reaction.

Such an equilibrium constant is the ratio of the mass law constants for the dissociation of the respective complexes into boron trifluoride and donor substance. A properly chosen series of studies with pairs of donors allows establishment of a 'boron trifluoride affinity' series; as an example, at a given temperature the substances water, methanol, ethanol, *n*-propanol and *n*-butanol constitute a regular series, the water – boron trifluoride complex displaying the greatest stability. Mixtures containing three or more donor substances also demonstrate the order in such a series. Of particular interest is the comparison of isomeric substances, in which cases rather remarkable differences in boron trifluoride affinity are often observed.

As the temperature of such a mixture as that cited above is raised, the two fluorine resonance lines are observed to broaden and ultimately to merge. This behaviour is typical of chemical exchange effects, as already observed in previous studies by one of us (R. A. O.)[1].

In qualitative terms, the line broadening occurs as the pseudo-monomolecular rate constant for the interconversion approaches in value the frequency separation of the lines. Systematic studies allow the evaluation of the rate constants at various temperatures, yielding the corresponding activation energies.

The equilibrium and kinetic studies indicated above are possible because of the rather striking variation of the fluorine resonance position ('chemical shift') as the donor substance is altered. The careful measurement of these chemical shifts, and their relation to structure and other properties of the co-ordination complexes, constitute another aspect of the entire programme. Of no less interest is the observation and interpretation of proton resonances. As an example, the formation of the boron trifluoride complex of ethanol results in a marked displacement (more than 100 c./s. as compared with pure ethanol) of the hydroxyl proton resonance toward lower magnetic field. The shift of the methylene resonance is in the same sense, but considerably smaller, while that of the methyl group resonance is negligible.

An extended programme of studies is in progress with the aim of following in systematic fashion the dependence of the various measurable quantities upon the molecular structure of the donor substances.

We wish to acknowledge the assistance of the Swiss National Fund, which has made possible the acquisition of the nuclear magnetic resonance spectrometer. We also appreciate the interest and advice of Prof. P. Huber, director of the Physical Institute.

This work was supported in part by a grant from the National Science Foundation.

Absorption Spectra of Flat Flames using a Multiple-Reflexion Technique

MANY previous attempts to detect absorption bands of intermediate oxidation or pyrolysis products in premixed (Bunsen-type) flames have failed. There are several difficulties in studying absorption spectra of flames; the reaction zone where intermediate products may be expected is usually extremely thin and often curved; it is necessary to have a background source the brightness of which exceeds that corresponding to the effective excitation temperature in the flame (which may sometimes be higher than the equilibrium flame temperature); the light beam may be thrown out of the flame by refraction effects; and the concentration of the absorbing species may be low because of their instability or reactivity at high temperatures, thus necessitating long path-length for their detection. To study a thin reaction zone, even if flat, it is necessary to restrict the light to a narrow beam of very small angular aperture.

We have recently made some progress in overcoming the difficulties by using (*a*) flat near-limit flames, of the type developed by Egerton and Powling[1], having a reaction zone which may be a few millimetres thick and fairly flat, (*b*) a very bright xenon high-pressure lamp ('Osram' type *XBO*.162) as background source, and (*c*) a system of mirrors, of the type employed by White[2], to reflect the beam of light backwards and forwards a number of times through the flame gases.

We have designed a metal flat-flame burner with a rectangular matrix, giving a flame about 8 cm. long. The burner has side-tubes containing the mirror system, with quartz windows for viewing. Front-surface aluminized mirrors were found to tarnish when exposed to some types of flame, and we have therefore used back-surface aluminized mirrors made from quartz, with the curvature of the surfaces so designed that images formed by reflexion from the front and back surfaces coincide.

Gradients of refractive index in the flame gases are low under our experimental conditions, and have not caused appreciable defocusing with less than twenty traverses.

Exposures of usable intensity on a medium quartz spectrograph have been obtained in 30 min., with twenty-four traverses in the region of 2500 A., and in 10 min., with thirty-six traverses in the visible region. With fewer traverses than those just quoted, it is possible to increase the spatial resolution in the flame gases by stopping down the vertical aperture. Good quartz/lithium fluoride achromat lenses have been used for ensuring good focus in the near ultra-violet as well as the visible.

Flames of diethyl ether with air show a weak cool flame below the main blue-flame front, near the rich limit. Under carbon-forming conditions, there is a dark zone between the main blue-flame front and the yellow carbon zone, and the gap separating the cool flame from the main flame is barely discernible; the carbon zone appears for only a relatively narrow range of mixture strengths, disappearing for the richest mixtures. For these ether flames we have found clear, strong absorption bands of formaldehyde (3500–2600 A.) which are strongest in the region between the cool and main flames. Under carbon-forming conditions and with a path-length of nearly 200 cm., benzene absorption bands have been found (λλ 2589, 2528 A.). The absorption bands of formaldehyde have also been detected in flames of acetaldehyde and methanol with air; the latter did not show a discernible cool flame. The hexane/air flame shows the benzene bands much more clearly than the ether flame; also an unidentified band of intensity comparable with the benzene system has been observed at about 2750 A. The bands first occur in the preheating zone well below the main flame front and persist through to the carbon zone. They do not, however, show any marked increase in intensity towards the carbon zone. Some continuous absorption is also observed in the short-wave ultra-violet in the dark space between the main flame front and the carbon zone, but no formaldehyde has been detected. For this work, the hexane was carefully freed from contaminating benzene. A trace of benzene absorption has been found in flames of methane and propane, but has not finally been confirmed.

Formaldehyde has previously been detected by Egerton and Pidgeon[3] in the slow combustion of hydrocarbons, and its occurrence in ether flames is not unexpected. The new observation of benzene is more interesting and could be used as an argument to support a theory of ring closure as a stage in carbon formation, rather than one depending on breakdown of acetylene to carbon. Processes of carbon formation have been discussed by Street and Thomas[4] and Gaydon[5]. The presence of benzene and weakness of formaldehyde in the hexane flame suggest that, in premixed flames of hydrocarbons, formation of pyrolysis products is more rapid than that of partial oxidation products. Recent work[6] on benzene absorption at high temperatures shows a loss of structure; the banded absorption observed by us probably comes, therefore, from the cooler parts of the flame, and the continuous absorption in the dark space of the hexane flame may also be caused, at least in part, by benzene.

For explosion flames of carbon monoxide, Knipe and Gordon[7] have given some evidence that part of the structure of the carbon monoxide flame bands may be due to absorption, possibly by carbon monoxide molecules in the $a^3\Pi$ state. We have looked for both the triplet and third positive systems of carbon monoxide in absorption, using up to thirty traverses through a rich-limit flame of undried carbon monoxide, but have seen no signs of them.

We wish to acknowledge financial assistance from a United States A.R.D.C. contract.

Low-angle X-ray Observations on Glass

Various low-angle X-ray scattering effects from some glasses have been reported by Hoffman and Statton[1]. Essentially the same experiment has been carried out on similarly heat-treated silica-glass plates using monochromatic X-radiation, and no low-angle diffraction effects of any sort have been observed. A possible explanation of the observations of Hoffman and Statton is considered here.

Lu and Chang[2] also observed some low-angle diffraction effects from glasses, which were explained by Rooksby and Thomas[3] as due to the very short wave-lengths of the white radiation present in the nickel-filtered X-ray beam used. The same effect appears to be operative in the experiments of Hoffman and Statton. This has been confirmed by taking a photograph of a silica plate, first with crystal-reflected monochromatic copper K_α radiation, and then with nickel-filtered copper K_α radiation. A low-angle diffraction ring is observed with the nickel-filtered radiation (Fig. 1).

The position of the low-angle ring will depend on the peak voltage of the X-ray tube used. At high tube-voltages, the band will move into the backstop and appear as diffuse low-angle scattering. This would account for the different behaviour of quenched and annealed samples of silica glass and of a

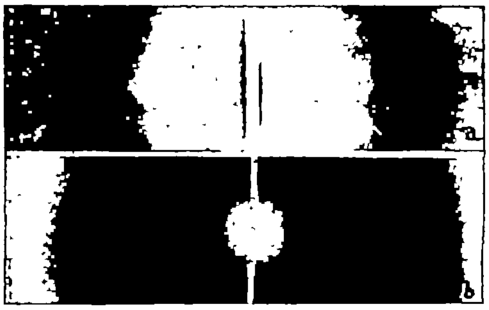

Fig. 1. X-ray photographs of a silica plate, 0·18 mm. thick, using (*a*) monochromatic copper $K\alpha$ radiation, by reflexion from a lithium fluoride crystal. The photograph was taken in vacuum, in a focusing camera, 7 cm. in diameter; (*b*) nickel-filtered radiation. Photograph taken in air, on a flat plate, 7·5 cm. from specimen. The peak voltage of the X-ray tube was 35 kV., and the nickel foil was 0·001 in. thick. In the case of the nickel-filtered radiation, a low wave-length component of the white radiation remains, which produces the low-angle inner ring

soda–magnesium oxide–silica glass reported by Hoffman and Statton. Their observations on a glass fibre are affected by the different absorption effects perpendicular and parallel to the axis of the glass fibre. The sharpness of the low-angle ring will depend on the thickness of the nickel filter, the thickness of the specimen, type of film emulsion, condition and type of X-ray tube, conditions of collimation of the X-ray beam, and the absorption edges of silver (0·48 A.) and bromine (0·92 A.). Evidently, Hoffman and Statton employed very delicate conditions, which produced a remarkably sharp low-angle band.

I am indebted to Dr. E. A. Calnan and Mr. H. P. Rooksby, with whom this phenomenon was discussed, to Prof. H. J. Emeléus for interest in the work, and to the Owens-Illinois Glass Co. for supporting the work.

Guarded-Field Thimble Ionization Chambers

IN a previous communication[1] a new guarded-field principle as applied to ionization chambers was outlined, together with its attendant advantages. A thimble chamber employing the new system comprises a cylindrical conducting wall, subdivided into a number of annular sections of equal width ω situated between two end-sections of width ½ω, as shown in Fig. 1,*a*. These wall-sections are all insulated from one another, either by narrow surface grooves in the case of a wall of insulating material having a conductive coating, or by thin insulating washers in the case of a wall of conducting material. The two half-sections at either end are in electrical continuity with the adjacent (plane) end-surfaces of the cylindrical chamber cavity. If equal potential differences are maintained across each of the insulating gaps in the cylindrical wall, the associated electrostatic field distribution is somewhat as shown in Fig. 1,*a*. (An alternative mode of subdivision of the wall into sections of equal width throughout is also possible, but involves the use of unequal voltage steps.)

For a given chamber-cavity radius R, and annular wall-section width ω, there will be a corresponding cylindrical volume, coaxial with the chamber cavity and of radius r, throughout which the field lines will be sensibly straight. Thus a circular collecting-electrode of radius r can be employed, comprising a part of one of the plane ends of the chamber cavity, but separated by a narrow gap (of the order of one- or two-thousandths of an inch in practice) from the guard surface surrounding it. Clearly, the volume from which ions are collected by such an electrode is given accurately (and simply) by $\pi r^2 L$, where L is the length of the chamber cavity. Thus, for the practical purpose of chamber design, it is required to know the relation between r,R and ω which will guarantee adequate linearity of the field lines terminating on the collecting electrode.

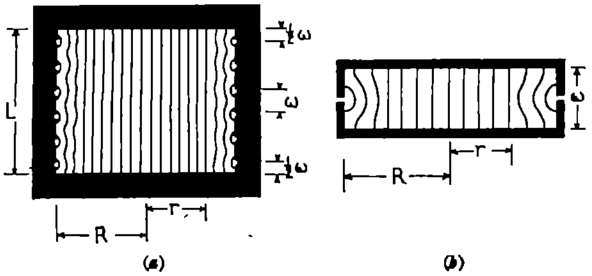

Fig. 1. Two types of guarded-field chamber: (*a*) multi-section; (*b*) single-section

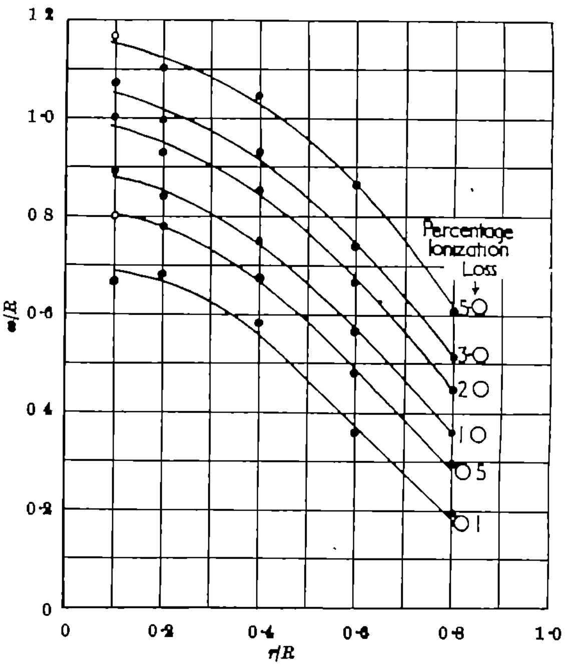

Fig. 2. Basic design curves for guarded-field thimble chambers, enabling the relationship between r, R and ω to be determined for any chosen level of ionization loss

We have investigated this relationship ionometrically in a series of precision experiments in which the ionization losses associated with a range of values of ω (for given r and R values) were studied, the gaps between the wall sections being maintained at 0·1ω throughout. (For these experiments a chamber 3 cm. in diameter was used, in conjunction with a telecobalt unit for the production of the ionization.) The results are given in Fig. 2, in which ω/R is plotted against r/R, with ionization loss as parameter. The range of values of r/R covered by the experiments was 0·1–0·8 inclusive, but the extrapolation of at any rate the lower loss lines towards the point $\omega/R = 0$, at $r/R = 1·0$, seems justifiable.

As an example of the use of these curves we may suppose that it is required to construct a chamber of cavity radius 1·5 cm., with a collecting-electrode radius of 1·0 cm., and that ionization losses are not to exceed 0·1 per cent. From the relevant curve in Fig. 2 (since $r/R = 0·67$) we obtain $\omega/R = 0·31$, whence, for $R = 1·5$ cm., $\omega = 0·465$ cm. Any convenient value of ω not exceeding 0·465 cm. may obviously be used.

This information can be utilized for the construction either of a multi-section chamber (Fig. 1,*a*) or a single-section chamber (Fig. 1,*b*). The latter might correspond to a so-called 'extrapolation-type' chamber, in which the earthed guard-surface surrounding the collecting electrode, and the upper (plane) surface of the chamber cavity (to which the polarizing voltage is applied), are each carried over by means of a conductive coating on to the cylindrical wall, being separated midway by a narrow gap. The data given in Fig. 2 will obviously enable such a chamber to be constructed with the maximum possible diameter of collecting electrode for given chamber dimensions.

A full account of this work and its application to radiation dosimetry will be published elsewhere.

Effect of Tube Diameter on the Pressures in Gaseous Detonation Waves

It has been shown by Kistiakowsky *et al.*[1,2] that the velocities of plane detonation waves in the steady state in gaseous mixtures contained in straight tubes are influenced by the energy losses to the walls of the tube. For tubes the diameters of which are less than 10 cm., the velocities are found to decrease with decreasing diameter; this effect is attributed to the formation at the wall of the tube of the rarefaction wave, which travels inwards with acoustic velocity, thereby causing a lowering of temperature and the rate of chemical reaction. Such a rarefaction can be produced by two mechanisms, namely, cooling of the gas in contact with the wall and frictional drag at the wall. The individual effects are indistinguishable experimentally.

It is of some interest to investigate the influence of tube diameter on the (pressure, time) relationships of the waves, since the effect in this case is likely to be more pronounced than in the case of velocity. A series of measurements, of both static and reflexion pressures, were carried out in three detonation tubes of diameters 10, 3·8 and 1·6 cm. Each tube was 10 ft. in length and detonation was initiated at one end by means of a copper acetylide match-head. Specially designed pressure bar-gauges were employed to record the pressures. Only the results obtained for the mixture $2H_2 + O_2$ will be described here. Typical (pressure, time) curves for the static condition are shown in Fig. 1.

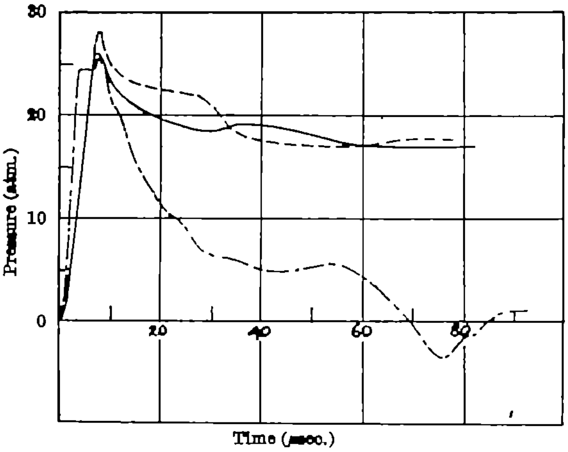

Fig. 1. Static (pressure, time) curves for plane detonation waves in a stoichiometric $2H_2 + O_2$ mixture in tubes of various diameters; 10 cm. diam., ——, 3·8 cm. diam. - - - -, 1·6 cm. diam. — - — -

In the static pressure records obtained in the 10 and 3·8 cm. tubes the initial peak lying in the region 0–20 μsec. can be attributed to a combination of dispersion effects in the bar of the gauge[3] and to excitation by the von Neumann pressure 'spike'[4] even though the gauge is incapable of resolving the extremely short-duration reaction zone. The Chapman–Jouguet pressures have therefore been taken to be the average values between approximately 20 and 80 μsec. In both these tubes, for this particular mixture, the measured Chapman–Jouguet pressures agree well with the theoretical value of 18·05 atmospheres. A completely different (pressure, time) relationship, however, is observed in the 1·6-cm. tube. Here the pressure, which has a peak value of 24·6 atm., drops rapidly after about 8 μsec. and thereafter oscillates about a low value. As would be expected, the reflexion pressure records do not exhibit such marked differences.

The original records show oscillations which have been smoothed out in Fig. 1 in order to show the general trend more clearly; the periods of these oscillations agree closely with the times of traverse of a sound wave in the hot gases behind the detonation front, across the respective tube diameter. These times in the case of $2H_2 + O_2$ for the 10, 3·8 and 1·6 cm. tubes are 63, 24 and 10 μsec. respectively. Confirmation of this fact was obtained in mixtures with different acoustic velocities, and it lends support to the hypothesis that energy is abstracted from the detonation wave through the formation of rarefaction waves at the wall of the tube.

We wish to thank Prof. R. M. Davies for his encouragement and interest in this work, and one of us (D. H. E.) would like to acknowledge his indebtedness to the University of Wales for an I.C.I. Fellowship, and the other (G. T. W.) to the Department of Scientific and Industrial Research for a maintenance allowance.

Adsorption of Water on Tungsten

The adsorption of water on tungsten and its subsequent desorption have been studied using the technique of field emission microscopy[1]. The field emission patterns obtained from a tungsten cathode at a pressure of water equal to 4 × 10^{-9} mm. are shown in Figs. 1 and 2. The times given are those for which the tip was exposed to water vapour after a 2-min. flash at 2,500° K. These patterns are quite different from those obtained during the adsorption of

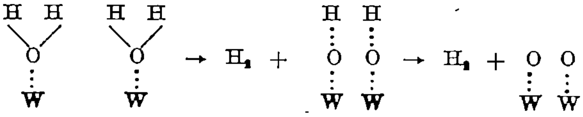
either hydrogen or oxygen on tungsten[1]. In Fig. 1, the central 011 plane appears to be strongly emitting, in contrast to oxygen adsorption when it remains dark for at least 20 min. at this pressure. Closer inspection reveals that the strongest emission is actually from the region immediately surrounding this plane. After prolonged exposure to water (Fig. 2), the 012 region is very dark and the main emission is from the 111 region. The abrupt change in work function in crossing a line drawn diagonally from the central 011 plane and just missing the 112 plane is most remarkable.

The tip was then heated, usually for 2 min. but sometimes for 1 min., at increasing temperatures about 100–150° apart. Some of the characteristic patterns obtained are shown in Figs. 3–6. At first the pattern changes but little, apart from a general brightening in the 001 region which commences at about 200° C. and indicates the desorption of water. The evolution of gas is confirmed by increased ion gauge pressure-readings, excess gas being pumped away so that a steady pressure of 4×10^{-9} mm. was maintained. This process is continued on raising the temperature to 460° C., which results (Fig. 3) in bright emission from the 001 region which is accentuated by a very dark surrounding ring. The remainder of the emission is largely from the 111 region. A very marked change in pattern occurs between 460 and 570° C., the pattern obtained after 1 min. at 570° C. (Fig. 4) strongly resembling the early stages of water adsorption. The strongly emitting 001 region is reminiscent of slight oxygen contamination, but the 111 planes are darker than is the case for oxygen adsorption.

Further remarkable changes are apparent after heating the tip for 2 min. at 710° C. The darkened 111 plane is now light again while higher index planes in that region remain dark (Fig. 5). The dark cross, so characteristic of oxygen adsorption, formed by the diagonals joining the 112 planes, is now evident together with bright patches due to emission from the 012 planes. The 001 region is, however, still very different from its appearance under an oxygen film. After 2 min. at 980° C., the 111 plane and the bridges (233, 122, 133) joining it to the 011-type planes present a 'built-up' appearance. This is a characteristic feature of an oxygen-contaminated tip after heat treatment and is due to the migration of tungsten under an oxygen layer. The 001 planes are, however, still dark. This latter feature is finally removed at 1,200° C., resulting in a pattern indistinguishable from those observed during the desorption of oxygen.

To summarize: desorption of water occurs between 200 and 460° C.; between 460 and 570° C. abrupt changes occur in the field emission patterns, which, as the temperature is further increased, show an increasing resemblance to those of oxygen on tungsten. The desorbed water probably comes from the second layer. When the first layer is laid bare, decomposition of water occurs, possibly by the mechanism:



This results in a layer of adsorbed oxygen. The reaction appears to take place first on the 111 planes at about 700° C., but a completely water-free oxygenated tip is not obtained below 1,200° C. Fuller details of this work will be published elsewhere.

Excess Volumes in Binary Liquid Mixtures of Simple Molecules

Recent statistical theories of liquid mixtures have made it possible to calculate the excess thermodynamic functions of binary mixtures from the parameters characterizing the intermolecular potential-energy curves for the two pairs of like molecules. For small molecules, between which only dispersion forces are supposed to operate, these parameters may conveniently be taken to be ε_{11}, the minimum value of the potential energy, and r_{11}, the molecular separation corresponding to this minimum (for a pair of like molecules of species 1). The theories are of two types. Those of the first type use a definite model for the liquid, and enable the excess functions to be calculated from the appropriate ε and r values alone. This applies to the treatment of Prigogine and Mathot[1] (and its extension by Prigogine and Bellemans[2]) and to that of Salsburg and Kirkwood[3]. In treatments of the second type[4,5], based on the theory of corresponding states, the excess functions are expressed in terms of (*a*) the ratios $\varepsilon_{11}/\varepsilon_{22}$ and r_{11}/r_{22} and (*b*) the macroscopic properties of one of the two pure components, chosen as reference substance. Thus, the excess volume, V^E, depends on the molar volume of the reference liquid and the temperature variation of this volume.

These theories, which should be tested on systems composed of small, symmetrical, non-polar molecules, predict that V^E can either be positive or negative. Qualitatively, differences in ε tend to give rise to a

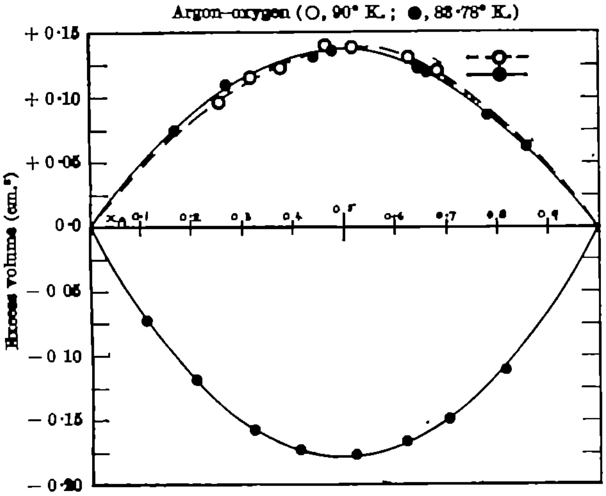

Fig. 1. Plot of the volume change on mixing V^E, in ml./mole, against x_A, the mole fraction of argon, in the systems argon–oxygen and argon–nitrogen

contraction on mixing, and differences in r to an expansion.

We have measured the excess volumes for the systems (*a*) argon–nitrogen at the triple-point of argon (83·78° K.), (*b*) argon–oxygen at 83·78° and at 90·00° K. The method used was essentially the same as that first applied to the system carbon monoxide–methane⁶, but its precision was considerably improved, principally by using a rather larger sample of liquid (~ 2·3 ml.) and by increasing the accuracy of the pressure measurements on which the determination of the amount of each component in the pycnometer depends. If $V_{\text{obs.}}$ is the molar volume of a mixture in which x_1 and x_2 are respectively the mole fractions of the components 1 and 2, and if V°_1 and V°_2 are the molar volumes of the two pure components, then $V^E = V_{\text{obs.}} - x_1V^\circ_1 - x_2V^\circ_2$. The experimental values of V^E in ml./mole are plotted in Fig. 1. They may be represented by the equation $V^E/x_1x_2 = A + B(2x_1 - 1)$, where subscript 1 refers throughout to argon, and where the parameters A and B have the following values: for argon/nitrogen at 83·78° K., $A = -0.7191 \pm 0.0022$, $B = 0.0025 \pm 0.0056$; for argon/oxygen at 83·78° K., $A = 0.5442 \pm 0.0028$, $B = -0.0011 \pm 0.008$; for argon/oxygen at 90° K., $A = 0.5508 \pm 0.0026$, $B = 0.044 \pm 0.009$. The method used necessarily yields values for the molar volumes of the pure liquids of high relative precision. These values in ml./mole are as follows: for nitrogen, 36·091 at 83·78° K.; for argon, 28·193 at 83·78° K. and 28·967 at 90° K.; for oxygen, 27·300 at 83·78° K. and 28·023 at 90° K.

We shall now compare experiment and theory for equimolar mixtures ($x_1 = x_2 = 0.5$). The necessary values of ϵ and r can be obtained from second virial coefficient data, from gas viscosity data, or by using relations between ϵ and r and the critical constants⁷. For the system argon–nitrogen, V^E is negative, being – 0·180 ml./mole at 83·78° K. Theories of the first type, however, predict a positive V^E, regardless of the source of the ϵ and r values. This is due essentially to the difference of ~ 0·3 A. between the r values for argon and nitrogen. To test the second type of theory, one of the two substances is chosen as reference, and for this it is necessary to know V°, V' ($= dV^\circ/dT$) and V'' ($= d^2V^\circ/dT^2$). We have combined our own values of V° with the data of Mathias, Crommelin and Onnes to give estimates of V' and V'' for argon, nitrogen, and oxygen. With argon as reference substance and with ϵ and r values taken from virial coefficient data, the theories of Scott⁸ and of Prigogine, Bellemans and Englert-Chwoles⁴ predict values of V^E of + 0·17 and + 0·12 ml./mole respectively. With nitrogen as reference substance, the corresponding values are –0·29 and – 0·32 ml./mole. Besides the change in sign with the choice of reference substance, another unsatisfactory feature here is the uncertainty about the convergence of the series expansions on which these treatments depend. Thus, our estimates of the quantities in the expression ($\frac{1}{4}TV' + \frac{1}{4}T^2V''$), which appears in the equation of Prigogine *et al.* for V^E, are for argon $\frac{1}{4}TV' = 5.3$, $\frac{1}{4}T^2V'' = 1.7$; but for nitrogen, the corresponding values are 8·5 and 17.

For an equimolar mixture in the argon–oxygen system, $V^E = + 0.136$ ml./mole. The critical constants of argon and oxygen only differ slightly, so it is not surprising that with values of ϵ and r derived from these constants the values of V^E calculated from the theories we are considering are numerically always much too small (< 0·005 ml./mole). Scott's treatment, in which the ϵ values are derived from vaporization energies and the r values from the molar volumes of the liquids at the temperature in question, also predicts a small V^E (< 0·01 ml./mole). If, however, we take the r values from second virial coefficient data and choose those quoted by Hirschfelder *et al.*⁷ to make the difference between them as large as possible (namely, $r = 3.838$ A. for argon and 4·02 A. for oxygen), the theories predict an expansion of the right order of magnitude. Thus, Salsburg and Kirkwood's equations⁸ give $V^E = 0.21$, and those of Prigogine, Bellemans and Englert-Chwoles, selecting argon as the reference substance, give 0·12 ml./mole. Nevertheless, an appreciable difference in r for the two sets of molecular pairs, in view of the near-equality of the critical constants, suggests that oxygen is not conforming closely to the principle of corresponding states in the simple form valid for spherical molecules. This is indeed implied by the figures of Table 4, 1–2, p. 245, of Hirschfelder's book⁷. In the argon–oxygen system, a contributory factor to attraction between oxygen molecules is their paramagnetism, and consequently an assumption made in all theoretical treatments we have considered, namely, that ϵ_{12} is the geometric mean of ϵ_{11} and ϵ_{22}, may be a less sound approximation for this system than for others. If an equilibrium governed by an ideal mass-action law is assumed to exist between O_2 and O_4 molecules, any contribution to V^E arising from the effect on this equilibrium of dilution with argon should in principle be an unsymmetrical function of mole fraction. In fact, V^E is an almost perfectly symmetrical function of composition at the lower temperature, though an increase in temperature appears to make it slightly less so.

It is hoped to measure other excess properties of these two systems, but it is clear that for testing and comparing various statistical theories it is just as important to have the best available information on intermolecular energy parameters and on the physical properties of the pure substances concerned as it is to obtain new experimental information about the excess properties of suitably selected systems.

We thank the British Oxygen Company for the award of a fellowship to one of us (R. A. H. P.).

A Dilatometric Method of following the Non-stationary State of Polymerization Reactions

IN recent years, several non-stationary state methods[1-5] have been developed for the measurement of kinetic life-times and hence the velocity coefficients for the propagation and termination steps in polymerization reactions. These methods, with the exception of that of Burnett[1], depend upon the system remaining virtually adiabatic for periods of at least 10 sec. following the commencement of irradiation; this is due to the very slow conduction of heat through the walls of the reaction vessels. Burnett's results, which were interpreted on the basis of the system remaining isothermal during the reaction, can alternatively be explained[6] if non-isothermal conditions prevail during the reaction. This, however, invalidates the method as a means of measuring non-stationary states. The method reported here, like that of Burnett[1], involves the measurement of change of volume immediately following the beginning of irradiation, but differs in that the non-stationary state period is measured from the volume expansion–time curve instead of the contraction–time curve.

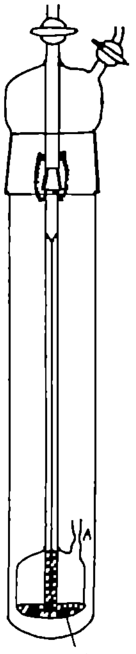

Fig. 1. Dilatometer and vacuum jacket. Constriction at A is sealed when dilatometer has been filled with monomer

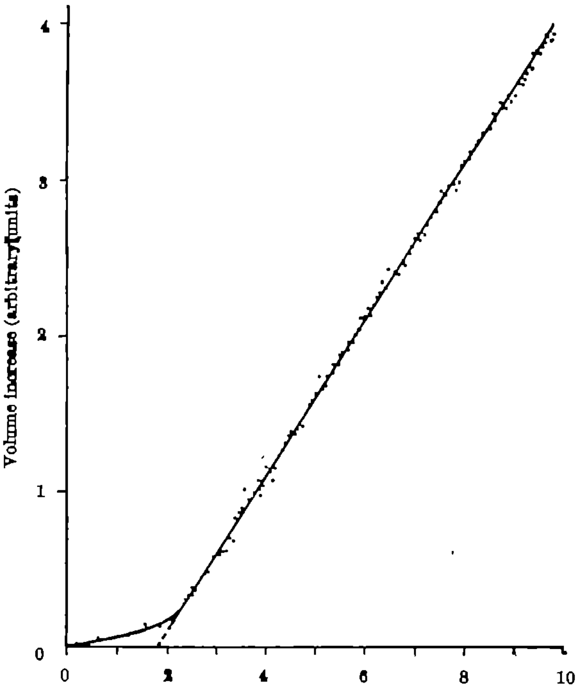

Fig. 2. The variation of volume with time immediately following the commencement of irradiation of vinyl acetate photosensitized with 1.1′ azo-*bis*-*cyclo*hexane carbonitrile at 25° C.

Preliminary experiments on the polymerization of vinyl acetate photo-sensitized with 1.1′ azo-*bis*-*cyclo*hexane carbonitrile indicated that the reaction was adiabatic for approximately 8 sec. when a dilatometer of about 50 ml. capacity was used, the dilatometer being immersed in a thermostatically controlled water-bath. This period could be increased five-fold or more by placing the dilatometer inside a glass jacket which was afterwards evacuated. The final arrangement used, shown in Fig. 1, consists of a dilatometer bulb of about 20 ml. capacity attached to constant bore (Veridia) capillary tubing of 0·4 mm. diameter. The height of the meniscus in the capillary tubing can be adjusted by the addition or removal of mercury.

The usual method of following the movement of the meniscus with a cathetometer could not be employed as the system remained adiabatic for only about 30 sec. The movement, however, could be photographed through the telescope of a cathetometer using a ciné-camera. Alternatively, the cross wire in the telescope of a cathetometer could be replaced by a piece of processed film on which is printed a series of equidistant parallel lines. As the meniscus crosses each of these lines in turn, the observer could record the time by depressing a button switch which applied an electromotive force to the pen-recording voltmeter. Either method was satisfactory, but the latter method proved to be much less time-consuming.

An expansion–time curve for the polymerization of vinyl acetate is shown in Fig. 2. In this particular experiment a ciné-camera was used and operated at a speed of 16 frames per sec. It will be seen that the rate of expansion rises to a steady value after the first few seconds. The observed expansion is clearly the net result of a rise in temperature due to the heat of polymerization less the contraction due to polymerization. Now as both the expansion and contraction are proportional to the rate of polymerization, it is possible to calculate the rate of reaction from the overall expansion–time plot, and the kinetic life-time from the extrapolation of the linear portion of the curve as shown in Fig. 2. From a number of results an average value of 2·9 × 10^{-5} was obtained for the ratio k_p/k_t at 25° C. which is in quite good agreement with results obtained by other methods[3,4,7-9]. A detailed account of the method will be published later.

I am grateful to Prof. H. W. Melville and Prof. P. D. Ritchie for their interest in the work.

Relationship between the Concentration of Anionic Surface-active Agents and the Electrophoretic Mobility and Viability of *Aerobacter aerogenes*

As part of a detailed study of the electrical properties of *Aerobacter aerogenes*, it was considered that useful information on the action of phenol could be obtained by following changes of the electrophoretic mobility of the organism after treatment with this reagent.

Cells of this organism, grown in synthetic medium[1], were harvested early in the logarithmic growth phase, washed twice with phosphate buffer solution (ionic strength = 0·018, pH = 7·00) and then suspended in buffer solutions containing various concentrations of phenol. The suspensions (3 × 10^8 organisms per ml.) were aerated for thirty minutes at 40° C.; the organisms were then washed and suspended in phosphate buffer solution and the mobility distributions determined[1]. The histograms (Fig. 1) show the distributions of mobility after treatment; these are reproducible after prolonged keeping of the final suspension. At low concentrations, the mobility (homogeneous) is less than that of the control, but at higher concentrations than those used previously[2] higher mobility values (negative) were obtained, first as a heterogeneous and finally as a homogeneous population.

The initial decrease of mobility may be attributed to the bonding of phenoxy ions with receptor sites throughout the depth of the cell wall, resulting in a partial neutralization of negative charges (cf. ref. 2). However, only changes in those layers which contribute to the ζ-potential (possibly only the upper layers) will be observed by this technique. The subsequent increase in mobility, which cannot be reconciled with this theory, is believed to be due to the adsorption of a second layer of ions by van der Waals forces, with their polar groups oriented outwards. A study of the pH/mobility relationship for the treated cells, and also the similar behaviour on treatment with sodium dodecyl sulphate lend support to such a theory. It has not been possible to confirm this by analysis, since the chemical methods of determining the very small amounts of phenol adsorbed are not sufficiently sensitive; it is hoped, however, to pursue this further, using phenol labelled with carbon-14. A similar theory has already been advanced to explain certain anomalous characteristics of complexes formed with sodium dodecyl sulphate and gelatin[3] and with hæmoglobin[4].

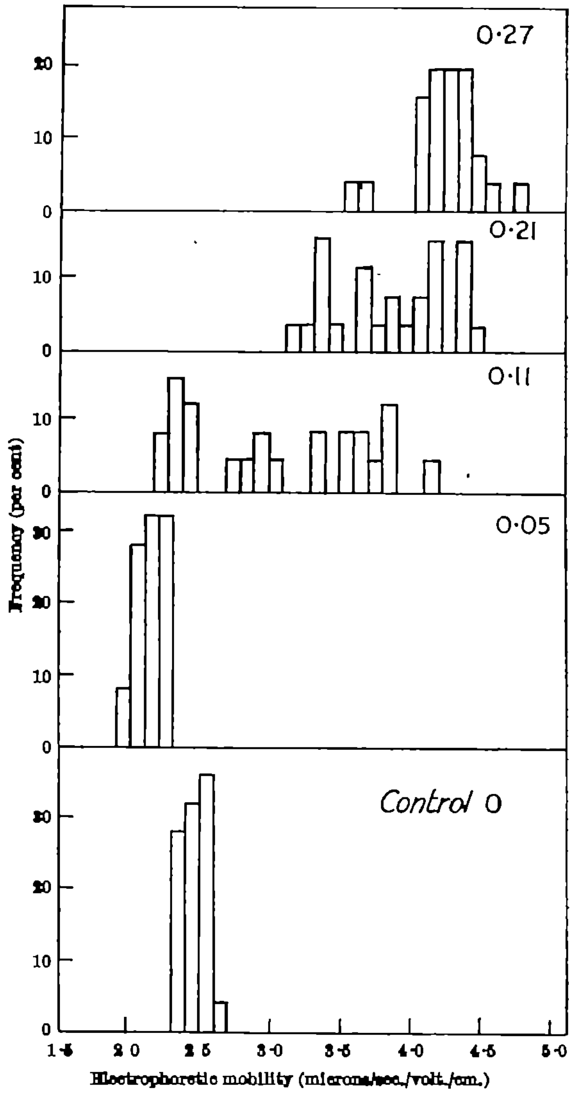

Fig. 1. Histograms showing the distributions of electrophoretic mobilities of *Aerobacter aerogenes* in buffer solution, after treatment with phenol. (Numbers refer to molarity of phenol used for treatment)

On this hypothesis it is most likely that the first layer of ions is nearly complete before the second layer starts to form, with the resulting increase of mobility. It was found that the concentration of phenol causing 100 per cent death of the organisms coincided with that at which the first layer is complete. There thus appears to be some correlation between the change of electrophoretic mobility and the viability. It is not suggested that this is a cause-and-effect relationship; more likely, parallel adsorption to that demonstrated electrophoretically is occurring at some point within the bacterial cell wall, for example, the cytoplasmic membrane[5]. A sufficient amount of phenol adsorbed here could give rise to general disorganization and finally lysis.

Similar correlation was found with both *p*-methyl- and *p*-ethyl-phenols, although the comparable changes of electrophoretic mobility and viability occurred at much lower concentrations (namely, a quarter and one-twelfth of the concentration of phenol respectively). Sodium dodecyl sulphate and some of its homologues respond in a similar manner, but again at lower concentrations. The final high mobility of the organisms is the same after treatment with any of these substances. With sodium dodecyl sulphate there appears to be some correlation between change of electrophoretic mobility and critical micelle concentration. Inhibition of yeast fermentation by sodium dodecyl sulphate is closely related with the critical micelle concentration[6], as is also its maximum adsorption on alumina[7], with the formation of a bimolecular layer.

From this work it appears that anionic surface-active agents, including those which do not form micelles in solution (for example, phenols), will at a definite concentration start to be adsorbed from solution when a suitable surface is provided. Although the nature of the receptive sites in the cell wall is not known, possibilities include keto-imide groups in proteins, imino groups in aminopolysaccharides and lipids. Bacteria, possessing different quantities of these materials in the cell wall and membrane, will therefore take up varying amounts of these reagents and hence have different sensitivities. Although, as yet, Gram-positive organisms have not been studied, it would appear that their different sensitivity to phenols may well be attributed to different amounts of anion receptor sites. Further, the evidence from the homologous series of phenols studied gives a better understanding of the phenol coefficients, each additional CH_2 group lowering the concentration at which adsorption on suitable sites can occur.

Further work is in progress on the confirmation of the double-layer theory. It is hoped to present a more detailed account of this work later, together with a full discussion of the significance of the histograms.

A Simple Device for forming Solution Concentration-gradients

The following device for producing nearly linear gradients of concentration can easily be assembled from materials at hand in most laboratories. This design solves the problems arising in such devices from unequal densities of the stock solutions, and has the further advantage of economical operation.

The device, shown schematically in Fig. 1, comprises two identical conical flasks, one upright and one inverted, which feed by gravity to a mixing chamber *M* of small volume. In general, mechanical stirring (magnetic coupling) is desirable in *M*, although in some cases flow through a pebble-bed provides adequate mixing.

The composition of the effluent from *M* is shown in the upper curve of Fig. 2 (calculated on the principle of Ling and Bock[1]). In practice only a truncated conical section of the flasks can be used, so a gradient is begun at $H = 0 \cdot 3$ and ended at $H = 0 \cdot 7$. Between these limits a nearly-linear S-shaped gradient is generated. Fig. 2 shows the effect of changing the height of one flask relative to the other. The lower curve is obtained when the bottom of cone *B* is raised from $H = 1 \cdot 0$ to $H = 0 \cdot 9$. Thus a small misalignment has a slight effect on the linearity of the gradient, but a considerable effect on its slope. When such variations in successive gradients are undesirable, flasks *A* and *B* should be fixed in position and re-filled through their delivery tubes.

A number of devices for producing gradients have been described[1,2], and although the present one embodies no new principle, it possesses two novel features.

First, if *M* is chosen to have a small volume relative to *A* and *B*, there will be negligible holdup in *M* at any fraction of the total volume delivered. Recovery of unused solutions from *A* and *B* can be essentially complete, in contrast to the situation found in devices with a mixing-chamber of large volume. When expensive solvents are employed, the economy afforded by the present device may be significant.

The second point relates to differences in density between the solutions in *A* and *B*. If these differences are large, there will be considerable deviation from the idealized gradients of Fig. 2. This can be over-

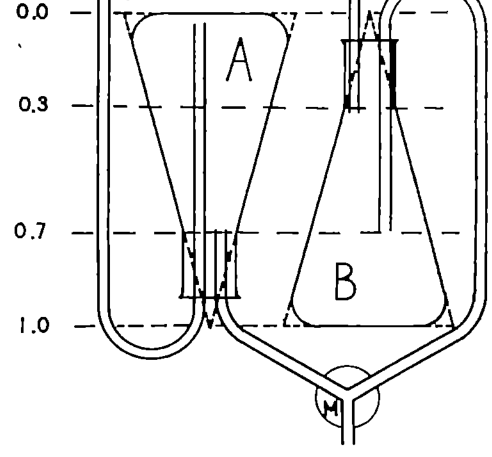

Fig. 1. Apparatus for producing linear gradients of concentration, cones *A* and *B* are both of height $H = 1 \cdot 00$

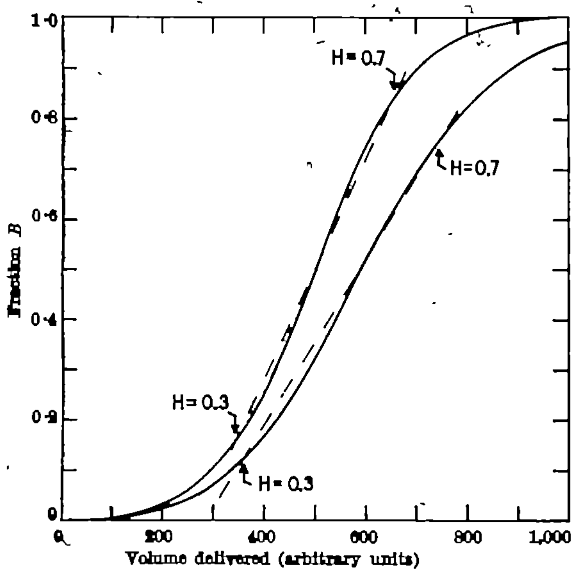

Fig. 2. Gradients generated by flow from cones paired as in Fig. 1. Volume of cone A = volume of cone B = 500 units. Upper curve, cones at same height; lower curve, at different heights

come by the application of an external air pressure P from a manostatted reservoir to the air inlets of both A and B. Then $P + h_{AM}\, d_A = P + h_{BM} d_B$, where h_{AM} is the height between the liquid levels in A and M, d_A is the density of the liquid in A, etc. It is seen that the inequality between h_{AM} and h_{BM} can be made negligible by minimizing the initial values of these quantities and by increasing P (in most cases P can be less than 1/3 atm.). On the application of an external pressure, the flow-rate will of course increase, and it may become necessary to use a flow-resistance element[3] in the effluent tube from M. This solution to the problem of inequalities in density will apply to many devices for producing gradients.

This work was done during the tenure of a research fellowship of the American Heart Association.

Effect of Prolonged Thyroid Administration on Aged Male Rats

TISSUES from nineteen aged unaltered male Holtzman strain rats (average body-weight 374·4 gm.) which had been administered orally 0·18 mgm. of 'Proloid' daily (Warner-Chilcott purified thyroid extract) from the age of 14 months to death at 24 months were compared anatomically with those of ten control animals (average body-weight 352·7 gm.) to note any gross or histological anatomical variations induced by the drug. The tissues were fixed immediately following death in buffered 10 per cent formalin and processed routinely by the paraffin method. The tissues examined were testis (including epididymis), kidney, liver, pancreas, buccal gland, seminal vesicle, aorta (both thoracic and abdominal), superior and inferior vena cava, heart, spleen, pituitary, adrenal, prostate and thyroid glands, costal cartilage with surrounding skeletal muscle, diaphragm, trachea, lung, levator ani muscle, abdominal skin and all levels of the gastrointestinal tract including upper and lower œsophagus, fundic and pyloric stomach, duodenum, jejunum, upper and lower ileum, cæcum, ascending, transverse and descending colon and rectum. The sections were stained for examination by the following methods[1-3]: (1) hæmotoxylin and eosin; (2) the Goldner connective tissue stain; (3) the McMannus periodic acid–Schiff technique; (4) the catalysed lead tetraacetate–Schiff technique; (5) the Rinehart–Abu'l-Haj modification of the Hale dialysed iron procedure for acid polysaccharides; (6) the periodic acid–Foot reticular connective tissue stain; (7) the orcein procedure for elastic tissues. It was felt that these methods, when used in comparison, would adequately disclose any possible histochemical variations from the normal.

Prior to fixation, all organs to be processed were carefully examined for gross pathological changes and certain of them were weighed. Weight averages of experimental and control animal organs are listed in Table 1.

Table 1. AVERAGE ORGAN WEIGHTS AT NECROPSY

Organ	Experimental animals	Control animals
Testis	2·94 gm.	2·92 gm.
Kidney	3·12 gm.	3·18 gm.
Spleen	0·70 gm	1·32 gm.
Seminal vesicle	0·487 gm.	0·388 gm.
Heart	1·28 gm	1·24 gm.
Pituitary gland	13·9 mgm.	13·2 mgm.
Suprarenal gland	50·8 mgm.	49·8 mgm.
Prostate gland	372·5 mgm.	330·9 mgm.
Thyroid gland	24·1 mgm.	22·6 mgm.
Levator ani muscle	125·7 mgm.	100·6 mgm.

Grossly, no significant pathological variations were noted between the experimental and control organs, either in appearance or by weight; while microscopically, no consistent significant pathological alterations were discernible other than slight generalized fibrosis and the usual changes associated with sexual senility. Changes in the architecture of vascular structures such as arterial muscular and elastic coats and the cardiac muscle fibres were negligible. Ground-substance changes as shown by the histochemical polysaccharide methods could not be considered significant in either series of tissues. It would appear that anatomically this dosage of thyroid preparation over a prolonged period had no material effect on the microscopic or gross architecture of the organs investigated in comparison with the tissues of control animals of equivalent age.

The basal metabolic rates were determined on all the animals just prior to necropsy. These were assessed on the basis of an average of four 10-min. periods and expressed in terms of litres per square metre per hour (l./sq. m./hr.). There was fair correlation between the runs on different days and the thyroid animals averaged 2·84 l./sq. m./hr., while the average of the control group was 1·519 l./sq. m./hr. Heart-rates were determined just preceding death, with the average of the thyroid-fed animals 431·5 beats per min. and those of the control group 416·0 beats per min.

1 c.c. of water containing 4·8 mc. of iodine-131 was administered intraperitoneally to each rat 36 hr. before death. Scintillator counts taken over the thyroid area 24 hr. later averaged 4,998·9 per min.

for the thyroid-fed animals and 6,431·6 per min. for the control group. Planchet counts performed at necropsy on weighed portions of thyroid glands (corrected for total gland) averaged 36,557·8 counts per 3 min. for the experimental animals as compared with an average of 40,808·1 counts per 3 min. for the control group.

The animals receiving the exogenous thyroid had a statistically significant increase in basal metabolic rates over the control group in spite of the decreased thyroid function of the experimental animals as indicated by iodine-131 uptake studies. It is also of interest that the average heart-rate of the thyroid-fed animals was not significantly higher. Thus, it would seem that when exogenous thyroid has been administered to the aged rat over a prolonged period of time thyroid function is to some extent altered; but this depression is not sufficient to counteract the additional stimulus produced by the thyroid fed to the animal.

The anatomical phase of this investigation was supported by research grant *H*-1907 (*C*1), National Heart Institute, National Institutes of Health, United States Public Health Service.

Calorigenic Action of Glucagon

A recent investigation carried out in this laboratory revealed that rats treated with glucagon gained less weight and contained much less fat, protein and water than pair-fed controls. Since the calorie intake of the two groups was identical and the calorie values of the carcasses of the glucagon-treated rats was much lower than that of the controls, the effect of glucagon on the metabolic rate of rats was investigated.

Male Wistar rats were used throughout the investigation. Of the eight animals used for each experiment, four were injected subcutaneously with 1 mgm. of crystalline glucagon (Lilly, Lot No. 258–234–*B*–54–2) suspended in neutral saline. The remaining four rats served as controls and were injected with saline. The oxygen consumption of each animal was determined at an environmental temperature of 28° C., according to the method of Ferguson and Sellers[1] at the intervals shown in Table 1. Four identical experiments were performed in this manner using rats that ate *ad libitum* up to the time of injection. A second group of similar experiments was carried out using rats that had been fasted 24 hr. prior to injection.

It is evident from Table 1 that glucagon induced a rise in the metabolic rate of the fed animals of approximately 35 per cent. The increase in oxygen consumption was maximal 1 hr. after the administration of glucagon and decreased slowly throughout the 7-hr. observation period. It is also evident from Table 1 that this effect of glucagon is only slightly reduced when the animals are fasted 24 hr. before treatment.

Table 1. The Effect of Glucagon on the Metabolic Rate of Rats

		Change (per cent)				
		25·3	20·0	16·9	0·5	6·4

* Standard error of the mean

A stimulating effect of glucagon on the metabolic rate has not been noted previously. The mechanism(s) involved is (are) not known. It does not appear that hyperglycaemia is a significant contributing factor since in fasting rats glucagon failed to elevate the blood-sugar level but raised the metabolic rate by approximately 25 per cent. Conversely, when hyperglycaemia was induced by administering glucose to intact rats, only a slight increase (4 per cent) in the metabolic rate was observed.

Additional experiments have shown that the calorigenic action of glucagon is greatly reduced by pretreating the animals with dihydroergotamine and is abolished completely by adrenalectomy; thus the possibility that adrenal hormones are involved in this phenomenon merits careful investigation. A more detailed account of these and other experiments will be the subject of another communication.

Transport of Potassium-42 and Rubidium-86 by Kidney Cortex Slices: the Effect of Varied Concentration Gradients

A comparison of the transport of potassium with that of rubidium has been made in earlier work[1], in which some evidence was obtained that, in contrast to sodium, the transport of both potassium and rubidium across the membrane of renal tubular cells is determined only by electrochemical gradients. A deficiency in this work was that the rubidium content of tissue slices had to be estimated from differences in potassium content as compared with control slices. For this reason, the experiments have been repeated using potassium-42 and rubidium-86, to give a direct estimation, both being present only in the incubating medium (a modified Krebs–Ringer phosphate medium containing the indicated concentrations of potassium and rubidium, with 0·005 *M* alpha-keto glutarate as substrate, at 25° C.). Activity was measured in neutralized nitric acid digests of tissue slice samples, using aluminium dishes, with values corrected for decay, dilution, extracellular space, etc. Since the specific activities of the two isotopes were different by a factor of 4·0, the rubidium

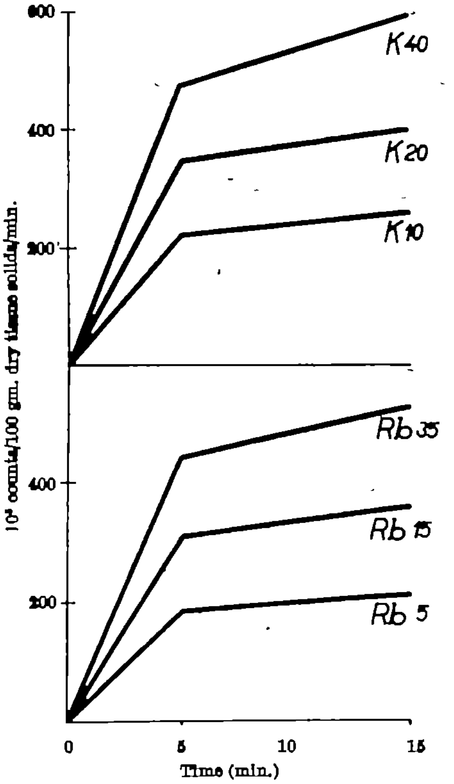

Fig. 1

counts were arbitrarily divided by this factor to give a better comparison of results. Isotope measurements for rubidium-86 in samples containing both potassium-42 and rubidium-86 were carried out five days after the actual experiment, at which time potassium-42 activity was nil. Measurements of potassium-42 activity in tissue samples were not complicated by the presence of rubidium-86. Details of composition of the media are given in ref. 1.

The results are shown in Fig. 1. They extend the previously published evidence that the accumulation of potassium and rubidium after leaching in 0·154 *M* sodium chloride for 2 hr. is exponential in time and linearly related to concentration gradient, and that both cations show the same type of curve.

It appears, then, that under the above conditions, renal tubular cells cannot differentiate between potassium and rubidium. It has been suggested that this is true under physiological conditions[2], and that both cations behave as if passively transported at the cell membrane. This is consistent with the similar particle diameters of the two hydrated cations in aqueous solution (K^+, Rb^+, ~ 3 A.) as opposed to the larger hydrated sodium ion (~ 4·5 A.) which is actively transported by renal tubular cells[3].

Biosynthesis of γ-Guanidinobutyric Acid from γ-Aminobutyric Acid and Arginine

THE recent discovery by Irreverre *et al.*[1,2] of γ-guanidinobutyric acid in mammalian brain and other tissues stimulated research on its biosynthesis and physiological role. Thoai *et al.*[3] have shown that in many invertebrates γ-guanidinobutyric acid is synthesized by the oxidation of arginine through the action of L-amino-acid oxidase. The present communication shows that in mammals it is synthesized by a transamidination reaction[4] involving γ-aminobutyric acid and an amidine donor such as arginine.

Initial experiments showed the activity to be present only in kidney, with rat kidney being more active than that of guinea pig. The localization in kidney, the higher activity in rats than in guinea pigs[4], the requirement for both γ-aminobutyric acid and arginine, the inhibition with parachloromercuribenzoate and the lack of inhibition by cyanide, all suggested a transamidination reaction.

When transamidinase was isolated from pig kidney[5] it was found to catalyse the formation of γ-guanidinobutyric acid from added γ-aminobutyric acid and arginine. Identification of the enzymatically formed γ-guanidinobutyric acid was established using chromatography on paper by comparison with authentic γ-guanidinobutyric acid in two different solvent systems (*tert.*-butanol, formic acid and water, 70 : 15 : 15, and *n*-butanol, pyridine and water, 1 : 1 : 1). Quantitative analysis of the guanidino compound was performed using the Sakaguchi reaction as modified by Van Pilsum *et al.*[6]. Analytical specificity was obtained by the removal of residual arginine by incubation with arginase (Worthington). Arginase was found to have no action on γ-guanidinobutyric acid, β-guanidinopropionic acid and guanidinoacetic acid.

In a typical system containing 1·57 units of enzyme[5], 0·180 μmole of γ-guanidinobutyric acid was formed in 1 hr. β-Alanine was also found to be an amidine acceptor with the formation of 0·068 μmole β-guanidinopropionic acid under the same conditions. With glycine as amidine acceptor, 1·57 μmoles of guanidinoacetic acid were formed in 1 hr. as calculated from a 10-min. incubation when only 0·26 μmole of inhibitory ornithine was formed. Borsook and Dubnoff[4] and Walker[7] were unable to show activity for β-alanine under their experimental conditions. The average relative rates of transamidination for the three acceptors were glycine, 100; γ-aminobutyric, 10; and β-alanine, 3. Incubations were usually performed at 38° C. in tubes containing 20 μmoles arginine, 30 μmoles amidine acceptor, 100 μmoles phosphate buffer *p*H 7·5, in a final volume of 1·5 ml.

In keeping with the general properties of the transamidinase reaction[4,7–9], γ-guanidinobutyric acid was found to be an amidine donor to ornithine or glycine with the formation of arginine or guanidinoacetic acid as revealed by paper chromatography. In other experiments it was found that ornithine was a powerful inhibitor of the arginine-γ-aminobutyric acid transamidination, and that guanidinoacetic acid could be a substitute for arginine as an amidine donor.

Studies on the localization of the enzyme have shown that washed mitochondria have about as much activity as the soluble cellular fraction.

The physiological significance of γ-guanidinobutyric acid is unknown. However, recent reports that γ-aminobutyric acid may have a role as a neurohumoral agent[10] suggest that γ-guanidinobutyric acid may be similarly involved. Experiments performed by Drs. C. Edwards and S. Kuffler, Johns Hopkins Medical School, Baltimore, have shown that the threshold-level for inhibition of the crayfish stretch receptor is about $7 \times 10^{-4} M$ for γ-guanidinobutyric acid in contrast to $2 \times 10^{-5} M$ for γ-aminobutyric acid. However, no physiological studies have as yet been carried out with mammalian systems.

Full details of the experiments described above will be published elsewhere.

We are indebted to Dr. F. Irreverre for a generous supply of γ-guanidinobutyric acid and for valuable suggestions concerning methodology.

A Semi-continuous Method for the Large-scale Production of Tetanus Toxin

THE production of large quantities of tetanus toxin for human immunization was greatly facilitated by the isolation of the highly toxigenic Harvard strain of *Cl. tetani* by the late Dr. J. H. Mueller and by his success in the provision of a medium suited to this strain. This preliminary report concerns the adaptation of small-scale experimental work to large-scale semi-continuous production, and since it has been possible to reproduce in large vessels the results obtained in 6 in. × 1 in. test-tubes it may be of help to others to describe the lines we have followed and the results that have been obtained.

The Harvard strain of *Cl. tetani* originally isolated by Mueller and Miller[1] was used.

The medium was essentially that of Mueller and Miller[2]. In converting to large-scale work one of the most important factors was found to be the amount of autoclaving to which the medium was subjected, since over-autoclaving may lead to poor toxin titres. When large volumes of 70–150 l. were used the following procedure was adopted. The medium was filled into 15-l. borosilicate bottles, which, after an initial steaming for 90 min., were autoclaved for 15 min. at 117° C. They were then allowed to cool at room temperature and stored in an incubator at 35° C. When required, the medium was siphoned aseptically from these bottles into the growth vessel.

For experimental work 6 in. × 1 in. test-tubes were used. In scaling up to production-levels, it was found, in common with the results of other workers[3], that toxin yields were dependent upon free access of the culture to the atmosphere. The growth vessel adopted was an 80-l. open tank of aluminium with an outlet at the bottom. It was flanged at the top so that a covering of cotton-wool between two layers of muslin could be held in place by an aluminium ring bolted to the flange. Upon this ring a stainless steel bar was bolted to accommodate a propeller-type stirrer (blades 3½ in. × 4½ in.) with a sterile gland and a slow-speed motor. The motor and the gland were removed before autoclaving the vessel.

The sterile tank was filled with approximately 70 l. of autoclaved medium at 35° C. After inoculation with 100 ml. of a 24-hr. culture of the Harvard strain it was incubated at 35° C. and the contents stirred continuously at 60 r.p.m. for 2 days. At this time the culture was tapped off into sterile 10-l. bottles which were incubated for a further 2 days at 35° C. Approximately 1 l. of culture was left in the tank as an inoculum for the next batch of medium which was siphoned in as soon as the tank had been emptied. This procedure of emptying and filling, with mechanical stirring during the growth period was repeated continuously and 70 l. of culture was thus produced every 48 hr.

The densities of micro-organisms reached in the tank were greater than those attained in test-tubes or in open unstirred vessels. When the tank harvests were transferred to 10-l. bottles there was no further increase in density, although, in some cases, gas production continued for several hours. The further incubation served mainly to autolyse the organisms and to release toxin. The toxin-values of cultures removed from the tank were initially 0–6 units/ml. and after two days incubation in the bottles reached the maximum values shown in Table 1. In Table 1 the results of three experiments are summarized. In the first, *M* 667, the tank was emptied and replenished every three days; the other two were run on a two-day cycle. The initial low results in the third experiment were due to the use of a poor tryptic digest of casein, which was replaced later by a more satisfactory batch. A feature of the results obtained was the regular fluctuation in the titres of successive harvests. This might be related to the state of the inocula of the batches. In *M* 667, for example, harvests *A* and *C* were partially autolysed and therefore the inocula for *B* and *D* were old and the viable populations present therein were small. It is possible,

Table 1. SEMI-CONTINUOUS PRODUCTION IN ALUMINIUM TANK WITH CONTINUOUS STIRRING

	Growth period in tank	Subsequent growth period in bottles	Lf./ml.	L+/ml.	M.L.D./ml.
M 667 *A*	3 days	2 days	80	83	
B			60	70	
C			30		
D			54		
M 680 *A*	2 days	2 days	26		
B			70	72	
M 690 *A*	2 days	2 days	30	33	1·0 × 10^6
B			42	45	1·25 × 10^6
C			26	36	0·75 × 10^6
D			54	57	1·5 × 10^6
E			57	57	1·0 × 10^6

therefore, that in batches *B* and *D*, which produced the higher toxin titres, the lag phase was relatively long while in the poorer batches *A* and *C*, inoculated with a higher concentration of young organisms, the lag phase was short. In addition to this, the total number of generations in batches *B* and *D* would be higher than in *A* and *C*.

Continuous culture procedures were less successful than the simpler process described above, since the titres obtained did not exceed 40 units/ml. and there was a tendency for the strain to lose toxigenicity.

Since there seems to be some confusion at present as to the units used to evaluate tetanus toxin (due presumably to the change in unit in 1950), it is emphasized that those used here conform to the present international standard.

Inhibitory Effect of 5-Hydroxytryptophan on Acid Gastric Secretion

WE have recently described the effect of 5-hydroxytryptamine on acid gastric secretion elicited by histamine in dogs[1]. Recent experiments with its precursor 5-hydroxytryptophan have shown that this substance is also capable of inhibiting acid secretion. A technique has been used for recording the secretory-rate from a gastric cannula in anaesthetized dogs, as drops per min. on a kymograph. The acid output is expressed as mille equivalents, and is fairly constant after 1 hr. during histamine administered by continuous infusion (Table 1,*a*).

Infused 5-hydroxytryptamine rapidly lowers the secretory-rate induced by histamine while with 5-hydroxytryptophan there is a latency before secretory and blood-pressure changes. Whereas 5-hydroxytryptamine led to changes in blood pressure and secretion within 2 min. after starting the infusion, there was a delay of 10–15 min. before similar effects were noticed after starting the 5-hydroxytryptophan infusion. Table 1,*b* illustrates the inhibitory effect of varying doses of 5-hydroxytryptophan, and three experiments are recorded which show a marked fall in acid secretory output elicited by histamine, again delayed until the end of the infusion period. Repeated infusions of 5-hydroxytryptophan can be seen to lead to a more prompt inhibition of secretion when given after 2 hr. of histamine stimulation than when given earlier after half an hour of secretion. These effects are very similar to those already found in experiments with 5-hydroxytryptamine.

Dalgliesh and Dutton[2] have recently pointed out that the argentaffin cells of the alimentary tract might be the only source of 5-hydroxytryptophan, the biological precursor of 5-hydroxytrypytamine. The former might be released from this cellular site as a general hormone to be converted locally in various tissue to 5-hydroxytryptamine by specific decarboxylase activity and 5-hydroxytryptophan may thus control the rate of metabolism of 5-hydroxytryptamine. We have inferred by our experiments that 5-hydroxytryptophan leads to an inhibition of gastric secretion due to its conversion to 5-hydroxytryptamine by a mechanism such as this.

Occurrence of an Amine Oxidase in Horse Serum

MUCH work has been done on the intracellular amine oxidase, a mitochondrial enzyme widely distributed in vertebrate and invertebrate tissues. This enzyme is a catalyst of the biological inactivation of 5-hydroxytryptamine and of the sympathomimetic amines.

In recent years another enzyme has been described in the blood plasma of ruminants which acts mainly on spermine and spermidine, substances which are not oxidized by the intracellular amine oxidase. The spermine oxidase acts slowly also on many amines which are substrates of the intracellular oxidase[1,2].

We have now made observations on a new type of amine oxidase which occurs in horse serum. Horse serum is without significant action upon spermine and spermidine, but we have found that it oxidizes many amines, some rather slowly. These amines include 5-hydroxytryptamine, a number of sympathomimetic amines, cystamine and homocystamine, and some long-chain polymethylene diamines. All these substances are also oxidized by ruminant plasma. Of all the compounds tested so far, benzylamine is the substrate most rapidly oxidized by horse serum. The reaction catalysed is an oxidative deamination, indistinguishable from that catalysed by the intracellular amine oxidase. In its inhibitor specificity the enzyme in horse serum resembles histaminase and the spermine oxidase of ruminant plasma.

In order to distinguish the new enzyme from other amine oxidases, we shall, for the time being, call it benzylamine oxidase. Possibly its main substrate remains to be discovered. However, it is important to remember that, in some mammalian species at least, the blood may take a part in the biological inactivation of amines like 5-hydroxytryptamine or the sympathomimetic amines.

Choline-Oxidase Activity of Host-Livers of Tumour-bearing Animals

CHOLINE-OXIDASE converts choline to betaine through an intermediary step of betaine aldehyde formation[1]. Betaine, which is a trimethylglycine, initiates the transfer of methyl groups in stages, with the formation of dimethyl and monomethyl glycine[2]. Since in tumours there is a rapid turnover of nucleic acids[3], it was thought that all the processes, including transmethylation, leading to precursor formation, may also be accelerated. It was thus anticipated that choline-oxidase activity might be higher in the host tissues of tumour-bearing animals. Miller[4] has shown that the overall choline-oxidase activity requires diphosphopyridine nucleotide as an activator, but whether the choline-dehydrogenase or the betaine aldehyde dehydrogenase requires it has not been established[5]. During the course of our studies on tumour–host relationships it was observed that the diphosphopyridine nucleotide-levels in host tissues were considerably diminished[6]. One would anticipate from this a lowering of choline-oxidase activity in host tissues deficient in diphosphopyridine nucleotide. In view of these mutually exclusive and apparently contradictory possibilities it was considered necessary to study the influence of tumour on the levels of choline-oxidase in host tissues.

In the present studies, transplantable Yoshida sarcoma (originally obtained through the courtesy of Prof. H. Druckrey of Freiburg im Breisgau by Dr. A. R. Gopal-Ayengar of this Division), maintained by intraperitoneal transfer of ascites cells in Wistar rats, was used throughout. The tumour grows rapidly and results in the death of the animals in 7–8 days. For the study of choline-oxidase activity, all the animals, controls as well as tumour bearers, were killed by dislocation of the cervical vertebræ on the fourth day after transplantation. Livers were dissected, blotted free of blood, and immediately chilled in ice–salt mixture. The chilled-liver samples were then homogenized in 0·039 *M* phosphate buffer at *p*H 7·4. The final volume was adjusted to contain 1 gm. of liver per 6 ml. of the homogenate. The assay system was essentially the same as used by Williams *et al.*[7]. Endogenous respiration and substrate oxidation were determined by the Warburg technique[8]. To study the effect of diphosphopyridine nucleotide on the choline-oxidase system, 133 μgm. (sigma) were added to each of the Warburg flasks and the rate of oxidation studied for 1 hr. at 37·5° C. The enzyme activity was expressed as μl. of oxygen uptake per hr. per 100 mgm. of dry weight of tissue.

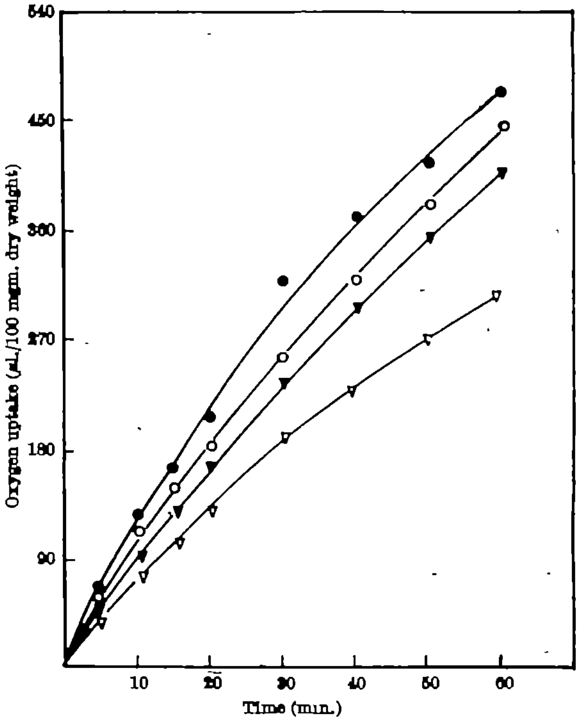

Fig. 1. Substrate oxidation of livers. From normal animals: Control, ○—○; supplemented with 133 μgm. of diphosphopyridine nucleotide, ●—●. From animals bearing Yoshida sarcoma: Control, ▽—▽; supplemented with 133 μgm. of diphosphopyridine nucleotide, ▼—▼

The results of these experiments are given in Fig. 1. It will be seen that the livers of the tumour-bearing animals showed considerably diminished choline-oxidase activity. Endogenous respiration, however, was not appreciably different in the livers from normal and tumour-bearing animals. In substrate oxidation, however, a marked lowering to the extent of 31·2 per cent was seen in the tumour-bearing animals. Thus, while the enzyme activity of the normal livers was 452 μl., the activity of the host livers was only 311 μl. of oxygen per hr. per 100 mgm. of dry weight.

The effect of fortifying the system with diphosphopyridine nucleotide has also been tested. It was found that its addition increased choline-oxidase activity of host liver homogenates by 32·1 per cent while the normal livers showed an increase in activity by 4·0 per cent only. These results suggest that lowering of diphosphopyridine nucleotide-levels may be an important factor in determining the choline-oxidase activities of host livers. In this connexion it is pertinent to point out that adenine is a common precursor of nucleic acids and of pyridine nucleotides. Our previous work has shown that there is a preferential utilization of adenine for nucleic acid synthesis in actively growing tumour tissues, which probably results in deprivation of host tissues of available adenine for pyridine nucleotide formation[6].

These observations lead us to the conclusion that choline-oxidase activity is not only not increased in host tissues of tumour-bearing animals, but is actually found to be decreased. It appears that the mechanism by which the tumour obtains its increased requirements of precursors for nucleic acid synthesis is not by an acceleration of formation of precursor in host tissues, but by an appropriation of all the available precursors of the body at the cost of depriving the host tissues of some essential metabolites. Neoplasm is unique in this respect, because during its evolution it has acquired the characteristics of maintaining its high rate of growth even in absence of adequate levels of some of the essential co-factors such as pyridine nucleotides, which are so necessary for the economy of normal tissues.

Natural Occurrence of a New Aldoheptose Sugar

AT the present time aldoheptose sugars are known to occur naturally only in bacterial polysaccharides. The first of these 7-carbon sugars was recorded by Jesaitis and Goebel[1] in a *Shigella sonnei* product, and during the past few years it has become increasingly clear that aldose sugars of this series are common constituents of bacterial polysaccharides[2]. Only in three instances have aldoheptoses been isolated and identified; the aldoheptose components of both *Shigella flexneri* and *Escherichia coli* products were shown by Slein and Schnell[3] and Weidel[4] to be L-glycero-D-mannoheptose and in a *Chromobacterium violaceum* (BN) polysaccharide MacLennan and Davies[5] identified D-glycero-D-galactoheptose. In many other polysaccharides the aldoheptose constituent could not be distinguished chromatographically from L-glycero-D-mannoheptose (or its optical enantiomorph D-glycero-L-mannoheptose)[6].

The presence of a 7-carbon sugar in a polysaccharide of *Chr. violaceum* (N.C.T.C.7917) was recorded by Davies[7], but it was not established that it differed from either of the aldoheptoses already isolated. This most unusual polysaccharide contains a sugar of a series not previously known, a 2-amino-6-deoxy sugar[8] recently identified as fucosamine[9]. The aldoheptose constituent has now been found to differ from L-glycero-D-manno- and D-glycero-D-galactoheptoses (or their optical enantiomorphs).

After treatment of the *Chr. violaceum* (N.C.T.C. 7917) polysaccharide with sulphuric acid–cysteine (Dische test)[10], an absorption peak at 505 mμ was found, which is characteristic of heptose sugars under the conditions used. Examination of acid hydrolysates on paper chromatograms showed the presence of an aldoheptose by the characteristic purple-coloured spot revealed by spraying with anisidine hydrochloride. Using the data on aldoheptose identification already recorded[3] the new sugar could be clearly distinguished from ten of the sixteen D-aldoheptose configurations, these were D-glycero-D-galacto-, D-glycero-L-galacto-, D-glycero-D-gluco, D-glycero-L-gluco, D-glycero-D-allo, D-glycero-D-gulo, D-glycero-D-altro, D-glycero-D-talo-, D-glycero-L-talo- and D-glycero-D-ido-heptoses (or their optical enantiomorphs). Using three different solvent systems (*a*, butanol–pyridine–water, 6 : 4 : 3; *b*, *n*-propanol–benzyl alcohol–formic acid; *c*, 95 per cent (v/v) acetone–water)[3] the new sugar could not be distinguished from D-glycero-D-mannoheptose but the D-glycero-L-manno-configuration could not safely be ruled out. In phenol–ammonia (*d*) the latter travels faster than glucose (R_{glucose} = 1·03) whereas the former travels more slowly than glucose (R_{glucose} = 0·95), and using this solvent system it was clear that the new sugar was not D-glycero-L-mannoheptose (or its optical enantiomorph L-glycero-D-mannoheptose, already isolated) but still matched D-glycero-D-mannoheptose (or its optical enantiomorph L-glycero-L-mannoheptose).

Four aldoheptose sugars have not yet been synthesized and are not, therefore, available for direct comparison; these would be the -L-ido, -L-allo, -L-gulo and -L-altro configurations in the D-glycero-series. From data given by Davies[3] the D-glycero-L-ido sugar could be safely excluded, from its expected similarity in behaviour to that of D-glycero-D-idoheptose in all the solvent systems. By similar reasoning the other three configurations could be regarded as unlikely to match the *Chr. violaceum* (N.C.T.C. 7917) heptose by the expected behaviour of D-glycero-L-alloheptose in solvents *a* and *d*, of D-glycero-L-guloheptose in solvent *d*, and of D-glycero-L-altroheptose in solvents *a* and *c*.

The amount of the aldoheptose sugar present in the polysaccharide cannot be estimated by the Dische method[10] until its identity is firmly established because different aldoheptoses give different amounts of absorption in this test; also D-glycero-D-mannoheptose has not yet been obtained in crystalline form for comparison on a weight basis and is only available in solution. As judged by the appearance of hydrolysates on chromatograms, however, the sugar appeared to be present in an amount of the same order as of the other sugar constituents (glucose, galactose, fucosamine), and estimated as D-glycero-L-mannoheptose gave a figure of about 25 per cent.

The new sugar would thus seem most likely to be D-glycero-D-mannoheptose (or its optical enantiomorph L-glycero-L-mannoheptose from which it would not be distinguishable chromatographically); but it is hoped to establish its true identity by isolation.

I am greatly indebted to Dr. N. K. Richtmyer, National Institutes of Health, Bethesda, Md., and Dr. H. S. Isbell, National Bureau of Standards, ashington, D.C., for samples of many of the aldo-ptose sugars used as reference standards.

Effect of Prolonged Administration of Reserpine on the Endocrine Glands of the Rat

IT has been shown that reserpine influences the anterior[1] and the posterior[2] lobes of the hypophysis, the thyroid gland[3], the adrenal medulla[4] and cortex[5], and the endocrine cells of the gonads[1]. In most of the work on this subject, the short-term effects have been investigated. Therefore, we undertook a study in which the effect of prolonged administration was examined.

Young male rats were injected subcutaneously with 0·04 mgm. of reserpine daily for 2 months. The controls were given the same volume of physiological saline. The animals were killed 9 days after the last injection. Table 1 shows the effect of reserpine on the body-weight and on the size of various organs. Reserpine caused a pronounced retardation of growth, which was statistically highly significant ($P < 0{\cdot}0001$). The mean kidney-weight of the reserpine rats was significantly lower ($P < 0{\cdot}02$) than that of the controls. No other significant differences were observed. The lower kidney-weight in the reserpine group is probably essentially due to the retarded growth.

Hypophyses were examined histologically for the cell types in the anterior lobe, using a periodic acid–Schiff trichrome stain, and the posterior lobe for the amount of neurosecretory substance, using Gomori's chrom-hæmatoxylin stain. The thyroids were studied qualitatively for the relative amount of epithelium and colloid, and for the height of the epithelial cells. Distribution of lipids in the adrenal cortex was examined in sudan-stained sections. Adreno-medullary catechol amines were studied with the aid of the chromaffin reaction and formol-induced fluorescence, as well as by quantitative determinations of adrenaline and noradrenaline content. In none of these respects were significant differences found between the reserpine group and the control group.

Table 1

Variable	Reserpine rats (9)		Saline controls (9)	
	Mean	S.D.	Mean	S.D.
Initial body-weight (gm.)	111·1	16·2	95·6	16·7
Final body-weight (gm.)	122·2	24·2	156·1	27·8
Gain in weight (gm.)	11·1	18·6	60·6	15·1
Adrenal weight (mgm.)	12·3	1·0	11·4	1·8
Medullary volume (arbitrary units)	10·1	1·5	9·5	1·4
Thyroid weight (mgm.)	17·6	3·6	16·2	2·2
Testis weight (gm.)	2·19	0·52	2·45	0·16
Kidney weight (gm.)	1·18	0·23	1·45	0·22

The histological structure of the testis was studied in hæmatoxylin–eosin-stained sections. Normal spermatogenesis was found in all animals, but there seemed to be a tendency towards smaller amounts of interstitial cells in the testis of the reserpine-treated rats. To study this subject more carefully, the testis slides of the control group and those of the reserpine group were mixed. They were then examined in random order for the amount of interstitial cells, using two categories, 'much' or 'little', for the evaluation. The result is illustrated in Table 2, which shows that, even after the precautions taken to avoid subjective bias, all rats of the reserpine group fell into the 'little' group for interstitial cells, whereas six of the nine rats of the controls came into the 'much' group. The probability of such an event occurring by mere chance was calculated using the exact treatment, as described by Fisher[6]. It was thus revealed that the observed difference is statistically significant ($P < 0{\cdot}005$).

Table 2

	Much	Little	Total
Reserpine	0	9	9
Controls	6	3	9
Total	6	12	18

The observations indicate that doses of reserpine sufficient to cause a pronounced arrest of growth have little effect on most endocrine organs 9 days after the discontinued treatment. Failure to confirm earlier reported changes caused by reserpine (see refs. 1–5) is probably explained by the relatively long recovery time, which allowed for the restitution of the normal state. It is the more noteworthy that regressive changes in the interstitial cells of the testis, earlier reported by Tuchmann–Duplessis[1] in reserpine-treated rats, were still persistent.

This study was supported by grants from the State Commission of Natural Sciences and the Sigrid Jusélius Foundation.

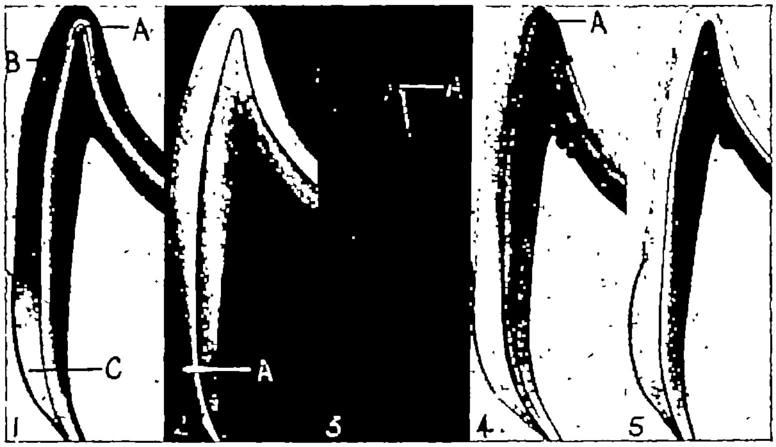
Assessment of Mineral Content in Water-mounted Sections of Dental Enamel

RECENTLY, a new technique for identifying areas of reduced mineral content in ground sections of dental enamel by their light-scattering properties when examined in distilled water, was published[1]. It was shown that when viewed by transmitted



Figs. 1–5. 1, Ground section of a deciduous right maxillary central incisor from two-weeks old infant. Ordinary transmitted light. In distilled water (× 10); *A*, small zone of translucent well-mineralized enamel along the incisal amelo-dentinal junction; *B*, dark opaque zone which has expanded to involve all but the cervical enamel; *C*, cervical zone of poorly mineralized immature enamel which still appears translucent. 2, Microradiograph of same section as Fig. 1. Exposure time 5 min. (× 10); *A*, area of lowest mineral content in the cervical enamel. 3, Microradiograph of same section as Fig. 1. Exposure time 15 min. (× 10); *A*, area of highest mineral content in the incisal amelo-dentinal junction region. 4, Same section as Fig 1, but partially demineralized. Ordinary transmitted light (× 10); *A*, previously translucent zone along the incisal amelo-dentinal junction now appears opaque. 5, Same section as Fig. 1, but completely demineralized. All parts of the enamel are translucent. Ordinary transmitted light (× 10)

light, areas of reduced mineral content in sections of erupted teeth or teeth in the late stages of development appeared dark and opaque, while normally mineralized mature enamel was transparent or translucent.

During a recent investigation, it was decided to extend the scope of this technique by applying it to ground sections of deciduous teeth in the early stages of development.

100μ-thick longitudinal labio-lingual or bucco-lingual ground sections were prepared from deciduous teeth ranging in age from 26 weeks *in utero* to 18 months postnatal. These sections were placed in distilled water and examined in transmitted ordinary light. Microradiographs of the same sections were then taken and compared with the results obtained in the ordinary light examination. By varying the X-ray exposure time, while keeping all the other factors constant (30 kV., 20 m.amp., copper target, nickel filter), a series of microradiographs was obtained for each section. This procedure made it possible to assess more completely the variations in X-ray absorption within the enamel of any given section as the illustrations show (Figs. 2 and 3). The sections were then demineralized in a routine histological decalcifying fluid composed of formic and citric acid and re-examined in distilled water by transmitted ordinary light.

Using these methods of examination, the following results were obtained. In the early stages of development the undecalcified enamel when examined in water by transmitted light appeared translucent with a faint yellow coloration (Fig. 1,*C*). A dark opaque area then developed in the incisal enamel and with advancing age extended cervically to include all the enamel (Fig. 1,*B*). Finally, a translucent zone appeared in the incisal amelo-dentinal junction area (Fig. 1,*A*) and extended slowly in a peripheral and cervical direction, until the somewhat variable translucent appearance of the mature enamel was attained everywhere.

The microradiographs of the same sections, prior to decalcification, showed that the extent of the zone of high X-ray absorption, and hence the proportion of mineral matter present, steadily increased with age until the mature enamel absorption was reached. This increase in absorption, which was first noted in the incisal amelo-dentinal junction area (Fig. 3,*A*), expanded in a fairly regular peripheral and cervical direction.

During the demineralization of the sections, enamel in the early translucent stage of development remained virtually unaltered. Enamel in the opaque stage of development, however, became translucent and colourless (Fig. 5); and enamel in the later translucent stage of development became opaque (Fig. 4,*A*) and finally translucent and colourless again (Fig. 5).

Correlating these results, it now appears that the relationship between mineral content and the appearance of water-mounted sections of enamel in transmitted light is as follows: (1) areas devoid of mineral matter appear translucent and colourless; (2) areas with a low mineral content appear translucent with a faint yellow coloration; (3) areas with an intermediate mineral content appear dark and opaque; (4) areas with a high mineral content, but not necessarily fully mineralized mature enamel, appear translucent and colourless.

Translucency in water is therefore not a reliable indication of high mineral content when ground sections of enamel in the early stages of development or advanced stages of demineralization are being examined.

A full account of this investigation will be published later.

I wish to thank Dr. J. J. Hodson for advice and encouragement during this investigation, Dr. J. L. Emery for necropsy material, Prof. A. G. Quarrell for permission to use the X-ray equipment and Mr. M. Rudland for technical assistance.

Incidence of Abnormal Hæmoglobins in Jamaica

Widespread studies have been carried out in Africa concerning the incidence of the abnormal hæmoglobins *S* and *C*, showing a very different geographical distribution for these two[1].

From the sixteenth until the early nineteenth century the slave trade brought large numbers of Africans to the North American continent and to the Caribbean territories, where these Africans are still found in a relatively pure state. In the United States there have been several reports on the incidence of hæmoglobins *S* and *C* [2]; in the Caribbean only one

Table 1

	No.	*S* gene	*C* gene	Average hæmoglobin (gm. per cent)	Range
Genotype *AA*	878	0	0	11·2	6·6–15·0
Genotype *AS*	106	106	0	11·2	7·8–13·2
Genotype *AC*	30	0	30	11·3	8·6–14·7
Genotype *SC*	2	2	2	11·6 10·3	
Genotype *SS*	1	2	0	8·0	
Genotype *S*-Thal	1	1	0	12·5	

Total *S* genes 111 (10·9 per cent)
Total *C* genes 32 (3·1 per cent)

report on the incidence of sickling has appeared hitherto[3]. Further studies in this region were considered to be important. This is the second report on work done in Jamaica. This work will be extended to other islands in the Caribbean.

The people investigated were 1,018 pregnant women who attended the ante-natal clinic of the University College Hospital. This group was selected because blood samples were taken routinely and it represented a random sample of the population around Kingston, comprising about one-fifth of the total Jamaican population. All the blood samples were subjected to paper electrophoresis of hæmoglobin[4]. A sickling test was done on all specimens which gave an *AS* pattern. This sickling test was positive in all cases, thereby excluding hæmoglobin *D* in our group.

The results are given in Table 1. A possible fallacy arising out of studies on the distribution of genetic factors should be stressed. When the incidence of a given gene is low, for example, the *C* gene in my series, then quite erroneous results can be obtained when only small numbers are studied. For example, in the first 400 women investigated, I found 19 with a *C* gene (4·7 per cent); in the last 400 I found only 7 (1·7 per cent).

A correct evaluation of racial mixtures occurring in the group was impossible; but it seems likely that it consists of about 90 per cent pure Negro and 10 per cent Negro mixed with White, Chinese and Indian. These percentages are based on the 1946 census figures in Jamaica. The gene frequencies given in Table 1 would therefore have been slightly higher had it been possible to select Negroes only.

Accepting that the gene frequencies in Table 1 are correct for the population as a whole, then one would expect that, of every 1,000 children born, 3 would have true sickle-cell anæmia (genotype *SS*) and 1·6 would have sickle-cell hæmoglobin *C* disease (genotype *SC*). The incidence as it was found for the genotype *SC*(2) fits very well with the expected figure.

This suggests that the mortality in this genotype is not materially different from the mortality in the population as a whole.

From our knowledge of the survival-rate in true sickle-cell anæmia[5] it is clear that one would expect to find in adults a much lower incidence than the calculated one in this condition. In addition, it is probable that if a woman with sickle-cell anæmia reaches the age of reproduction she will be less fertile or that very early abortion will occur. The one case of true sickle-cell anæmia found in my series is remarkable in that she has had three healthy children in four pregnancies and is pregnant again. We could prove beyond any doubt that she has the genotype *SS* from studies on her three children, seven siblings and both parents[6].

The other case of electrophoretically apparent sickle-cell anæmia was found in fact to be heterozygous for the *S* gene (from the father) and to have inherited from the mother a thalassæmia-like gene which gave rise to fœtal hæmoglobin-levels of 24, 26 and 16 per cent respectively in her mother, her brother and one of her children[7]. The only other hæmoglobin present in these three was hæmoglobin *A*.

Another fact emerging from this study is that the average hæmoglobin-levels for the first three groups in Table 1 are identical. This is additional proof that the possession of the *S* trait or the *C* trait is no disadvantage to a person so far as hæmoglobin synthesis is concerned, even under the additional stress of pregnancy.

I am very much indebted to Miss D. Watson for technical assistance.

Specific DDT-Resistance in Houseflies

Two strains of houseflies (*Musca domestica* L.) have been derived by selection for a number of generations from a DDT-susceptible colony which originated from wild flies collected in 1939. The colony had been mass-reared in the laboratory for fourteen years without exposure to insecticides. Selection was by two different methods. One strain (*D*) was derived by incorporating DDT wettable powder in the larval medium at 80 p.p.m. DDT for the first three generations, 160 p.p.m. for generations 4–9, and 320 p.p.m. for all subsequent generations. The other strain (*L*) was started ten generations later than *D*; it was selected on the basis of slow pre-adult development, that is, by breeding only from flies emerging from the cultures towards the end of the emergence period, and its breeding stock was not exposed to insecticides. Pimentel *et al.*[1] had found that late-emerging flies were more tolerant of DDT than early emerging ones, and that, in four DDT-resistant strains, resistance was associated with prolonged larval period.

As selection proceeded, the susceptibility of the strains to DDT was determined periodically by dosage-mortality tests in which batches of 40 flies of each sex, 5–6 days old, were dosed with six DDT-kerosene solutions applied by microburette[2] to their mesonota. 'Dioxan' was used as auxiliary solvent when necessary. The volumes applied were of the order of 0·08 and 0·13 μl. for males and females respectively, with slight variations to compensate for differences in batch weights. Treated flies were supplied with 10 per cent sucrose solution and held at 25° C. for mortality counts at 24 hr. after treatment. For comparison the unselected parent strain (*U*) was similarly tested.

Both selected strains developed significant resistance to DDT. After an initial rapid rise during the first four generations, resistance showed no further change of a major nature for thirty subsequent

Table 1

	Strain *U* Male	Strain *U* Female	Strain *D* Male	Strain *D* Female	Strain *L* Male	Strain *L* Female

*LD*50 DDT			77†	155†		

* All *LD*50's as μgm./gm. of flies.
† Test flies reared in medium containing DDT
‡ Per cent w/v causing 50 per cent mortality in 17 hr

generations, during which it fluctuated within the ranges $R_D = (15 \pm 5)R_U$ and $R_L = (11 \pm 3)R_U$, where R_U, R_D and R_L are the *LD*50's for the respective strains.

In thirty successive generations, strains *D* and *U* were compared with respect to the time from oviposition to maximum daily emergence of adults. No significant difference between the strains was found. A similar comparison of strains *L* and *U*, over sixteen generations, indicated that a selection had retarded pre-adult development by a significant mean amount of 1·6 days.

Resistance in strain *D* was expected to be specific for the DDT type of insecticide, since DDT had been the sole selective agent. No evidence of increased tolerance to the BHC group of chlorinated hydrocarbons[3] was found in tests with γ-BHC applied by the same topical dosing method, or to sodium arsenite fed in sucrose solution. Strain *L*, which had not been selected with DDT, was tested more extensively, and was found to be non-resistant to γ-BHC, allethrin, diazinon and sodium arsenite. (McKenzie and Hoskins[4] have also found a similar specific DDT-resistance in their substrains selected for late pupation.) The toxicity of DDT to the resistant strains was increased considerably by the synergistic action of DMC, this compound being much less toxic than DDT when applied alone[5]. The results (first part of Table 1) indicated that a similar type of specific DDT-resistance had developed in both selected strains.

Since DMC had been shown to inhibit the dehydrochlorination of DDT by resistant flies[6], the three strains were examined for the presence of DDT-dehydrochlorinase[7]. Acetone–ether powders were made from 10-gm. samples of 5–6 day old flies of each sex. The test flies of strain *L* were taken from the eighteenth generation, those of strain *D* from a special twenty-eighth generation culture containing no DDT. Samples of buffered aqueous extracts of the powders, each equivalent to 40 flies, were incubated under nitrogen with 400 μgm. of DDT (deposited on glass chips) in the presence of glutathione for 6 hr. at 37° C. Cyclohexane extractions were then carried out and the amounts of unchanged and dehydrochlorinated DDT determined spectrophotometrically. Concurrently, the susceptibility of each strain to DDT was determined. In strain *D*, flies grown in medium with and without DDT were both tested. The *LD*50's thus obtained are grouped with the enzyme test results in Table 1 (second part).

In strain *D* the test flies reared in DDT-medium showed normal resistance for this strain, but exclusion of DDT from the rearing medium resulted in a fall in resistance to the same level as that of strain *L*. Extracts of flies of both resistant strains showed significant enzyme activities of a similar order. Comparing the sexes, in both strains males were less resistant, but showed higher enzyme activities than females—a non-conformity which remains unexplained. As expected, enzyme activity in the DDT-susceptible strain *U* was insignificant. Since the selected strains developed similar enzyme activity and DDT-resistance, although selected by different methods, it seems likely that enzymatic dehydrochlorination of DDT was the major factor in resistance.

The occurrence of DDT-dehydrochlorinase and specific resistance to DDT in strain *L* has some interesting implications. It establishes that production of the enzyme is not necessarily dependent on a stimulus from DDT in the environment, and it precludes any possibility that this type of resistance is due to a mutagenic action of DDT. The function of the enzyme in flies of strain *L* which had never been exposed to DDT is not known.

Concerning the origin of resistance in the two strains, the fact that on two occasions, ten generations apart, resistance began to develop immediately selection was started suggests that the parent colony contained a self-propagating small proportion of abnormally DDT-resistant individuals already possessing the enzyme, and that this proportion was increased by selection, either with DDT or for slow pre-adult development, until it constituted a majority in the resistant strains. If a functional relationship exists between DDT-resistance, due to the possession of the enzyme, and rate of pre-adult development, it is at present obscure, since the flies of one resistant strain (*D*) showed no sign of retarded development, while those of the other (*L*) were significantly slower in development.

Infectivity of Influenza Virus Filaments

ALTHOUGH the presence of filamentary forms in preparations of influenza virus was first noted in 1946 [1], the finding remained one of academic interest until the demonstration by Chu, Dawson and Elford in 1949 [2] that recently isolated influenza *A* strains contain a high proportion of filaments. These forms have since been shown to possess many of the biological characteristics of spherical influenza virus particles[3,4]; but the question of the number of filaments needed to induce infection was not considered until recently. The main contribution in this direction has been the pioneer work of Donald and Isaacs[5], who used quantitative counting techniques. They, however, did not claim any differences in the relative infectivity of virus filaments and spheres. Valentine and Isaacs[6] have since suggested that, owing to the tendency of filaments to break up during adsorption on red cells, the actual counts of Donald and Isaacs[5] are over-estimates of the number of filaments initially present, and hence there is an increased probability that filaments are infectious. In connexion with nucleic acid studies on filaments, we have used a strain of filamentary virus (Ryan) that has a mean ratio of 50 per cent egg infectivity dose/agglutinating dose of the same order as that given by strains which exist almost exclusively as spheres. Using the counts of Donald and Isaacs[5] together with our 50 per cent egg infectivity dose/agglutinating dose value, it can be calculated that, for this strain of virus, fewer filaments than spheres are necessary to induce infection in the embryonated egg.

The *A* strain Ryan was isolated from the 1954 influenza epidemic in Melbourne. It has been passaged sixteen times at limit dilution in eggs. Following inoculation of 0·05 ml. at a 10^{-3} dilution into 10-day embryonated eggs, the allantoic fluid was harvested after 72 hr. incubation at 35° C.; the classical *A* strain *PR*8 was grown and all hæmagglutinin and infectivity determinations carried out as described previously[7]. These techniques are similar to those used by Donald and Isaacs[5]. In nineteen experiments, the mean ratio ($\log_{10}$) 50 per cent egg infectivity dose/agglutinating dose value for Ryan was 6·0 ± 0·5; in twelve experiments, for *PR*8, 6·0 ± 0·3. The average proportion of filaments in Ryan allantoic fluid is 30 per cent; their morphology is similar to that of filaments in *A*/Persian Gulf/2/52 [6] and upon fragmentation there is an increase in hæmagglutinin. Donald and Isaacs[5] have shown that the ratio ($\log_{10}$) of particles to agglutinating dose for non-filamentary strains is 7·2 ± 0·13 (that is, 16×10^6 particles = 1 agglutinating dose) while for a strain in which the proportion of spheres to filaments is approximately 50 : 50, the ratio ($\log_{10}$) is 6·6 ± 0·08 (that is, 4×10^6 particles = 1 agglutinating dose). In the latter case, the contribution due to the spheres is 2×10^6 particles, which is ⅛ of the agglutinating dose given above for *PR*8. Hence that due to the 2×10^6 filaments is ⅞ agglutinating dose. Thus in a preparation containing filaments only, $2 \cdot 3 \times 10^6$ units = 1 agglutinating dose. From this, it can be calculated that in a preparation containing 30 per cent filaments, $6 \cdot 1 \times 10^6$ particles = 1 agglutinating dose, that is, $10^{6 \cdot 78}$.

The ratio ($\log_{10}$) particles/agglutinating dose for *PR*8 = 7·2; for Ryan = 6·78. The ratio ($\log_{10}$) 50 per cent egg infectivity dose/agglutinating dose for *PR*8 = 6·0; for Ryan = 6·0 Therefore, the ratio ($\log_{10}$) particles/50 per cent egg infectivity dose for *PR*8 = 1·2; for Ryan = 0·78. The number of particles/50 per cent egg infectivity dose for *PR*8 = 16; for Ryan = 6·1.

Of this figure 6·1 for Ryan, 70 per cent or approximately four particles are spheres and contribute a quarter of the 50 per cent egg infectivity dose. Therefore, two or three filaments are equivalent to one 50 per cent infectivity dose. In view of the finding[3,4,6] that filaments break down during manipulation, it appears possible that one filamentary particle as present in unharvested allantoic fluid may induce infection.

This calculation assumes that the spheres present in Ryan preparations have the same relative infectivity as *PR*8 spheres. Two observations support this. (1) The value of the ratio 50 per cent egg infectivity dose/agglutinating dose for spheres isolated by filtration from *A*/Persian Gulf/2/52 was not appreciably different from that of the allantoic fluid preparation[6]. (2) In three preparations the value of the ratio ($\log_{10}$) 50 per cent egg infectivity dose/agglutinating dose of a strain of Ryan, derived from the parent strain by passage at low dilution and containing very few filaments[4], ranged from 6·2 to 5·9.

The finding that considerably fewer filaments than spheres are needed to induce infection has a number of important implications. These will be discussed in conjunction with the results of the nucleic acid studies in a paper to be published elsewhere.

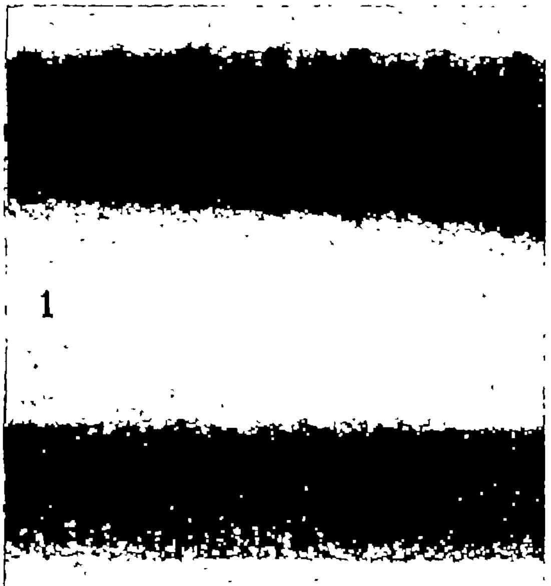
Structure of Molluscan Tropomyosin

CERTAIN molluscan smooth muscles contain protein filaments with a regular and characteristic fine structure[1–3] to which the name paramyosin has been given[4]. Neither the chemical nature nor the function of these filaments is understood, and attention is once more drawn to these problems by the recent discovery in the same muscles of an asymmetric globulin[5,6] precipitating in the form of needle-shaped 'crystals'. This was found[6–8] to have the amino-acid pattern of a tropomyosin, and the large amounts present in slow lamellibranch adductor muscles suggested that it might be responsible for the paramyosin structure, an inference supported by some preliminary studies of the X-ray diffraction pattern[6,7]. These 'crystals' have now been studied by electron microscopy.

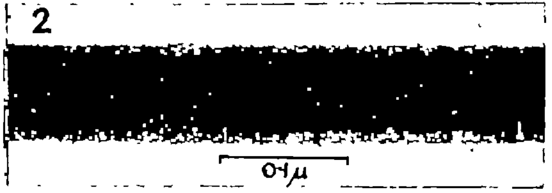
The protein was usually made from the white part of the adductor muscle of the oyster (*Gryphaea angulata*), but similar results were obtained with the equivalent muscle of *Pinna nobilis*. Fresh muscles were homogenized in 0·04 *M* potassium chloride buffered at

pH 7·0 with 0·0067 M Sörensen phosphate buffer. Microscopic examination showed that the muscle fibres had been broken up and many paramyosin filaments released; these are visible in a phase-contrast microscope with an objective of $N.A.$ 1·3. The homogenate was washed twice in a large volume of the same weak potassium chloride solution to remove water-soluble proteins; centrifugation at about 2,000g brought down all the filaments. The washed homogenate was then suspended in 1·0 M potassium chloride buffered at pH 7·0 with 0·0067 M phosphate buffer, and again centrifuged at 2,000g. The supernatant protein solution, which contained no visible filaments, was dialysed[6] against a series of potassium chloride solutions (0·75, 0·5, 0·3 and 0·15 M), all of them buffered at pH 7·0 with 0·0067 M phosphate buffer. The small amorphous precipitate which formed at 0·3μ was removed. Needle-shaped 'crystals' were precipitated at 0·15μ and were placed on grids bearing carbon films. They were fixed and stained for two minutes with an unbuffered 0·1 per cent aqueous solution of phosphotungstic acid and then washed with water. The preparations were studied in a Siemens 'Elmiskop I'.

The long needles are transversely striped and several different band patterns are found. The simplest pattern (Fig. 1) repeats every 145 A. and the bands are demarcated by fine dense lines. All the other patterns repeat every 725 A., and are elaborations of the simple pattern in which certain bands or pairs of bands are denser than the others; in each of these modified bands the dense material lies mainly next to the two lines that demarcate it (Fig. 1).



1



2

Fig. 1. Two 'crystals' (lying side by side) of water-insoluble tropomyosin from the white adductor muscle of the oyster

Fig. 2. A paramyosin filament isolated from the white adductor of the oyster

Tropomyosin needles with the simple pattern show a banding which very closely resembles that of paramyosin filaments isolated from the same muscles and fixed and stained in the same way (Fig. 2). We find that the pattern of dots described in the original account[2] of paramyosin structure appears only when the filaments are beginning to dissolve.

The tropomyosin needles with the 725 A. period somewhat resemble 'paramyosin-long-spacing', the name given by Hodge[9] to 'crystals' precipitated from solutions of structural proteins extracted from the adductor muscles of *Venus mercenaria*. However, Hodge used a different method to extract the protein and to precipitate it.

At the molecular level, the tropomyosin of *Pinna nobilis* has been studied by light-scattering, sedimentation, diffusion and viscosity methods. Theoretical considerations have led one of us (C. M. K.)[10] to propose that the protein is rod-like, of length 1400 A. and only 19 A. in width. The length is thus twice that of the paramyosin period and equal to that of the 1400 A. band structure of Hodge's[9] acid-reconstituted 'paramyosin-long-spacing' fibrils. For a molecular weight of 134,000, the protein is one of the most asymmetrical yet discovered, and probably exists for the greater part of its length in the α-helical configuration of Pauling and Corey.

The simplest hypothesis to account for all the present findings is that paramyosin and water-insoluble tropomyosin are identical. The fact that the band patterns of the re-precipitated material are variable is not inconsistent with this suggestion. A similar phenomenon is well known in the case of collagen where, according to Schmitt[11], it is due to different modes of aggregation of the same macromolecules.

Lethality for Guinea Pigs of Ultrasonic Extracts of *Pasteurella pestis*: Its Relationship to Death of Guinea Pigs from Plague

A PUZZLING feature of studies on the basis of pathogenicity of *Pasteurella pestis* is the relationship of the behaviour of the so-called toxin[1-4] in guinea pigs to infection in the same host. This toxin is lethal for mice but not for guinea pigs[4,5], although the two hosts are equally susceptible to plague[1,6]. This anomaly led us to consider whether, in plague, guinea pigs are killed by a toxin different from that killing mice, or whether the 'toxin' as previously isolated is a degraded form of a native toxin that kills both species. The results described below support the latter view and give a reasonable explanation for the death of guinea pigs from plague.

Our work had two main innovations: (1) *P. pestis* and its extracellular products were obtained from infected guinea pigs and examined for any lethal component possibly absent from artificial cultures as was the anthrax toxin[7]. (2) The extraction of the organisms was milder and more complete than the saline extraction of acetone-dried organisms[3,8] or the autolysis of cells by prolonged incubation[1,2,4,5] hitherto employed.

Organisms were separated from the body fluids of guinea pigs which died from infection with *P. pestis* (strain *L*.37) by the methods described[9] for the collection of *Bacillus anthracis* grown *in vivo*.

The sterile filtered plasma from dying guinea pigs which originally contained $1-3 \times 10^9$ organisms per ml. had a small but variable toxicity for mice ($LD50 >$ 1 ml.; 0·1 ml. given intravenously) and no detectable toxicity for guinea pigs (10 ml. given intravenously). For the following reasons, it was concluded that no purely extracellular toxin was produced *in vivo* by *P. pestis*, and that the slight toxicity of the plasma resulted from the liberation of intracellular material. First, the toxicity was absent or minimal if the plasma collected from a dying animal was rapidly cooled and filtered. Secondly, there was an increase in toxicity if the unfiltered plasma was stored at 0°.

Attention was turned to the organism as a source of toxin. Treatment with ultra-sonic waves proved the most satisfactory method of breakdown. Organisms grown *in vivo* were suspended in water (10^{10} per ml.) and subjected to ultra-sonic waves (Mullard Ultrasonic Generator, 2 megacycles per sec., 500 watts) at + 3° for 1 hr.; the organisms were mainly disintegrated and after centrifugation the extract was filtered through 'Millipore'.

Several batches of the filtrate (1 ml. = 1×10^{10} organisms) had a mouse (20 gm.) *LD*50 of 1/800 ml. (given intravenously) and when 2,000, 4,000 and 8,000 mouse *LD*50 were injected intravenously into guinea pigs (250 gm.) death-rates of 3/11, 8/10 and 5/5 respectively were obtained. Hence, the *LD*50 for a guinea pig is about 3,000 times larger than that for the mouse. On a body-weight basis, the resistance of a guinea pig to this toxic extract is about 250 times that of a mouse. This ratio is far smaller than the 5,000 indicated from the figures quoted by Schar and Meyer[4] for their plague 'toxin' and that indicated by the statement of Schar and Thal[5] that even in amounts of 300,000 mouse *LD*50 the plague 'toxin' never exerts a lethal effect on guinea pigs.

It seems, therefore, that the same toxin can be responsible for the death of guinea pigs and mice. The species difference in susceptibility of 250-fold is of the same order as that obtained with some other toxins[10]. In both mice and guinea pigs the toxin acted quickly; deaths occurred mainly within 12 hr. with clinical signs of shock and the presence of exudate in the body cavities. Furthermore, the *LD*50 of our toxic extract for guinea pigs was obtained from approximately 4×10^{10} organisms, which number is less than the total *P. pestis* organisms (at least $5-16 \times 10^{10}$) present in a guinea pig (250 gm.) killed by plague.

The properties of the toxic extract described above raise doubts as to whether the toxin as previously isolated is the true toxin of *P. pestis*. This is underlined by the finding that similar extracts have now been obtained from organisms grown *in vitro*. Thus, ultra-sonic extracts of organisms obtained from shaken cultures (28°) of *P. pestis* (strain *L*.37) in a medium similar to that of Higuchi and Carlin[11] (30 hr.), and another medium used by Davies[12] (40 hr.) killed, respectively, 2/4, 3/3, 1/1 and 2/8, 3/12, 7/8 guinea pigs (250 gm.) when 2,000, 4,000 and 8,000 mouse *LD*50 were injected intravenously. It appears, therefore, that *P. pestis* contains a toxic complex which hitherto has only been isolated in part due to deficiencies in previous methods of extraction.

The continued use of ultrasonic waves to form more complete extracts of *P. pestis* than hitherto examined may well shed light on other chemical aspects of the pathogenicity and immunity to plague. Already the technique has been the means of separating *P. pestis* grown *in vivo* into two constituents, namely, the highly toxic soluble material which appears to contain very little protective antigen and a residue which readily immunizes guinea pigs.

Enhancement of Mouse-virulence of Group *A* Streptococci

THE virulence of organisms can be enhanced by a variety of substances, mainly of carbohydrate nature (see review by Olitzki[1]). Current interest centres on mucin, which was found by Smith and his co-workers[2-4] to owe its activity to the synergic action of three factors—viscosity, a particulate residue and a heparin. The present communication shows that bacteriological peptone and some of its hydrolysis products also have considerable virulence-enhancing activity.

It was first observed that the minimal lethal dose (*LD*100) of group *A* streptococci injected intraperitoneally into mice was considerably reduced when organisms were suspended in broth instead of saline: the reduction was of the order of a thousand times. The effect was observed only when organisms and broth were both injected intraperitoneally.

All experiments were carried out on *W*-Swiss mice weighing 25–35 gm. 18-hr. old broth cultures of mouse-pathogenic group *A* streptococci were used; all injections were made intraperitoneally and the volume kept constant at 0·5 ml. The *LD*100 of the cultures in saline was 0·5 ml. of a 10^{-2} suspension, the *LD*50, 0·5 ml. of a 10^{-3} suspension; 0·5 ml. of a 10^{-4} suspension was invariably non-lethal. Animals died within four days and group *A* streptococci were recovered from the heart blood. In control mice broth and peptone caused shock; neither they nor any of the subsequent virulence-enhancing preparations by themselves killed mice.

Viable counts[5] of broth and saline suspensions yielded the same number of colonies suggesting that the reduction of the minimal lethal dose was not due to the streptococci dying in saline. Evidence that a true virulence-enhancing mechanism was involved was given by the fact that broth, injected intraperitoneally as much as 1 hr. after a non-lethal saline suspension of organisms (0·5 ml. of a 10^{-4} suspension), converted the non-lethal dose into an *LD*100.

The constituents of the medium were next examined. The medium consists of 2 per cent 'Oxoid' peptone, 0·8 per cent 'Oxoid Lab. Lemco' broth powder, 0·2 per cent glucose, and 0·2 per cent sodium bicarbonate in distilled water; the glucose and bicarbonate were added to the autoclaved basal medium. The peptone was found active, 0·25 mgm. giving the virulence-enhancing effect; other peptones—B.D.H., 'Difco Bacto' and 'Difco Proteose'—were equally active. 'Lab. Lemco' broth powder was also active, the activity corresponding roughly to the peptone content of the preparation as indicated by the makers. Glucose and sodium bicarbonate were inactive.

Peptone, as the most active constituent of broth, was further examined. It was hydrolysed for 24 hr. with constant-boiling hydrochloric acid. The total hydrolysate, after removal of acid and readjustment of *p*H to 7·4, was as effective in enhancing virulence as the original peptone. The hydrolysate, which contains an acid-insoluble fraction generally referred to as humus, was then centrifuged. The supernatant showed only slight activity. Of 22 individual amino-acids examined only 4 were active, L- and DL-aspartic acid at 0·5 mgm. per mouse, L-lysine, DL-threonine and L-tryptophan at 5 mgm. On the other hand, the sediment, when washed with saline and extracted into sodium bicarbonate, proved most active: weight for weight it was a hundred times more active than peptone. As little as 2·5 μgm. reduced the *LD*100 from 0·5 ml. of a 10^{-2} dilution to 0·5 ml. of a 10^{-5} dilution.

Duration of Spermatogenesis in the Mouse

A RISE in frequency of dominant lethals in matings at successive intervals during the first few weeks after irradiation of male mice has been observed by Brenneke[1] and Hertwig[2] for X-rays, and by Russell *et al.*[3] for neutrons. Thus Bateman's[4] results with exposure to 200 r. of X-rays confirm the earlier observations. Bateman's[4] interpretation of his data and the subsequent discussions by Auerbach[5] and Sirlin and Edwards[6] concern the determination of the stage in which gametes available at successive weeks were irradiated. As emphasized by Auerbach[5], and now accepted by Bateman[7], Bateman's results[4] do not contradict the essentially parallel response of mice and *Drosophila* that had been partially demonstrated in the earlier work. However, in spite of the attention this subject now has received, several points need clarification, especially in relation to the description and timing of normal spermatogenesis in mice.

First, a point that is mentioned frequently is the possibility of a bias in estimates of the duration of spermatogenesis obtained from irradiated material. A discussion of this point is presented in my paper on the duration of spermatogenesis[8], but does not appear in the advance abstract from which Sirlin and Edwards[6] obtained my estimate of 34·5 days for the duration of spermatogenesis. Sirlin and Edwards[6] state that it is possible that this figure is "increased by delay due to irradiation". Auerbach[5] also states that in Bateman's experiment with 200 r. ". . . spermatocytes are probably not killed—although their development may be somewhat delayed. . . ". Experiments both by other investigators and by us indicate that doses as high as 1,000 r. have no retarding effect on meiosis, or on spermiogenesis of cells irradiated as spermatids. Maturation of spermatids arising from cells irradiated as spermatocytes probably is retarded at high doses, but not by 100 r. Furthermore, we have found the timing, based on irradiations with 100 r., to be completely reliable in experiments where doses as low as 5 r. of gamma-rays from cobalt-60 have been used. We have concluded, therefore, that our estimate of 34·5 days for the duration of spermatogenesis is not seriously biased.

Most of the confusion in description of normal spermatogenesis and in interpretation of irradiation effects results from misclassification of preleptotene spermatocytes. On the basis of their morphology, these cells have been mistaken by various authors for type *B* spermatogonia and for type *A* spermatogonia. Yet in terms of both developmental potentiality and radiation response[9], they are clearly primary spermatocytes. A further confusion, arising from terminology, can be avoided if one retains the definition of primary spermatocytes long accepted by cytologists, and recently emphasized by Hoffman[10] and by Tobias[11] as ". . . those cells which arise after the last mitotic division of spermatogonia and become transformed after the first meiotic division into secondary spermatocytes". This restricts the term 'spermatogonia' to cells capable of mitosis.

It at first appears as if the estimate of the duration of spermatogenesis obtained[12] by labelling adenine with carbon-14 does not agree with our results based on irradiation with 100 r. The results are in agreement, however, if the proper correction is made for identification of cell stages initially labelled. Ortavant[13] concluded that the uptake of phosphate (labelled with phosphorus-32) occurs primarily in preleptotene spermatocytes, and that estimates of the duration of spermatogenesis obtained by this method must be corrected to include the time required for spermatogonial divisions. The photomicrographs (Fig. 4) of Pelo and Howard[12] strongly suggest that they have misclassified primary spermatocytes as "resting spermatogonia". In addition, cells identified by Sirlin and Edwards[6] simply as "early meiotic prophase", "early spermatids" and "free sperm in the tubules", are not adequately defined, for in the mouse meiotic prophase requires 12½ days, spermatid stages 9¼ days, and the last four stages of spermiogenesis (easily confused with mature sperm in routine staining) require 5½ days for completion. Exact definition of cell stages, most easily obtained by use of periodic acid – Schiff staining, must be used in the interpretation of autoradiographs before accurate estimates of the duration of spermatogenesis can be obtained by tracer techniques. Confusion over identification of cell stages labelled by adenine containing carbon-14, and inadequate definition of reference points selected in stages of several days duration, easily account for the fact that the second column in the table of Sirlin and Edwards[6] does not agree with our results. It is apparent that correct interpretation of the tracer technique would give better agreement.

The first column of the table presented by Sirlin and Edwards[6], which is based on an advance abstract of my results, also needs revision, because the relative frequency of tubule stages in the rat[14] cannot be applied to the mouse. Sirlin and Edwards incorrectly state that Roosen-Runge and Giesel[15] and Leblond and Clermont[14] "... determined the relative durations of the spermatogenic stages in the normal rat and mouse. . . ". The quantitative results given by these authors are based exclusively on the rat. The only published results available on relative frequency of stages in the cycle of the seminiferous epithelium of the mouse are given in my recent paper[8]. The fact that the relative frequency of tubule stages in the rat cannot be applied directly to the mouse should have been apparent from an earlier publication[16], where it was shown that only twelve stages can be identified in the mouse instead of fourteen as described for the rat.

In order to clear up the confusion over estimation of duration of stages in cell development, Table 1 was prepared from our results. The estimates were obtained by combining the qualitative description of cell types present in each of the twelve stages of the cycle of the seminiferous epithelium[9] with a frequency distribution based on a sample of 3,000 randomly selected tubule cross-sections of normal mice[8].

Table 1. TIMING OF CELL DEVELOPMENT IN SPERMATOGENESIS OF THE MOUSE (BASED ON REFS. 8 AND 9)

Stage	Duration (hr.)	Interval to release of mature sperm from tubule (days)	
		Minimum	Maximum
Spermatogonia :			
Type *A*	Always present	33·5	35·5
Intermediate	27·3	28·8	30·0
Type *B*	29·4	27·6	28·8
Primary spermatocytes :			
Resting (preleptotene)	31·0	26·3	27·6
Leptotene	31·2	25·0	26·3
Zygotene	37·5	23·4	25·0
Pachytene	175·3	16·1	23·4
Diplotene	21·4	15·2	16·1
Diakinesis + metaphase I	10·4	14·8	15·2
Secondary spermatocytes	10·4	14·4	14·8
Spermatids	220·2	0·0	14·4

WE wish to comment on Dr. Oakberg's criticism of our communication[1]. We stated there that the transcription of frequency of tubule stages from rat to mouse could provide only "approximate intervals". However, when our communication was written, Oakberg's paper on the timing of spermatogenic stages in the mouse[2] was not available to us, and we had to extrapolate from the rat[3] on the assumption that spermatogenesis in these species was similar: this we clearly stated[1]. We realized, therefore, that only "reasonable agreement" could be expected between the cytological and tracer results as we presented them, and that work similar to that of Ortavant in the ram[4] gives a clearer indication of the duration of spermatogenesis[5]. Furthermore, Oakberg has obviously overlooked the assumption, based on the work of Swift[6], that we made in our calculations on the tracer results[1], namely, that preleptotene spermatocytes were initially labelled by adenine.

Using the maximum timing of spermatogenic stages given by Oakberg (preceding communication) and a total spermatogenic cycle of 34·5 days[2], the values in the first column of our Table 1[1] should be increased by one day for spermatogonia *B* and resting spermatocytes, and decreased from 9 days to 8·2 days for leptotene (from the estimates of Leblond and Clermont[3] we previously used the equivalent of the maximum timing[1]). The latter correction will reduce the figures in the second column by 0·8 day. The first appearance of spermatids (early spermatids) which is the crucial one for determining the interval of transit through the vasa, and therefore for the sampling of the spermatogenic stages at insemination, remains 20 days as given. Our estimates[1] appear, therefore, to be "without serious error". If the stages responsible for oligospermia and aspermia are recalculated using the time ranges proposed by Oakberg the results remain identical with our original calculations[1]. Furthermore, our Table 2 (of the approximate stages of spermatogenesis sampled in ejaculated spermatozoa) remains as given but for the substitution of spermatogonia *A* for intermediate spermatogonia at centre of week 6. It must be stressed that these calculations are based on the average rate of spermatogenesis[4,7] (see below).

We would like to make two further remarks on Dr. Oakberg's present communication. First, the tracer results are not quite in agreement with the cytological results as he claims. The front of labelled deoxyribonucleic acid shows a precedence of about four days, already apparent at the earliest spermatid stages and preserved until ejaculation, over the cytological timing (unpublished work). The latter is an average timing whereas the tracer observations detect the faster rate of development of certain spermatogenic cells. This situation is evinced in the mixing of stages and in the character of the cytological scores commented on by Oakberg[2] (p. 514). Lastly, we can extend Oakberg's statement that there is no delay during meiosis due to irradiation. The interval from zygotene to ejaculation is not increased after 200 r. of X-rays (unpublished work). This also indicates that the vasa are not damaged by this dose, at least so far as progression of spermatozoa is concerned, and that there is no significant *vis a tergo* from the testis.

Primary Sex Ratio of Fowl

THE only information concerning the primary sex ratio of birds, based on acceptable criteria, is to be found in a publication by Hays which relates to Rhode Island Red fowl[1]. Hays's results give the sexes in the progenies of 39 hens which in the course of a ten-year period had shown 100 per cent fertility and 100 per cent hatchability of their eggs during the two-months hatching season of one of these years. The 39 hens in question had a total of 931 offspring: 61 chicks were lost before the sex could be ascertained; among the remaining 870 chicks, 432 were males and 438 were females. These results clearly pointed to equality of the sexes as determined at fertilization. Yet, Hays suggested (see below), that significant differences may have existed between individual hens in the sex ratios of their offspring.

It seemed desirable, therefore, to collect additional evidence bearing on both problems, namely, the primary sex ratio and its variance between groups of progenies. Such results are here presented for White Leghorn and for Black Minorca fowl. The conditions laid down for inclusion of results in our tabulations were as follows: each hen must have laid a minimum of three eggs a week for at least three consecutive weeks; all of the eggs must have been fertile and all embryos must have survived the eighteenth day of incubation. Sex of the hatched chicks and of the embryos that had died after the eighteenth day was ascertained by dissection. There were four pen matings of each of the two breeds.

Table 1. SEX RECORDS OF WHITE LEGHORN EMBRYOS AND CHICKS

Pen	No. of progenies	Embryos and chicks		
		Total	♂♂	♀♀
23	18	493	259	234
24	16	502	249	253
25	16	581	297	284
26	15	476	246	230
Total	65	2,052	1,051	1,001

Table 2. SEX RECORDS OF BLACK MINORCA EMBRYOS AND CHICKS

Pen	No. of progenies	Embryos and chicks		
		Total	♂♂	♀♀
19	17	486	239	247
20	10	235	106	129
21	15	421	214	207
22	16	362	173	189
Total	58	1,504	732	772

The sex ratio data, summarized by pens, are given in Tables 1 and 2. There were 65 progenies of White Leghorns with a total of 2,052 embryos and chicks. Among these were 1,051 males and 1,001 females or 51·2 ± 1·12 per cent males. For Black Minorca fowl we had 58 progenies containing a total of 1,504 embryos and chicks; among these were 732 males and 772 females or 48·7 ± 1·29 per cent males. It is clear that for both breeds, as was true for the results on Rhode Island Red fowl obtained by Hays, the primary sex ratio does not deviate significantly from equality.

In the presentation of his results, Hays gave the sex records of the progenies of those eleven hens in which no chicks had been lost (his Table 2). Without analysing these results statistically, he concluded "that great variability occurs in the primary sex ratio between different families". Hays continued: "This variability may be ultimately traced to gene differences. It is not at all unlikely that sex in domestic chickens may depend upon many genes and that many of these are located in the autosomes". What is the evidence? We have determined for each of our eight pen matings, and also for the entire groups of White Leghorn and Black Minorca fowl, whether significant heterogeneity in the sex ratio of their progenies existed between hens. The values for χ^2, degrees of freedom and probability are summarized in Table 3. The results are entirely negative, that is, there is no evidence for or suggestion of

Table 3. SIGNIFICANCE OF DEVIATIONS FROM EQUALITY OF THE TWO SEXES BETWEEN PROGENIES OF INDIVIDUAL HENS

Pen	χ^2	D.f.	*P* (about)
19	11·81	16	0·75
20	8·79	9	0·46
21	15·61	14	0·45
22	5·11	15	>0·99
All Minorca	43·43	57	>0·50
23	21·30	17	0·25
24	15·08	15	0·40
25	12·47	15	0·60
26	12·40	14	0·60
All Leghorn	62·08	64	>0·50
Hays's Rhode Island Red (his Table 2)	11·66	10	0·30

heterogeneity. Included in Table 3 is also a χ^2 analysis of the data presented by Hays in his Table 2, and this again failed to produce any proof for independent variation between hens in the sex ratio of their progenies. It may be concluded, therefore, from Hays's results as well as from our own, that in fowl equal numbers of males and females are determined at fertilization. There is no evidence whatever for autosomal sex-determining genes or for variations in sex ratio determined by such autosomal genes or by any other agency. Coles[2] has recently published results for a flock of White Leghorn fowl which, he believed, demonstrated a significant deficiency of males in the primary sex ratio of the progenies. The statistical evaluation of his data was made on the unproved assumption that embryonic mortality prior to the tenth day of incubation affects the two sexes in equal proportions. Moreover, the possible significance of selective mortality in unrecognized early stages of segmentation (likely to be classified as 'infertile') was not taken into account. But for a critical evaluation of the primary sex ratio, data should not be accepted in which 'infertility' and early mortality play an unknown part—unless it can, indeed, be shown that on the most unfavourable assumption, namely, all unknowns being of the sex that is deficient in numbers, the deviation of the primary sex ratio from equality remains significant.

Weir[3] and McWhirter[4] have published evidence suggesting that in mammals, with male heterogamety, the primary sex ratio can be modified by specific physiological conditions of the male parent (blood *p*H), and that these conditions can be affected by selection. In animals with female heterogamety, such as birds, it is less likely that similar attempts (though positive results by dietary means have been claimed[5]) will be successful; not, in any event, without a corresponding loss in fecundity or 'fertility'.

Alimentary Lipæmia and Resistance to Altitude Anoxia

Several recent clinical studies[1] have pointed out important relationships between alimentary lipæmia and the function of the circulatory system after a single large fat meal. The occurrence of typical attacks of angina pectoris especially was observed at the peak of the serum opalescence, accompanied by changes in the electrocardiogram and ballistocardiogram. According to various authors many factors participate in these disturbances: increased blood sedimentation-rate and viscosity, decreased fibrinolysis, agglutination of erythrocytes in the blood vessels, and other factors. The possible effect of a relative lack of oxygen in the tissues when the organism is suddenly overloaded with fat was not taken into account. Therefore an experimental study of the effect of alimentary lipæmia upon the resistance of the animal organism to lack of oxygen was undertaken, as the first step towards solving this problem.

The experiments were carried out on *H*-mice of both sexes. Hyperlipæmia was produced by olive oil (0·4 ml./20 gm. body-weight) which was given by means of a metal gastric tube, and the resistance of the animals to altitude anoxia was measured first by determining the mean lethal altitude[2] and then by observing the average survival time at a constant simulated altitude.

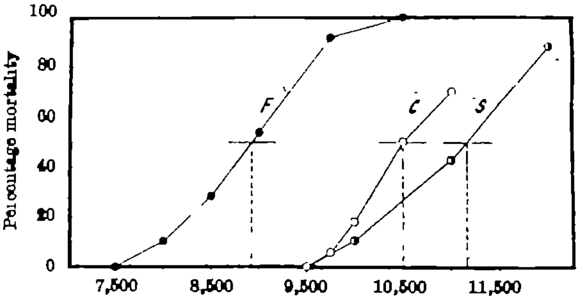

Fig. 1

The mean lethal altitude was studied in three groups of forty mice. Four hours after the administration of fat, that is, at the time when the maximum lipæmia might be expected, small groups, with five in each, of control and fat-treated animals were exposed to simulated altitude of 7,500 m.–11,000 m. The maximum altitude was reached in 1 min., held for another minute and then followed a gradual descent. The percentage mortality in the different altitudes was expressed according to Behrens, the significance between the mean lethal altitudes in the different groups being determined by means of a graphical modification of the probit analysis according to Lichtfield and Wilcoxon[3]. The difference of mean lethal altitude of the control group (*C*) and the fat-treated group is highly significant and amounts to about 1,500 m.

There is no significant difference between the control (*S*), which received an isocaloric amount of starch by means of the gastric tube, when compared to the control (*C*).

The average survival time at the constant altitudes of 11,000, 10,000 or 9,000 m. above sea-level was determined by the last breath (Fig. 2). At the altitude of 11,000 m., 4 hr. after consumption of the

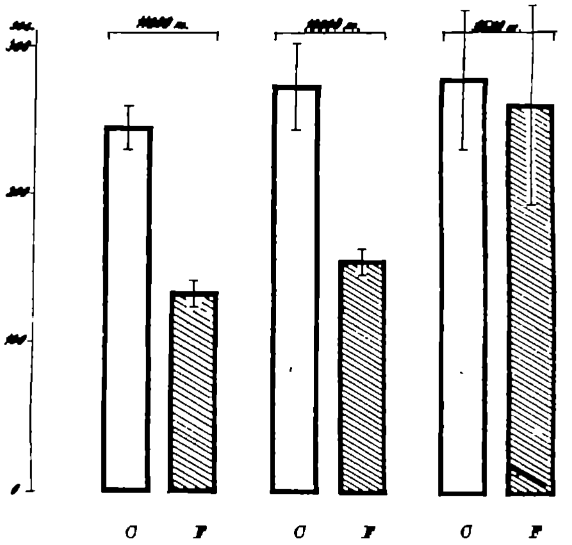

Fig. 2

olive oil it was 133·5 ± 10·2 sec. (variation coefficient 7·5 per cent), in the control group 245·0 ± 7·3 sec. (variation coefficient 7·3 per cent), that is, 65 per cent longer than in the fat-treated group. The time of survival at the altitude of 10,000 m., again 4 hr. after the ingestion of fat, was 156·0 ± 11 sec. (variation coefficient 22·3 per cent); in the control group 272·8 ± 30 sec. (variation coefficient 33·3 per cent), that is, 60 per cent longer. The difference is highly significant at the 1 per cent level. The significance of the difference of survival times disappears at an altitude of 9,500 m., 24 hr. after the administration of oil or starch.

The results presented in this report show a decreased tolerance of anoxia in mice 4 hr. after the application of a single dose of olive oil. Furthermore, they provide evidence for the participation of the above-mentioned relative hypoxia of the tissues after a single load of fat in the different unfavourable changes of the circulatory system due to an increased demand of oxygen in the tissues or due to an altered mechanism of oxygen transport. The different factors are fully analysed in further experiments which will be published in detail elsewhere.

Lævan-forming Halophilic Bacteria

NON-HALOPHILIC bacteria which are able to form lævan from sucrose have been described within several genera, for example, *Bacillus*[1], *Pseudomonas* and *Xanthomonas*[2], *Streptococcus*[3], *Aerobacter*[4], as well as *Corynebacterium*[5]. However, lævan-forming bacteria occurring among the halophiles offer special interest from the enzymological point of view and, in addition, are of considerable economic importance.

Strains of bacteria which produce a viscous slime on nutrient agar containing six per cent sucrose and eight per cent sodium chloride were isolated from 'ropy' herring brine. These bacteria are non-spore-forming, non-motile, Gram-negative rods. They are obligate halophiles of the moderate type, showing maximal growth at 1–2 *M* sodium chloride, within the temperature range 20–30° C., and around *p*H 7. Neither acid nor gas is formed from carbohydrates. The bacteria are aerobic, but are able to grow under anærobic conditions in the presence of nitrate which is reduced to nitrite and gas. Provisionally, they have been classified within the genus *Achromobacter*.

Neither lithium nor potassium can be substituted for the sodium ions, but bromide, sulphate and phosphate may partially replace the chloride ions.

The bacteria may be grown in synthetic media, supplemented with thiamine. Glutamic and aspartic acids are utilized as sole sources of carbon, energy and nitrogen. In the presence of ammonium salts, pyruvic, citric, succinic, fumaric and malic acids as well as α-alanine support growth. No other amino-acid tested could be used as sole carbon source, in spite of the fact that the readily water-soluble amino-acids are all oxidized rapidly by washed cells in the Warburg apparatus. None of the carbohydrates tested, for example, arabinose, xylose, glucose, mannose, galactose, fructose, sucrose, maltose, lactose, raffinose and starch, can be used as carbon and energy source; nor are these substances oxidized in the Warburg apparatus. Thus, these bacteria do not attack carbohydrates, with the one exception that sucrose is transformed to a slime if the bacteria are at the same time provided with some source of carbon and energy which they can utilize, for example, certain amino-acids, pyruvic acid, or intermediates of the tricarboxylic acid cycle.

The slime formed from sucrose was precipitated by the addition of two volumes of 96 per cent ethanol. It was found to contain less than 0·05 per cent nitrogen. After hydrolysis[6] by heating in 0·1 *N* oxalic acid for 45 minutes at 70° C., neutralization with calcium carbonate and centrifuging, the hydrolysate gave only one spot on the paper chromatogram. By means of its R_F value and colour reaction with naphthoresorcinol, this spot was identified as fructose. The results indicate that the slime substance is a polysaccharide of the lævan type and the enzyme active in its formation a lævansucrase.

For the study of the enzyme activity, acetone-dried preparations of the bacteria were used. The relative increase of viscosity, caused by the acetone-dried cells in a solution containing 0·08 *M* sucrose, 8 per cent sodium chloride, and 0·1 *M* phosphate buffer, *p*H 7·0, was taken as a measure of the enzyme activity. The lævansucrase was found to be constitutive and bound to the cells, showing little or no activity in solutions without added sodium chloride, with maximal activity in the range 1–3 *M*. Very low activities were obtained when the bacteria were washed several times with lithium or potassium chloride solutions before the acetone treatment, and determinations of the activity were made in solutions containing either of these chlorides instead of sodium chloride. It appears that the lævansucrase of these bacteria is specifically activated by sodium ions.

Whereas non-halophilic lævan-forming bacteria form slime from raffinose as well as from sucrose, the bacteria studied in the present work are only able to use sucrose as substrate. Other sugars, added to the sucrose-containing solution, inhibit the slime formation to varying degrees, the strongest effect being obtained with lactose.

Although the lævansucrase is a constitutive enzyme, the growth conditions of the bacteria seem to affect the amount of enzyme formed or its activity. From bacteria grown in aerated media or in the presence of nitrate, acetone-dried preparations of much higher activity were obtained than from cells grown under limited oxygen supply.

A detailed report of the results will be given elsewhere.

Respiratory Metabolism of Aerated Potato Disks

Research in several laboratories has clearly demonstrated that aerated potato disks develop an increased capacity for uptake of oxygen[1-7]. This additional respiratory capacity is not increased by 2,4-dinitrophenol[7] and is relatively insensitive to inhibition by cyanide[8] and carbon monoxide[5,6]. However, cyanide[8], low temperature (0–5° C.)[7] or absence of oxygen at normal temperature[8] will prevent the development of the increased respiratory capacity.

In view of these observations, it became of interest to us to learn whether the development of increased respiratory capacity requires the synthesis of new protein and whether the increased oxygen uptake is coupled to phosphorylation to give an increased work capacity. In our experiments (Table 1) the presence of the protein synthesis inhibitor, chloramphenicol, during the 24-hr. aeration of the potato disks prevented increase in respiratory capacity. Because the presence of chloramphenicol during the measurement of uptake of oxygen has little effect on the respiration of either fresh or aerated disks, it can be concluded that protein synthesis is a necessary part of the development of an increased capacity for uptake of oxygen.

Table 1. The Effect of Chloramphenicol on the Development of an Increased Respiratory Capacity by Aerated Potato Disks. Oxygen uptake (µl. O_2/500 mgm./hr.)

Fresh control	Fresh + chloramphenicol	Inhibition (per cent)	Aerated control	Aerated in the presence of chloramphenicol*	Inhibition (per cent)
24	19	25	106	33	69
24	25	−4	50	16	68
32	29	9	101	55	46
Av. 27	24	10	86	35	61

* Potato disks were aerated in the presence of 1 mgm./ml. chloramphenicol for 24 hr.

Each Warburg flask contained: 0·01 *M* phosphate, *p*H 6·9, 500 mgm. potato disks (1 cm. × 1 mm.), 3 × 10^{-4} *M* hydrogen cyanide or 1 mgm./ml. chloramphenicol, 20 per cent potassium hydroxide in the centre well. Incubation temperature, 30° C.

The phosphorylative capacity of the potato disks was measured by determining the extent of incorporation of phosphorus-32 into organic phosphate esters during the measurement of uptake of oxygen. Results obtained in this way indicate that the increment of respiratory capacity is coupled to phosphorylation (Table 2). The incorporation of phosphorus-32 into the aerated disks is not as sensitive to inhibition by cyanide as that of fresh disks. However, the phosphorylation of aerated disks is inhibited by the same levels of dinitrophenol required to inhibit the phosphorylation of fresh disks.

Table 2. Effect of Cyanide on the Phosphorylation Capacity of Fresh and Aerated Potato Disks

Incorporation of phosphorus-32 into organic esters. (Per cent of total counts in the cells)

Fresh control	Fresh + HCN	Inhibition (per cent)	Aerated control	Aerated +HCN	Inhibition (per cent)
32·6	13·7	58	23·6	30 1	—27 5
12·6	4·2	67	27·6	24·5	11 2
23·9	8·1	66	32·7	25 6	21 7
—	—	—	23 5	18·3	22 1
—	—	—	19·9	25 0	−25·6
Av. 23·0	8·7	64	25 5	24·7	0 4

Incubation with phosphorus-32 was conducted in a Warburg flask during measurements of oxygen uptake. The flasks contained 0·01 *M* phosphate buffer, 500 mgm. (fresh weight potato disks), 3 × 10^{-4} hydrogen cyanide and 20 per cent potassium hydroxide in the centre well. Incubation was at 30° C. for 3 hr.

These results lead us to the conclusion that the increased respiration of aerated potato disks is mediated by enzymes which are synthesized during the aeration period. Further, it appears that this additional electron transport to oxygen is coupled to phosphorylation because the phosphorylation observed in a fixed incubation time is not sensitive to a level of cyanide sufficient to inhibit 64 per cent of the phosphorylation of fresh disks. If the additional respiration were not coupled to phosphorylation, then the phosphorylation after 24-hr. aeration should still be sensitive to cyanide inhibition.

The results reported here can be accounted for by the hypothesis that cytochrome oxidase is a limiting factor in the respiration of fresh potato disks; and that on aeration, there is a net synthesis of an excess of cytochrome oxidase so that this cyanide-sensitive step is no longer limiting.

Ion Permeability of the Plasmalemma of the Plant Cell

Walker[1] has suggested that for *Nitella* there is evidence for a layer on the outside of the cytoplasm, a plasmalemma, which offers considerable resistance to the passage of ions. In support of this suggestion he advances two pieces of evidence—the bulk of the high d.c. resistance across the cytoplasmic layer from vacuole to outside solution of chloride lies in the cytoplasm and not in the tonoplast, and secondly, that the equilibrium concentration of calcium ions in the cytoplasm calculated from the potential difference is absurdly high.

If the tonoplast is practically impermeable to cations, then the conductivity of the cytoplasm and tonoplast will depend on the concentration and mobility of anions in these phases. If they are similar for both phases, then the bulk of the resistance will reside in the cytoplasm because of its much greater thickness. The average resistance of 6,000 ohm sq. cm. with a thickness of 10µ would be appropriate for a concentration of chlorine ion in the cytoplasm of 2·6 µequiv./l. This is the equilibrium concentration if the external solution has a concentration of 1·5 m.equiv./l. and a potential difference relative to the cytoplasm of 160 mV. If the external cation were univalent then the concentration of non-diffusible anion would be 0·87 equiv./l. The external concentration and that of non-diffusible anion would be smaller if the potential difference were less. The concentrations used ranged from 0·05 to 1·0 m.equiv., but the values for the potential difference with these solutions are not given.

The calculation of calcium ions in the cytoplasm is valid if the potential difference of − 160 mV. is the correct value for the cells in pond water (potassium, 0·03; sodium, 0·5; and calcium, 0·5 m.equiv.) and the estimation of calcium refers to the free ion. It is worth noting that Walker[2] reports − 160 mV. for cells in unspecified volumes of 0·0001 *M* potassium chloride and −123 mV. when the concentration was changed to 0·001 *M*. Unfiltered pond water may contain solid calcium carbonate. In any event the calculation, if based on firm premises, cannot tell us anything about mode of entrance of calcium, whether as ions or combined with carrier molecules, as Walker suggests; it can only tell us whether or not the cytoplasm and external solution are in equilibrium as regards calcium.

Control of Witchweed, *Striga hermonthica* Benth., in the Sudan Gezira

Recent work[1] has shown that the phanerogamic root parasite *Striga hermonthica* Benth. (witchweed), which causes considerable crop losses to sorghum (*Sorghum vulgare* Pers.) in the Sudan and elsewhere, can be controlled by spraying the young crop with hormone weed-killers of 2,4-D type two to three weeks after sowing. Although such measures often result in substantial increases in yield, there are several difficulties which at present preclude their general adoption in the Sudan Gezira. One is the extreme sensitivity of certain crops, notably cotton, to even minute traces of hormone weed-killers, together with the fact that such spraying has to be carried out at about the time of cotton sowing in the Gezira. Furthermore, spraying must be carefully timed and performed to avoid injuring the young sorghum plants, and involves the use of relatively costly and complicated spraying apparatus with which most Gezira cultivators are unfamiliar—the initial cost and subsequent maintenance of such apparatus discourage many cultivators from using this method of witchweed control.

An investigation of simpler methods of application was carried out on ridge-irrigated sorghum sown on July 14, 1956, in a plot with high natural witchweed infestation, and the results are given in Table 1. The fine spray was from a knapsack sprayer using some 92 gallons of weed-killer solution per acre. Sprinkler application was from an ordinary watering-can with a rather coarse rose, using about 184 gallons/acre. Jet application was from a watering-can delivering a narrow jet of solution, the open end of the spout being covered with a simple metal cap having a circular aperture, ¼ in. in diameter. This adaptation worked efficiently, did not become blocked and allowed application of the weed-killer solution at the rate of 46 gallons/acre. In all treatments except control, 1 lb. of 80 per cent 2,4-dichlorophenoxyacetic acid per acre was applied on July 31, seventeen days after sowing.

Table 1

Method of application	Percentage plant holes attacked by witchweed Aug. 22	 Sept. 5	 Sept. 19	 Oct. 3	Yield/acre Grain (ardebs)	 Straw (tons)
1 Control, untreated	32·9	71·4	97·6	98·8	3·020	1·309
2 Spray along ridges, continuous	2·5	27·0	82·4	93·0	5·030	1·979
Sprinkler along ridges:						
3 Continuous	2·6	21·0	91·2	93·2	5·080	2·080
4 Between plant holes	9·1	30·5	94·1	96·0	4·111	1·870
5 Over plant holes	8·1	32·3	85·0	94·7	4·404	2·050
Sprinkler along furrows:						
6 Continuous	22·5	46·1	93·2	96·2	4·171	1·585
Jet along ridges:						
7 Continuous	2·1	26·1	88·1	94·7	5·595	2·266
8 Between plant holes	9·4	37·3	91·5	95·2	5·181	2·289
9 Over plant holes	4·8	29·1	92·9	96·4	4·666	1·907
Jet along furrows:						
10 Continuous	36·7	61·2	95·1	96·8	4·167	1·578
Minimum significant difference						
$P = 0·05$					not sig.	0·474
$P = 0·01$						0·628

1 ardeb ≃ 332·6 lb.

All ridge applications (2–5, 7–9) greatly reduced early witchweed attack but not so the two furrow applications (6, 10); two months after sowing, witchweed infections, as judged by percentage infected plant holes, were about the same in all treatments. Yields of grain varied considerably within replicates of the same treatment, partly due to damage by birds and dura-midge (*Contarinia sorghicola*), and although treatments with heavy early witchweed attack tended to yield less grain, the differences were not quite significant at the P 0·05 level. Thus in the ten control (untreated) replicates yields of grain ranged from one to nearly six ardeb/acre, and plant holes infected by witchweed on September 5 ranged from 40·8–86·5 per cent. Analysis (see Table 2) of the results from these ten untreated replicates showed highly significant negative correlations between yield (grain and straw) and the percentage of infected holes on August 22 and on September 5, but not at later dates, when infection had increased to about the same level in all ten subplots.

Table 2. CORRELATION COEFFICIENT (r AND t) BETWEEN YIELDS OF GRAIN AND STRAW AND PERCENTAGE INFECTED HOLES ON AUGUST 22 AND SEPTEMBER 5

At $P = 0·05$, $t = 2·306$
At $P = 0·01$, $t = 3·355$

Aug. 22: Grain yield, $r = -0·844$, $t = 5·289$
Straw yield, $r = -0·825$, $t = 4·128$
Sept. 5: Grain yield, $r = -0·746$, $t = 3·168$
Straw yield, $r = -0·897$, $t = 5·740$

Straw yields were more consistent and were significantly increased by all treatments except the two furrow applications. Ridge application from watering-can, whether by sprinkler or jet, was as effective as spraying, and this method of application should reduce the cost and increase the simplicity of witchweed control. Jet application of the weed-killer solution would also lessen the danger of spray drift to nearby crops.

This control method delays witchweed attack by destroying the first flush of germinating *Striga* seedlings, but the weed-killer does not persist in the soil sufficiently long to destroy seedlings appearing later; that is to say, it reduces but does not eliminate the parasite. It is hoped to investigate whether pre-sowing application of persistent non-hormone weed-killers of the substituted urea type (CMU, DMU) will destroy germinating witchweed seedlings without adversely affecting the sorghum crop; the witchweed problem would be greatly simplified if effective control could be obtained by application of such compounds during the dry intercrop months before sorghum is sown.

'Compensatory Hyper-regeneration' in the Antennæ of Hemiptera

It has been observed by several authors[1] that antennæ of various Hemiptera, especially Lygaeidae, occasionally exhibit an abnormality in which the number of antennal segments is reduced but at the same time the length of the remaining ones is increased, as if the loss of one segment were compensated by an exaggerated growth of the rest. I have presented evidence[2] indicating that such cases in the Pentatomid bug *Raphigaster nebulosa* must be due to an incomplete regeneration after the loss of a normal antenna during nymphal stages, but so far neither experimental evidence for this nor a satisfactory explanation of the 'compensatory' nature of the abnormalities has been available. (Dr. H. Ruckes, of the American Museum of Natural History, New York, tells me that he has produced such 'compensatory hyper-regeneration' experimentally on antennæ of the Pentatomid bug *Euchistus variolarius*, but his findings have not been published.)

Experiments with the milkweed bug *Oncopeltus fasciatus* have now furnished direct proof that antennæ, showing the 'compensatory' phenomenon, that is, having fewer but larger segments than normal antennæ, can be produced experimentally by removing the original antennæ in early nymphal stages and allowing the organ to regenerate. The best results were obtained when the antennæ were amputated (on one side, so that the opposite side could serve as control) in first or second instar nymphs, that is, within six days after hatching at about 25° C. The antennæ were amputated either near the basal segment, removing three segments and leaving the basal one intact, or near the articulation of the second and third segments, removing the two terminal segments. In place of the amputated segments the regenerates had always one segment less than the normal antenna. If three segments were amputated, the regenerate had only two in their place; if two were removed, they were replaced by one only. The regenerated antenna as a whole never reached the size of the normal one, but its relative size in comparison to the normal varied a great deal, obviously due to differences in the physiological conditions of the insects during the process of regeneration. The length of the individual segments of the regenerates also often remained below normal, or just reached the normal size; but in about half the cases regenerated segments have appeared which were conspicuously longer than any of the segments of a normal antenna, just as in the cases found in Nature (Fig. 1,*a*). In addition, in most cases the regenerated segments, even the ones which were shorter than the normals, were considerably thicker and 'chubbier' than those of a normal antenna (Fig. 1,*b*). They often gave the same impression, when compared with normal antennæ, as that given by polyploid leaves or fruits of a plant when compared with the diploid organs (cf. Blakeslee[3]).

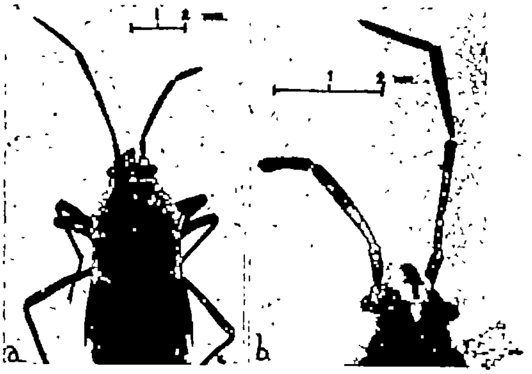

Fig. 1. *Oncopeltus fasciatus* adults, with regenerated antennæ. (*a*) right antenna was removed at the base of the second segment in the first nymphal stage—note the abnormally long second segment of the regenerate; (*b*) left antenna was amputated in the same place, same stage. Segments of the regenerate are shorter but thicker than normal

An attractive explanation of the cause of the oversize dimensions of the regenerated antennal segments offers itself, since it is known that in various post-embryonic developmental stages of insects chromosome duplications occur regularly in somatic cells without nuclear division[4] and this phenomenon, termed endomitosis, is particularly widespread in Hemiptera[5]. It seems that many organs of these hemimetabolous insects grow from nymphal instar to nymphal instar not by a multiplication of the number of the constituent cells but by a systematic increase in the size of the cells, due to repeated endomitotic polyploidization of the nuclei.

Studies in progress in this Laboratory on the cytology of *Lygaeus* and *Oncopeltus* under Prof. C. A. Berger (unpublished work by C. M. John and B. Sparano) indicate that practically all somatic tissues of these insects undergo progressive polyploidization during nymphal stages. It is therefore almost certain that the cells which form the regeneration blastema on the stump of an amputated antenna have a higher number of chromosome complements (and are consequently larger) than those which formed the anlage of the original antenna during embryogenesis. The result seems to be the observed increase in the dimensions of the regenerated structures when compared with the original ones. Whether the reduction in the number of antennal segments in the regenerates is a consequence of the polyploidy of the cells of the regeneration blastema or an independent phenomenon cannot be decided on the basis of the facts presented here. (Imperfect regeneration is widespread even in forms where somatic polyploidy does not occur.) But it may well be that increasing polyploidy affects adversely the capacity of the tissues to differentiate. It was observed, for example, that amputation of antennæ in late nymphal stages, when polyploidy reaches its maximum, no longer produces regeneration, but the stumps seem to be noticeably 'swollen', indicating that cell divisions have still occurred. Further studies in this direction, as well as in order to check this tentative explanation of the 'compensatory hyperregeneration' of Hemipteran antennæ, are in progress.

Lamprey Distribution in Streams and Rivers

IT has long been known that there is a close relation between gradients of rivers and their living population[1-5]. Many accounts have stressed the way in which these populations (especially fish) tend to move up or down a river, depending on its water-level and rate of flow. I have noticed that lampreys and their larvæ do not seem to do this. Apart from those instances where, during severe drought or drought followed by flooding, ammocoete beds dry out or are washed away, such beds and the ammocoetes in them usually remain where they are whatever the state of the river.

My own observations[6] point to two conclusions. (1) The building up of an ammocoete bed is a function of the gradient of a river and, once made, the bed will withstand severe changes in water-level and flow providing it does not dry out. (2) The ammocoetes themselves, by living in the ammocoete bed, are in fact not in the ecological environment of the main stream but in a micro-environment of their own.

Lampreys, like fish, are very sensitive to increases in the temperature and carbon dioxide content of water. Changes of this sort are less likely to occur in reaches of a river where the gradient exceeds 10 ft. per mile[5,7] and distribution records of the occurrence of lampreys, particularly the brook lamprey (*Lampetra planeri* Bloch), which I have collected over a number of years indicate a broad correlation between distribution of lampreys and gradients of stream of between 10 ft. per mile and 30 ft. per mile. In addition, however, I have found certain regular variations within these limits which require further investigation.

It is the purpose of this communication to seek the help of all those who know of stream or river localities in which lampreys occur, so as to increase the amount of information to a level where it can be analysed statistically.

The information sought is as follows: (1) Any evidence of the existence, or former existence, of lampreys or ammocoetes of any species in a particular stream or river. (2) Identification of the species, if possible. (3) An accurate description, preferably by map reference, of the locality. In Britain, 1-in. Ordnance Survey (2nd edition) is sufficient. (4) Date on which specimen was observed. (5) Any weather observation made at the time.

I shall be grateful to receive even single records. Such information from any part of the world will be of value as I have access to large-scale maps here in London which will enable me to determine the general geographical features of any locality.

Occurrence of *Elminius modestus* Darwin in Ireland

THE appearance, and subsequent spread, of the Australasian barnacle *Elminius modestus* Darwin in British and north European waters is well known[1]; but, hitherto, it has not been recorded in Ireland.

On September 12, six small specimens of *E. modestus* were found at Tralispean and on September 15, four more were discovered on the east side of the Coosh, near Lough Ine in south-west County Cork[2]. Both are sheltered localities. The specimens were found near low water, and the carino-rostral diameter of the largest specimen was 5 mm.

An immediate study of the general distribution of *E. modestus* in Ireland should establish its point of entry.

Some Further Visual Phenomena associated with Regular Patterned Stimulation

IN a recent article[1] I described some striking effects of visual stimulation by regular patterns. The principal feature of these is the appearance of what may be called a 'complementary pattern' the main outlines of which run roughly at right-angles to those of the stimulus-pattern. A 'ray' pattern of radial lines, for example, produces an after-impression of wavy lines moving in concentric circles; a pattern of concentric circles produces an after-image of wavy radial streamers. These complementary patterns may also be evoked continuously in stroboscopic light, or in a background of visual 'noise' (on a television screen) viewed through a transparency of the stimulus pattern.

Since the article was written a number of related effects have been discovered, two of which appear to be of special interest. The first is observed when a source of visual 'noise' is presented after a ten-second viewing of the stimulus pattern in normal light. The spots of light on the screen, which normally suggest an incoherent 'Brownian motion', are for a a few seconds organized into a vigorous scurry of apparent movement roughly along the lines of the complementary pattern. This after-effect shows little transfer (when the stimulus is presented to one eye and the screen is viewed afterwards by the other). It has been found, however, that if one eye views the stimulus pattern and the other simultaneously views the screen, some similar but less-violent motion of the spots on the screen can be seen continuously.

It has been found that this phenomenon, as well as those described earlier, is unaffected when the stimulus presented is stabilized against eye-movement. This has been done by mounting a photographic reduction of the pattern on a stalk 1·5 cm. long attached to a contact lens of + 60 dioptres power. (A similar method of stabilization has been used independently by Prof. R. W. Ditchburn of Reading in another connexion (personal communication).) The stimulus-pattern 'fades' irregularly, as expected, but even when it has faded the other eye can detect the complementary motion in the spots of 'noise' on the screen.

This evidence of limited transfer complicates an already puzzling picture, and suggests that in these phenomena we may be dealing not with a single localized activity but with an activity to be expected in the highly interconnected visual network at several, if not all, levels from retina to cortex.

The second effect to be reported is seen with a stimulus pattern consisting of concentric rings of increasing thickness (Fig. 1). Viewed monocularly in bright light, this evokes a radial complementary image which is seen in apparent rivalry with it. If now the stimulus pattern is moved slightly towards or away from the subject, the complementary image is observed to contract or expand rapidly, providing a strikingly sensitive indication of motion in depth. The apparent inference is that the elements the activity of which generates the complementary image are highly sensitive to the spacing of the stimulus-contours. The exaggerated sensitivity of the complementary image could then have somewhat the same explanation as the great sensitivity of moiré patterns to relative movement. An important observation, however, is that the phenomenon does not require central fixation. The pattern may be freely explored with eye-movements without disruption of the complementary image. Any explanation based only on the central symmetry of the retinal receptor-pattern would thus seem to be ruled out.

Lord Cherwell

THERE is little that need be added to the excellent obituary notice of Lord Cherwell in *Nature* of September 21, p. 579, but I should like to comment on the reference to the work in the Clarendon Laboratories in the 'twenties. It is true that the work was diverse, but any one of the problems being studied might have flared up into a whole school of research, which is indeed what many of them have since done.

Griffith was calculating the electrical conductivity due to electrons and ionized molecules in the upper atmosphere, which might very well have led to the work now associated with Appleton's name; Collie was trying to fix Wilson cloud-chamber tracks in gelatine, anticipating Powell's work at Bristol; I was working on the coherence of radiation at different parts of the wave-front, which is now being investigated by Hanbury-Brown and others. One day Lindemann asked me to apply thermodynamical theorems to chemical reactions at extremely high temperatures, beyond anything then known on Earth. The application to stellar constitution and nuclear explosions would have followed.

Lindemann's uncanny foresight revealed to him the importance of the solution of these problems; but, being himself outstandingly adept with his hands, he was apt to suggest experiments which demanded a technique difficult of attainment. In consequence many of the workers became involved in attempts to construct new types of delicate apparatus, and the solution of the main problem was indefinitely delayed.

Museums in Britain

THE article in *Nature* of October 19, p. 769, on this subject reported that several museums must close unless financial assistance is rapidly forthcoming. The Government at present considers that financial aid is a local matter. The Royal Institution of South Wales (founded 1835) in Swansea is in a similar position to some of the museums mentioned, but fortunately local industry has come to its support. An industrial section is being formed within this Museum, members of the local University College are co-operating, and funds have been provided by industry to prevent closure.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, November 25

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Mr. R. Mansell Prothero: "Heinrich Barth and the Western Sudan".

University College, London (in the Physiology Theatre, Gower Street, London, W.C.1) at 5 p.m.—Dr. H. Harris: "Human Biochemical Genetics" * (Further lectures on December 2 and 9.)

British Society for the History of Science (in the Council Room of the Science Museum, Exhibition Road, South Kensington, London, S.W.7), at 5.30 p.m.—Mr. I. B. Hopley: "Clerk Maxwell's Experiments on Colour Vision"

Institution of Electrical Engineers, Radio and Telecommunication Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Informal evening on "Problems of Sound and Television Broadcasting Coverage". Talk by Mr. G. Millington.

University of London (in the Assembly Hall, Institute of Education, Malet Street, London, W.C.1), at 5.30 p.m.—Mr. N. J. Graves: "Geography".* (Last of a series of lectures on "Contemporary Ideas on Teaching Method".)

Tuesday, November 26

Institution of Chemical Engineers (joint meeting with the Low Temperature Group of the Physical Society, at the Royal Institution, Albemarle Street, London, W.1), at 9.30 a.m.—Joint Symposium on "Recent Developments in Industrial Low Temperature Gas Separation".

Parliamentary and Scientific Committee, General Committee (in Committee Room 12, House of Commons, London, S.W.1), at 5.30 p.m.—Discussion on "Problems of Aircraft Research and Development in Great Britain", opened by Mr. H. G. Nelson, Sir William Farren, F.R.S., and Dr. A. E. Russell.

Royal Meteorological Society (in the Conference Hall, County Hall, London, S.E.1), at 5.30 p.m.—Mr. H. H. Lamb: "Weather in the Polar Regions" (Popular Lecture for Sixth-form Scholars).

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. G. Gordon: "Central Sensory Representation".* (Twelfth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation. Further lectures on November 28, December 3 and 5.)

Wednesday, November 27

Institute of Physics, London and Home Counties Branch (in the Lecture Theatre of the Royal Institution, 21 Albemarle Street, London, W.1), at 2.30 p.m.—Symposium on "The Design of Physics Research Laboratories".

Geological Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. S. Marchant and Mr. C. D. G. Black: "The Nature of the Clay Pebble-beds and Associated Rocks of South-West Equador": Dr. G. P. L. Walker: "The Volcanic Geology of the Reydarfjördur Area, Eastern Iceland".

British Institution of Radio Engineers (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Annual General Meeting. 7.15 p.m.—Dr. A. van Weel: "Transmission Standards and Signal Distortion in Television and Other Communication Systems".

Institution of Mechanical Engineers, Applied Mechanics Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6.45 p.m.—Discussion on "Fretting Fatigue".

Royal Institute of Chemistry, London Section (joint meeting with the South-West Essex College of Technology Chemical Society, at the South-West Essex College of Technology, Forest Road, London, E.17), at 7 p.m.—Dr. J. W. Rodgers: "The Extraction and Uses of Titanium and Zirconium".

British Psychological Society, Medical Section (at the Medical Society of London, 11 Chandos Street, Cavendish Square, London, W.1), at 7.30 p.m.—Prof. Michael Polanyi: "The Structure of the Modern Mind".

Royal Society of Medicine (in the Barnes Hall, 1 Wimpole Street, London, W.1), at 8 p.m.—Lord Adrian, O.M., F.R.S.: "The Analysis of the Nervous System" (First Sherrington Memorial Lecture).

Wednesday, November 27—Thursday, November 28

Institute of Fuel (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 10 a.m. daily—Second Conference on "Pulverized Fuel".*

Thursday, November 28

University of London (in the Wright-Fleming Institute Lecture Theatre, St. Mary's Hospital Medical School, Paddington, London, W.12), at 5 p.m.—Prof. G. Mayer (Bordeaux): "Physiological Factors in Implantation of the Egg".

Institution of Electrical Engineers (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. W. A. Sharpley and Mr. J. V. Oldfield: "The Digital Computer applied to the Design of Large Power Transformers".

Research Defence Society (in the Physiology Lecture Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—The Right Hon. the Lord Cohen of Birkenhead: "Some Reflections on Animal Experiments" (Twenty-sixth Stephen Paget Memorial Lecture).

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. H. J. Taylor: "Physiological Problems Associated with Diving and Underwater Swimming".* (Thirteenth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation. Further lectures on December 3 and 5.)

Institution of Mechanical Engineers, Graduates' Section (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Mr. R. E. Zoller: "Some Aspects of Hinkley Point Project"

Institution of Electronics (in the Assembly Hall of the University of London Institute of Education, Malet Street, London, W.C.1), at 6.30 p.m.—Mr. C. Brown: "The High Fidelity Reproduction of Sound" (Lecture-Demonstration)

Friday, November 29

Royal Society (at Burlington House, Piccadilly, London, W.1), at 10.30 a.m.—Discussion on "Observations of the Russian Artificial Earth Satellite and their Analysis", opened by Prof. H. S. W. Massey, F.R.S.

British Psychological Society, Industrial Section (in the Department of Psychology, Birkbeck College, Malet Street, London, W.C.1), at 1 p.m.—Mr. H. C. A. Dale: "Fault-finding: Some Recent Research".

Institution of Mechanical Engineers (in conjunction with the Industrial Administration and Engineering Production Group, at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Mr. J. L. Rice, Mr. R. W. Ruddle and Mr. P. A. Russell: "Recent Developments in the Manufacture of Castings".

Society of Cosmetic Chemists of Great Britain (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 7.30 p.m.—Dr. V. R. Wheatley: "Chemistry and Biochemistry of Sebum".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Dr. William Syer Bristowe: "A Smother of Spiders".

Saturday, November 30

Botanical Society of the British Isles (in the Lecture Hall of the British Museum (Natural History), Cromwell Road, London, S.W.7), from 2.30 to 5.30 p.m.—Annual Exhibition Meeting.

Royal Society (at Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Anniversary Meeting.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant (preferably with a good scientific education) in the Science Department, London Headquarters, for editorial and information duties—The Personnel Department, British Council, 65 Davies Street, London, W.1, quoting D 5 (57) (November 26)

Assistant (Grade B) in Physics—The Clerk to Governors, Woolwich Polytechnic, London, S.E.18 (November 30)

Assistant Lecturer, Grade B (honours graduate), in Physics at Brighton Technical College—The Director of Education, Brighton Education Committee, 54 Old Steine, Brighton 1 (November 30).

Lecturer in Theoretical Physics—The Registrar, King's College (University of London), Strand, London, W.C.2 (November 30).

Lecturer or Assistant Lecturer in Applied Mathematics—The Registrar, The University, Sheffield (November 30).

Lecturer (preferably with industrial and/or research experience) in Physical Chemistry; an Assistant (Grade B) in Biology and an Assistant (Grade B) in Mathematics—The Principal, Nottingham and District Technical College, Shakespeare Street, Nottingham (November 30)

Lecturer (with an interest in electronics, and preferably a knowledge of experimental stress analysis) in Textile Engineering—The Registrar, The Manchester College of Science and Technology, Manchester 1 (November 30).

Scientific Officer, to work at Dunholme Field Station, Lincoln, on fungus and virus diseases of sugar beet—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (November 30).

Senior Laboratory Technician for Science Department, having chemistry, physics and biology laboratories and general and glassworking workshops—The Secretary, Paddington Technical College, Saltram Crescent, London, W.9 (November 30)

Lecturer in Psychology at the University of New England, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, December 13).

Research Assistant (preferably with a postgraduate degree and suitable experience in biochemistry and microbiology) in the Department of Bacteriology to assist in a programme of work on immunochemistry—The Registrar, The University, Manchester 13 (December 14).

Scientific Officer (with a first- or second-class honours degree in chemistry or agricultural chemistry), for combined field experimentation and laboratory work on fertilizers and soil fertility problems (Ref. "A"); and an Experimental Officer (with a degree in chemistry or agricultural chemistry), to assist in research on crops and soils and in dealing with experimental data (Ref. "B")—The Secretary, Rothamsted Experimental Station, Harpenden, Herts, quoting appropriate Ref. (December 14).

Lecturer (with research experience in some branch of valve, transistor or circuit electronics, or in solid state physics, and preferably teaching experience) in the Department of Electronic Engineer-

ING—The Secretary and Registrar, University College of North Wales, Bangor, North Wales (December 15).

LECTURER IN PHYSICS—Prof. C. C. Butler, Physics Department, Imperial College of Science and Technology, London, S.W.7 (December 16).

CHAIR OF MATHEMATICS tenable at Bedford College—The Academic Registrar, University of London, Senate House, London, W.C.1 (December 20).

RESEARCH OFFICER (with at least a university honours degree in science with physics or mathematics as a major subject, or in physical engineering or equivalent qualifications together with appropriate research experience) IN THE DIVISION OF ELECTROTECHNOLOGY, C.S.I.R.O., National Standards Laboratory, Sydney, Australia, to undertake research and to develop techniques and equipment for establishing standards of electrical measurements at high frequencies—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 760/88 (December 21).

ASSISTANT LECTURER (graduate of a British University or equivalent qualifications and experience) IN PHYSICS at the University of Hong Kong—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Hong Kong, December 31).

LECTURER IN EDUCATION at the University of Tasmania, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, December 31).

DRUMMOND SENIOR FELLOW FOR RESEARCH IN NUTRITION—The Hon. Secretary, Drummond Trust, University College, Gower Street, London, W.C.1 (January 31).

ASSISTANT, Grade B (honours graduate in chemistry), TO TEACH CHEMISTRY at Bournemouth Municipal College of Technology and Commerce—Chief Education Officer, Town Hall, Bournemouth.

ASSISTANT, Grade B, TO TEACH CHEMISTRY WITH SOME PHYSICS OR MATHEMATICS—The Principal, North-West Kent College of Technology, Miskin Road, Dartford, Kent.

ASSISTANT, Grade B (with a good honours degree and preferably some previous teaching experience), FOR MATHEMATICS—The Clerk to the Governors, Mid-Essex Technical College and School of Art, Market Road, Chelmsford.

ASSISTANT, Grade B (with a good honours degree), FOR MATHEMATICS—The Clerk to the Governors, South-East Essex Technical College, Longbridge Road, Dagenham, Essex.

ASSISTANT HORTICULTURIST (with a horticultural degree or equivalent) IN THE POMOLOGY SECTION, for experiments in vegetable propagation—The Secretary, East Malling Research Station, East Malling, near Maidstone, Kent.

ASSISTANT RESEARCH OFFICER (with a university degree in mathematics or physics) IN THE NATIONAL TELECOMMUNICATIONS RESEARCH LABORATORY, South African Council for Scientific and Industrial Research, Johannesburg, for duties which include the compilation of ionospheric data and the preparation of radio propagation predictions—The South African Scientific Liaison Officer, Africa House, Kingsway, London, W.C.2.

ASSISTANT TECHNICAL SECRETARY (young graduate with scientific training) IN THE STEELMAKING DIVISION of the B.I.S.R.A., for research administration, liaison with industry, and the collection and presentation of information—The Personnel Officer, British Iron and Steel Research Association, 11 Park Lane, London, W.1, quoting "A.T.S.4".

BEIT FELLOW FOR SCIENTIFIC RESEARCH—The Registrar, Imperial College, South Kensington, London, S.W.7.

READER IN CHEMICAL ENGINEERING; a READER IN ENGINEERING PRODUCTION TECHNOLOGY—MATERIALS AND PROCESSES; and a READER IN AUTOMATIC CONTROL—APPLIED TO MACHINES AND PROCESSES—The Registrar, Loughborough College of Technology, Loughborough, Leicestershire, quoting "D.1".

SCIENTIFIC OFFICER (PETROLOGIST) (with a first- or good second-class honours geology degree and at least five years postgraduate experience in petrology) IN THE GEOLOGICAL SURVEY DEPARTMENT, Federation of Nigeria, for duties which include petrological and mineralogical work in the Geological Survey laboratories—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.105/14/04.

SCIENTIFIC OFFICERS (preferably under 45 years of age, with a good honours degree in natural science and preferably postgraduate experience in fishery research) IN THE FISHERY DEPARTMENT, Sierra Leone, to undertake research on fishery problems—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.65/15/01.

SENIOR SCIENTIFIC/SCIENTIFIC OFFICER (with a first- or second-class honours degree in physics or metallurgy or equivalent qualification, and preferably experience in the field of metallic coatings), to carry out research and development work on the electro-deposition of metals—The Senior Recruitment Officer, Atomic Weapons Research Establishment, Aldermaston, Berkshire, quoting Ref. B/1428/2/34.

STATISTICIAN (with a good honours degree in mathematics), for biometrical research and consultation in the Section of Statistics—The Secretary, National Institute for Research in Dairying, Shinfield, Reading, quoting Ref. 57/9.

TECHNICIAN IN THE DEPARTMENT OF BOTANY—The Registrar, University College of Wales, Aberystwyth.

SOLVENT EXTRACTION IN ANALYTICAL CHEMISTRY

by

George H. Morrison, PH.D.

(Head, Analytical Chemistry Research Laboratories, Sylvania Electric Products Inc.)

Henry Freiser, PH.D.

(Associate Professor of Chemistry, University of Pittsburgh)

This work deals comprehensively with the theory and practice of solvent extraction. The first part of the book, devoted to principles, offers a systematic classification of extractions. The second section is concerned with the practical aspects ; and the final section presents a selection of procedures for the extraction of elements.

Size · 9¼″ × 6″ 280 *pages* *Illustrated* 54*s. net*

FREE RADICALS IN SOLUTION

by

C. Walling

(Professor of Chemistry, Columbia University)

An up-to-date survey of the whole field of organic free radicals in solution. The author provides basic information and references which will enable a chemist to carry out research in the use of free radical reactions for synthetic purposes, in polymerization reactions, in halogenation, autoxidation reactions, etc.

Size: 9¼″ × 6″ 642 *pages* *Illustrated* 116*s. net*

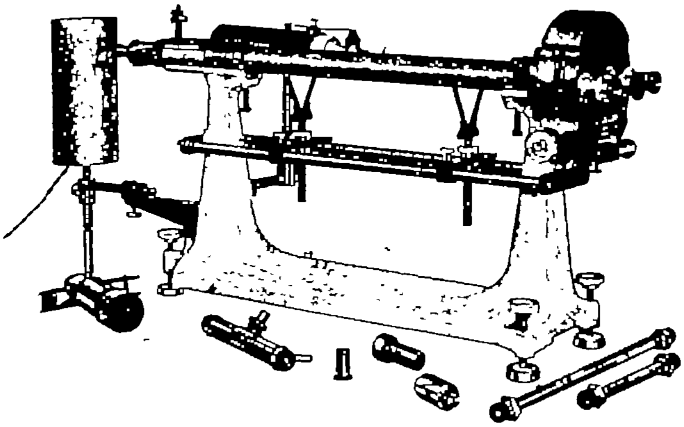
PRECISION BS INSTRUMENTS

Polarimeter Model A

This instrument gives the highest degree of accuracy with divided circle on glass reading to 0·01 degree



Circle centre on ball bearings.
Easily removable trough.
Divided drum replacing verniers.
Stationary observation telescope.
Circle reader enlarging image of scale.
Slow motion adjustment always in action.
Suitable, with additions, for measurement of rotatory dispersion.

This polarimeter has been supplied in large numbers both in this country and abroad and has always been acclaimed as being of advanced design and workmanship.

EDUCATION FOR MODERN NEEDS

IN the House of Commons on May 22, Mr. Michael Stewart urged that a fresh inquiry into the way in which the universities of Britain are meeting the varied and changing needs of the community is appropriate, and he suggested for this purpose the appointment of a Royal Commission as the best means of arriving at an informed and impartial judgment to which the universities could pay due attention without loss of dignity or detriment to academic freedom. Mr. Stewart gave as one reason for holding such an inquiry at the present time, the increased need for university graduates, especially in mathematics and the natural sciences. Graduates are also required in administrative work, and this point has been emphasized increasingly in recent months in respect of management, particularly in relation to automation, and the whole field of what is loosely described as industrial or human relations. Furthermore, the increasing dependence of the universities upon public funds, both directly, through those distributed through the University Grants Committee, and indirectly through the various types of awards from public funds which a majority of students now receive, have changed the relation of the universities to public bodies compared with a generation or two ago. There is also, he said, the profound influence which the universities exert over the whole educational system of the country, but more especially over the secondary schools through the examination system.

All this, as Mr. Stewart quite rightly pointed out, gives the community a deeper interest in the way in which the universities undertake their work, and it might well have been added that the maintenance of academic freedom itself depends on the effectiveness with which the universities are able to bring home to the community as a whole both the nature of their task and the essential conditions for its efficient performance. Unless that is clearly understood, neither the funds nor the freedom for their proper use are likely to be forthcoming. That is not necessarily to agree that a Royal Commission is the most useful means of interpreting the work of the universities, either to Parliament or to the community in general, though a Royal Commission might well prove a more effective instrument in securing answers to some of the questions to which Mr. Stewart suggested it might address itself than some other bodies that have handled them.

In the first place, Mr. Stewart suggested that we might seek to form an estimate of the proportion of the population of Britain which should enter the universities, bearing in mind the needs of teaching, industry, the professions, the departments of State, commerce, etc., and considering such evidence as we can obtain from the schools and elsewhere as to the proportion of school-leavers likely to benefit from a university education. On neither approach would it be wise to dogmatize ; but a sound judgment of the probable approximate proportion of the population capable of profiting by a university education is a fundamental condition of the wise expenditure of public funds on the expansion of the universities as well as of technological and technical education. Secondly, there is the removal of obstacles which at present prevent those who could profit from a university education from entering a university, whether the obstacles be of finance or of sex. Thirdly, Mr. Stewart suggested—and reasonably enough from the point of view of expenditure of public funds—that some inquiry is called for to consider wastage at the universities. If students are to make the best use of their opportunities there and an excessive proportion of failures is to be avoided, questions of selection as well as of teaching arise, and these are matters for expert inquiry. The recent report of the Committee on Halls of Residence hinted at the opportunities for experiment which lie in this field.

Mr. Stewart also suggested that the Commission might well consider what kinds of university we need, what range of pattern the university system of Britain ought to display and particularly as regards the distribution of undergraduate and postgraduate students. It could well arise, for example, in regard to university policy in relation to halls of residence, in order that the resources available for any foreseeable expansion are to be used to the maximum advantage. Here above all, however, there must be some clear conception of the answer to be given to Mr. Stewart's final question, as to the real function of a university, before sound decisions can be taken ; the comparative survey of the systems of all Western European countries, which Sir Henry Tizard suggested at the British Association conference at Leeds last July, on the supply of trained men and women might throw some light on this problem.

It was suggested, indeed, by Mr. Stewart that one of the real reasons for such a commission of inquiry is that the time has come to ask afresh what is the real purpose of a university, and while he recognized that it is part of the duty of a university to meet the vocational needs of the community, he reminded the House that it is also part of the duty of a university to hand on to the next generation standards of values and beliefs on which our civilization rests. Does the vocational work of the universities to-day hinder the performance of that duty of transmitting our cultural heritage ? Are the universities themselves satisfied that they can still effectively fulfil that cultural purpose ?

Whatever answers the universities themselves may give to such questions—and they may well, and with advantage to the community, vary from one university to another—the universities are liable to be under some external pressure from the Government or local authorities and from private benefactors if there is no general understanding and agreement as to their function. Apart from this, our conception of the purpose or function of a university largely determines decisions taken on practical questions which have been closely debated in recent months. That of halls of residence has already been mentioned. General education is another, whether in respect of the schools themselves or the nature or content of university courses. Training for management is a third; and the distribution of our resources between the universities, the colleges of technology and the technical colleges—the whole structure of technological and technical education—is ultimately determined by our idea of the place and purpose of a university.

A number of the questions that Mr. Stewart proposed are in fact already being examined. Besides the inquiry into halls of residence, a preliminary inquiry into applications for admission to universities has already been commissioned by the Committee of Vice-Chancellors and Principals of the Universities. Other questions have been touched upon in the course of an inquiry made by Political and Economic Planning, and sponsored by a joint committee of the Department of Scientific and Industrial Research and the Medical Research Council, into British industrial policy and practice in the recruitment, training and employment of university graduates, although PEP has had reluctantly to postpone, because of shortage of time and staff, a further inquiry into the views of the universities on the whole question of education for industry. Meanwhile, it is true that a closer and fruitful partnership is developing between industry and the universities, and a series of conferences arranged by the Federation of British Industries has contributed notably to a closer understanding by industry of university work and functions. Again, the Nuffield Foundation is sponsoring some investigations which should help to improve the professional training of the university graduate and the effectiveness of science teaching, both at school and university, as well as a study of factors which affect the supply and training of scientists, in particular of the difficulties which seem to exist in the full use of both graduate and non-graduate women in scientific and technical employment. Mr. Stewart also stressed the importance of making full use of women and seeing that those capable of profiting by a university education had the opportunity of getting it.

Whether or not a Royal Commission is the proper means, some support for Mr. Stewart's proposed inquiry can be found in many current discussions. Sir David Anderson's presidential address on education and training for the engineering industry to Section G (Engineering) at the British Association meeting at Dublin made a useful attempt to present a balanced picture in respect of one particular occupation. Without dealing with actual numbers, Sir David emphasized the importance of the sub-professional groups, including technicians, supervisors, foremen and skilled workers in making full use of the professional groups, and of the need to assess the relative contributions which technical colleges and the universities will make in supplying the engineering industry with trained men. Moreover, he pointed out that the industry is in keen competition with other industries and professions, and he was not too optimistic as to the extent to which we can increase the numbers in the professional groups. The chances of securing 20,000 graduates in science and engineering in Britain in the next ten years he regarded as slender. The major increase would come, he believes, from the technical colleges, because these institutions are linked with the stream of part-time education, in which there is an appreciable reserve of good brain-power, which could be selected and transferred to full-time courses. Unless considerably more young people show an interest in science, it is doubtful, he thinks, whether there is any appreciable reserve in the grammar and secondary schools for direct recruitment at sixth-form level. This, of course, confirms the importance of the studies which the Nuffield Foundation is sponsoring; but Sir David is convinced that the conferment of degree-granting powers on some of our leading technological institutions would greatly encourage young people to choose technology as a career.

Sir David also touched on the question of liberal studies in technological courses, and here again he indicated the scope for inquiry without attempting to offer a solution, though he believes the difficulty is exaggerated. Furthermore, he reminded us that the first-class thinker is rare. Most students have only moderate thinking capacity; and too much should not be expected from changes in teaching methods. The capacity to think, he remarked, is an inherent quality of the mind, and is probably much influenced by the way knowledge is presented and acquired. Nevertheless, the staff college for teachers recommended by the Willis Jackson Committee on Teachers for Technical Colleges might well make an important contribution by investigating this problem. On management studies Sir David's remarks ran largely with those in the PEP report; but he was emphatic that British industry should make a serious examination of the apprenticeship system. While the technician group does not appear to present any serious educational problems, he found it disturbing to reflect that in Britain a youth could become a skilled craftsman without having attended a single class or passed a single examination in the whole five years of his apprenticeship.

Sir David made several suggestions for co-operation between educational institutions and industry, largely on lines already emphasized in the PEP report. The importance of his address in this connexion is that it illustrates what is required generally, and not only in respect of engineering, though it by no means follows that inquiry by Royal Commission is the best means of collecting the further facts required or securing the necessary action. So far as co-operation or co-ordination is concerned, it might well suffice if some modification were made in our existing arrangements, and particularly in those relating to the universities and higher educational institutions.

In the first place, while the Advisory Council for Scientific Policy has from its establishment been concerned with the supply of scientific and technical man-power and has made during the past ten years various recommendations both for increasing that supply and for ensuring the more effective use of the existing resources of trained man-power, those recommendations have in large measure been disregarded. A prime measure of responsibility lies on the Lord President of the Council, particularly in respect of the utilization of scientific and technical man-power and of the demand for that man-power. Responsibility also rests between the Chancellor of the Exchequer, so far as the University Grants Committee is concerned, and the Minister of Education. Even so far as higher technological education is concerned, responsibility is divided between these two Ministries.

If the recommendation that responsibility for higher technological education should be placed unequivocably on the University Grants Committee or an analogous body for technological education had been given effect, it is improbable that we would have witnessed the diffusion of resources which has resulted in one of the major colleges of science and technology being compelled to cut down its plans for expansion, while plans are in train for the upgrading of institutions the fitness of which has yet to be demonstrated to the Minister of Education. Probably only an inquiry with the authority of a Royal Commission could establish convincingly the waste of resources inherent in some of the proposals of the White Paper on Technical Education; a fresh recommendation from a body of that standing would perhaps secure the control and co-ordinated planning that is required.

Technological education, moreover, has to be planned in relation to university education as a whole and to technical education, as well as in relation to the numbers and abilities of the school-leavers which secondary and grammar school education provides. Britain's needs in this respect can only be ascertained with the assistance of industry, and here the Ministry of Labour, as well as bodies like the Federation of British Industries, could do much to help. What is needed is not so much new bodies as the wise and determined use of existing means of collecting the information. Nevertheless, to secure that the information as to requirements of technical man-power, its relation to those for graduates of all types, and to the available resources of school-leavers is properly presented to the right quarters may well demand some changes. It is not simply a matter of seeing that the expansion of university education, technological education and technical education is planned in step, but equally of seeing that no opportunities are missed of guiding the school-leaver into the careers where there is most need.

This is only partly a question of public relations. It is essentially a question of balance, and here we touch on the vital question of the purpose and function of a university. No sound relation between university and technical education can be established without clear ideas as to the function of a university. This lies, too, at the root of the whole discussion on general education, what it should mean to-day and where it should be given. Unless it is given due attention, there is real danger that our plans for expanding university and technological education will fail to provide the scientists and technologists or art graduates equipped to live in the modern world.

Industrial leaders like Sir Alexander Fleck and Mr. A. D. Bonham-Carter, scientists like Sir John Cockcroft, have made it clear enough already that what industry is asking of the universities is a supply of graduates, in whatever faculty, who can think and act for themselves, capable of choosing between truth and falsehood, wisdom and folly, beauty and ugliness; nor can it be suggested that the State, the public corporations, local government and commerce need men and women less qualified in these respects. It may, of course, be necessary to revise our estimates of the numbers capable of profiting by a university education or its technological equivalent. There may be fresh ideas as to where technological education should be given and about the quantitative balance between technological and technical education. The content of university courses may need revision—to serve not simply vocational needs but also the cultural and human requirements of society—in accordance with our concept of the purpose of a university. Our ideas of the standards of accommodation at the universities may also need revision in this light. It might still prove possible, for example, to extend considerably our halls of residence without diminishing their cultural and general educational influence while heeding Mr. Stewart's plea for frugality.

What is most disturbing at the present time is, as the report "Industry and Technical Progress" emphasized, not the shortage of trained men and women, but the lack of evidence that effective corrective action is being taken, even to secure the further information needed as to the relative demand for particular categories and as to the more efficient use of scientific and technical staff—and probably professional staff generally—in industry. Moreover, this should be considered in view of the opinion expressed in the report that there is little likelihood of increasing appreciably the supply of really first-class minds, although in the middle ranks there is not sufficient evidence that the limits of the potential supply of able minds have yet been reached. Again, so far as the universities are concerned, the extent of their response to the national demand for more trained man-power is conditioned by the magnitude of the grants they receive from the Government; yet when those grants are halted or reduced in the name of economy, the Government fails to concert the measures required to secure the most efficient use of existing man-power, whether they be measures to keep the supply of different types of trained man-power in balance, to ensure that a sufficient supply of supporting technicians is available, to reduce the wastage of potential ability from the schools or in other ways, or to foster the information services and the national library system upon which that efficiency so largely depends.

It is not right to suggest that the universities of Great Britain are indifferent to the problems of fitting students for life in the modern world. The recent suggestion of the General Board of the Faculties of the University of Cambridge for a new Tripos examination, and Sir Eric Ashby's May Lecture to the Institute of Metals on "Technological Humanism" are examples of how university circles are prepared to consider ways of meeting these problems. Much, however, that remains to be done must fall on the professional institutions and learned societies and on industry itself, particularly in regard to the efficient use of existing man-power and in indicating the extent to which the supply of particular categories should be expanded. Nevertheless, the major contribution must come from the Government side. Neither the plea for further thought about the functions of the schools, the technical colleges, the colleges of technology and the universities in the light of the deeper question: What is the end and aim of a human life? nor the progress already made in the expansion of technical education or in co-operation between industry and the universities, should be allowed to distract attention from the shortcomings of the Government in these respects. The simple truth is that Britain's investment in her schools and technical colleges and universities is the surest safeguard of her future. It must be maintained and expanded to the limits which the inquiries adumbrated indicate, whatever the sacrifice to be made elsewhere in other social services or in the resources lavished upon recreation and amusement.

THE UNIVERSITY OF CALCUTTA

Hundred Years of the University of Calcutta

A History of the University issued in Commemoration of the Centenary Celebrations. Pp. xxi+539+258 illustrations. (Calcutta: The University, 1957.) Rs. 25.

UNIVERSITY histories are difficult both to write and to read. Piety demands a detailed record of professors and departments, of benefactors and officers, which is mostly of only local interest. It is difficult, through that mass of material, to display, or to grasp, the main themes of the story. Calcutta's centenary volume attempts it in the form of eight chapters, written by eight members of its staff, and although there is some overlap and some discontinuity, and catalogues cannot be entirely avoided, yet themes are conspicuous and they remain distinct.

Higher education on a Western model began in India a century and a half ago, in the form of sporadic colleges, some private, some with Government support. The first University was that of Calcutta, established in 1857 as an examining body, which affiliated colleges to itself, conducted entrance and degree examinations for their students, and thereby exerted an important but external influence on their teaching. Not until half a century later did it become a teaching institution itself and then only at graduate-level and in certain professional schools. Its 80,000 undergraduates are to-day still mostly in affiliated colleges. To adjust the relations between University and colleges has been a major and continuing problem. So also has been the relation between University and Government. The University, like some of its colleges, was a Government creation, largely Government managed. Too much Government control, in the pre-1947 years, was seen as foreign domination, but also as a limitation of academic freedom. In 1923 it was dramatically, but unsuccessfully, resisted, at a time when the University had weakened its own position through getting into financial difficulties; its famous vice-chancellor, Asutosh Mookerjee, then scornfully rejected Lord Lytton's offer to re-appoint him for a further term, because the offer was coupled with a condition that he withdraw his opposition to the Government's University Bill. The University is still more a subject of the Government than a partner with the Government, but a step towards responsible independence was taken in the Calcutta University Act of 1951, which recast the constitution and re-organized the administration.

Burdened on one hand by so large a brood of foster-children (there are now 123 colleges), and hampered on the other by severe financial limitation and close dependence on the Government, the University has nevertheless struggled to achieve good academic standards. In the work of its best scholars and in its development of research it has had undoubted success, but at undergraduate-level the recent flood of students has overwhelmed it. "There is hardly any doubt that the gain in quantity has been offset by the loss in quality. The mechanical examination system, defective teaching, expenses of education, decline of the middle class and many other factors are responsible for the fall of standard." So writes the author of Chapter 8; and the Vice-Chancellor in his crisp foreword, recognizing this situation, is much more concerned with the task of the future and the restoration of standards than with casting his eye over the past. So, among the handicaps, complacency is not one, and therefore in spite of the dismay that strikes the insular English visitor at the sheer size of the place and its problems, we may expect the University of Calcutta in its own way to find the answers, and to maintain the place of respect which it holds among the universities of the Commonwealth.

ROBERT AITKEN

INFECTION BY ANAEROBES

Biologie des Maladies dues aux Anaérobies

Par A. R. Prévot. (Collection de l'Institut Pasteur.) Pp. 572. (Paris: Éditions Médicales Flammarion, 1955.) 2,225 francs.

THIS book can be regarded as a continuation of the classic treatise of Weinberg, Nativelle and Prévot, "Les Microbes Anaérobies", which gave a comprehensive survey of the anaerobes and infections caused by them for the period 1877–1937. The present volume carries on where the earlier one left off, and deals with the period 1937–55.

In the admirable introduction the author explains the purpose of the book. The main emphasis is on the application of biological principles rather than on clinical details. Great importance is attached to the ways in which increasing knowledge of chemical microbiology, of serology, of pharmacology ('physio-pathologie') and of histopathology has advanced our understanding of the lines on which control of these infections can be achieved.

The first half of the book deals with 'exogenous' diseases caused by toxigenic anaerobes—tetanus, botulism and 'gangrenes'; the second half with 'endogenous' diseases caused by virulent but non-toxigenic organisms such as anaerobic cocci, fusiform bacilli, actinomycetes and others.

The first chapter is on tetanus. This is considered under the heading of bacteriology, toxin, anatoxin (toxoid), spontaneous and experimental tetanus, immunology, and finally treatment. The evidence on the route of transmission of the toxin is fully discussed, and great importance is attached to the decisive work of Payling Wright and his colleagues which has cleared up a number of controversial points. In a later section there is an interesting table showing the downward mortality trend for tetanus in France since 1943. The author points out that, in spite of this downward trend, tetanus with 577 deaths in 1953 killed nearly two and a half times as many people in France as poliomyelitis. In spite of all the advances in our knowledge tetanus still has an appallingly high mortality, varying from 50 up to even 90 per cent.

The chapter on botulism follows the same general plan. Here again, although we have learned a great deal about the biology of botulism in the past eighteen years, we still have no really rapid means of making a diagnosis before it is too late, and serum treatment, even though more effective than serum treatment of established tetanus, often fails.

The third chapter consists of several sections dealing with the different groups of *Clostridia* associated with gas gangrene and similar infections. The biochemical aspects both of the organisms and of their toxins are fully reviewed, and the work of Evans, van Heyningen, M. G. Macfarlane, R. G. Macfarlane, Miles, Oakley and others, is well discussed.

Part 2 of the book deals with the infections caused by 'endogenous anaerobes'. These infections are quite different from the intoxications dealt with in Part 1. The organisms live normally as saprophytes in various animal or human tissues and become virulent when there is a breakdown in the natural defences, when they provoke first a focal infection and later perhaps a generalized infection spread by the blood stream to distant parts of the body. Many of the organisms in this group are rare and little known; others are fairly common and well known, but the nomenclature used by Prévot, though generally recognized by Bergey, is by no means familiar to all bacteriologists. It would have been very useful to have a comparative table setting out the various alternative names for such words as *Ristella*, *Sphaerophorus*, *Zuberella*, etc., and to see side by side a few at least of the commonly accepted alternative names.

The book contains about 2,300 references. Since it covers a period of eighteen years, this represents an average of 127 publications each year. The author compares this with the average output of sixty each year in the earlier work. References are given at the end of each chapter or main section. It is a pity that authors' initials are not given. At best the omission is trying, at its worst it may be confusing as, for example, with the name Macfarlane, which in addition is spelt wrongly both in the text and in the bibliographies. The system of arranging references first under the appropriate year and then in alphabetical order has much to recommend it.

The book has achieved admirably the author's declared purpose—to give a comprehensive review of the biology of anaerobic infections from 1937 to 1955, and must be regarded as a standard work of reference on this interesting and still intricate branch of bacteriology.

R. Knox

EXECUTIVES IN INDUSTRY

Promotion and Pay for Executives

By Dr. George Copeman. Pp. 219. (London: Business Publications, Ltd., in association with B. T. Batsford, Ltd., 1957.) 18s. net.

FOR the scientist, the world of industry and commerce has long seemed to portray all the features of a dark impenetrable forest; its paths overgrown with tangled roots and creepers; its overhead foliage precluding the light of knowledge; its deeper recesses possibly hiding fearsome monsters. To launch one's life into so unknown and incomprehensible a domain could be hazardous in the extreme, and—more serious—could in the end turn out as a futile and unrewarding journey. So the scientist has sought his career in more readily appreciated territories.

Yet industry to-day needs the scientist almost more than anything else, and service in industry can afford to him a career with objectives of high national, social and professional purpose. A genuine barrier to entry into such service is found in the ignorance of opportunities—not so much in the sense of not knowing where the openings lie (for this gap in knowledge has been amply filled in recent years), but in lack of the means of assessing potential lines of advancement and the monetary rewards for high performance. Dr. Copeman's study is the first serious contribution to filling in that gap—hitherto only inspectors of taxes have known the secrets of financial advancement in terms of real sums of money.

Dr. Copeman's book, it is true, is no more than a minute contribution, for the sample of fifty executives is infinitesimal, and among these the proportion of scientists is very small. But this should not belittle the real value of the contribution. Its form is a series of detailed career patterns of a "fairly representative sample" of executives from different industries, in different localities, of varying ages, and ranging in present salary from £1,100 to £15,000. The data are reliable, for they are based on personal individual interviews, with guaranteed anonymity. For the benefit of those who enjoy comparative reading, the data are given in tabular form, concisely distributing the fifty specimens in terms of age-groups and salary-range. No general lessons are deduced, nor could they be; but the serious reader can draw for his own guidance useful ideas as to possible levels of salary and promotion, relative to age and length of service, in reasonably typical industrial environments. In no sense of the term is this study 'scientific' but it could be found of genuine practical value by many a qualified man attempting realistically to assess his prospects of fortune in an industrial career.

A second half of the book goes into more intangible realms, with chapters on "Qualities of Leadership", "Organising", "Ideas", "Frustration", "Seeking Promotion". Here the author has endeavoured to synthesize the views expressed by his fifty high-level 'guinea-pigs', with an added measure of his own interpretation. Here his study is correspondingly more open to argument, to disagreement and to scepticism. Inevitably, the range of views on any one topic is wide and diversified; the author's own interpretative synthesis has offset the mutually contradictory elements, and he has tried to emphasize the practical value of his findings by a brief summary of points at the end of each chapter. Yet their very succinctness posits superficiality. To the novice on the brink of a career they may well serve as the modern counterpart of the once-famous Dale Carnegie aphorisms on self-advancement; to the serious and established reader they may perhaps usefully serve as reminders—a simple guide to checking whether executive responsibilities are being competently and constructively discharged. Objective and permanent values apart, in all the aspects covered the study makes interesting reading. E. F. L. Brech

MECHANICS OF ELECTRONICS

Mechanical Design for Electronics Production

By John M. Carroll. Pp. xx+348. (London: McGraw-Hill Publishing Company, Ltd., 1956.) 49s.

If we were to represent the activities of those engaged upon the development and application of electronic equipment by a Gaussian distribution, we would see a few advanced designers and specialists rising above a wide base of detailers and technicians.

Among these 'other ranks', there will be few who would not benefit by a perusal of the present volume. So much detail must usually be delegated to others that it is most desirable to have a wide dissemination of knowledge of good current practices.

The circuit and system designer who can find time to study this book will uncover much food for thought, particularly concerning production processes, where some of the details given are unlikely to be known to those who have not had considerable experience in a number of the departments of a modern factory. The relation between system or circuit sub-division and modular construction is presented particularly well.

A high standard of mechanical construction is essential to-day for military equipment, and in waveguide systems a high degree of precision is required. These standards are not always found in laboratory-constructed equipment, and manufacture from the resulting 'prototypes' may be delayed by a further phase of production engineering which could be avoided or carried out at an earlier stage.

The organization of this book is interesting, as a method of putting forward up-to-date and comprehensive information in a field subject to rapid changes of technique. The author first published the material as a group of articles on mechanical design in the journal *Electronics* late in 1954, the contributions being made by some fourteen mechanical engineers experienced in the electronics industry.

As now published in 1956, the material has been re-arranged as chapters, and brought up to date with respect to mechanized assembly methods, automatic testing and materials. The references are mainly to sources and proprietary names known in the United States, but a British reader will not find himself handicapped appreciably. The book could have been prepared from British sources, but it is doubtful if we have the editorial resources to execute it.

The contents cover a considerable field in adequate detail, with much reliance on photographic illustrations of processes and line drawings of mechanical design details. Attention is given to the importance of mechanical design, and to the space-planning of equipment layouts. Chassis layout is dealt with in detail.

Processes used in the fabrication of cabinets, chassis and small parts are described rather fully, wiring and soldering are dealt with, and components and assembly methods described. Useful technical information is provided on mechanical design details, rotary machines, materials and environmental factors. D. L. Johnston

NEAR-EASTERN ADVENTURES

Adventures in the Nearest East

By Cyrus H. Gordon. Pp. 192+23 plates. (London: Phoenix House, Ltd., 1957.) 25s. net.

This is a very readable book. It has not been written for the academic specialist who requires all the details carefully documented, but in a pleasant manner it conveys a lot of interesting archæological information. The author knows what he is writing about and the result is a correct account of what he himself has seen and studied. For example, the chapter on the Dead Sea scrolls is an admirable account of the finds and their significance, though it is not intended to be in any way a detailed study of these important discoveries. Interspersed with the account of his journeys and digs, he gives us stories of such everyday trifles as how he had to play the part of an amateur doctor or oculist.

Prof. Gordon opens by telling his readers of his journeys in Edom and Moab, a land still little known, even under its new name of Transjordan. Other chapters deal with accounts of digs and of finds of works of art. The Ugarit Kingdom, which flourished during the Bronze Age in northern Syria, is still little known to the average archæologist; yet it is of considerable importance. There a number of tablets have recently been unearthed, the language being akin to Phoenician and Hebrew. Many of the texts are mere business documents, others are of a ritual nature. A number record poetically the lives of the North Canaanite gods whom the Israelites are forbidden in the Old Testament to worship. But there appears also in some of these texts the indication of the beginning of an ethical religion such as we do not find again until it reappears with the early Hebrew prophets of the eighth century B.C. A chapter on the military correspondence of the last days of Judah gives a useful commentary on the immediately pre-exilic period there, and should be read alongside the Old Testament story. Final chapters deal with "The Fathers of Egypt" and "A World of Demons and Liliths". The work is well illustrated, and there are at the end a number of notes and a short bibliography. Many people, both archæologists *de métier* and interested amateurs, will read Prof. Gordon's book with pleasure and profit. M. C. Burkitt

Physiopathology of the Reticulo-Endothelial System

A Symposium organized by the Council for International Organizations of Medical Sciences. Edited, under the direction of B. N. Halpern, by B. Benacerraf and J. F. Delafresnaye. Pp. xii+317. (Oxford: Blackwell Scientific Publications; 1957.) 45s. net.

It is greatly to the credit of Dr. Bernard Halpern and his colleagues that this symposium was organized and its proceedings compiled.

Generally speaking, the reticulo-endothelial system has not made sufficient impact on the medical world and its significance and importance are more or less poorly understood. A monograph of this kind containing formal papers, as well as summaries of discussions, is of special value since it shows the manner in which research results were studied and compared by investigators from different countries. It brings to light many factors of the physiology and pathology of this system applicable to the clinical field. Three of its important functions were specially studied—its phagocytic activity, its metabolic functions and its role in defence against bacterial infection. It was shown that phagocytic activity is influenced by the size of the liver and spleen, which are the main phagocytic organs, the volume and velocity of blood flow, the functional state of the phagocytes, and the chemical constitution, size and number of the particles of injected substances. Evidence was also presented indicating that the reticulo-endothelial system is also concerned with the elimination of blood cells, with iron and fat metabolism, with the formation of antibodies, with the production of fibrosis, and with the removal of bacteria from the circulation. It appears to be the most efficient line of defence against bacteræmia.

It is surprising, however, that no direct reference has been made to the influence exerted by the steroid hormones, which have been found to be the greatest stimulants of reticulo-endothelial activity. Further, in our laboratory vitamin B_{12} and choline were found to be mild depressants and not stimulators, as here reported.

This symposium has been a valuable contribution to research on the reticulo-endothelial system and provides the most up-to-date account of the subject available. It is hoped it will be followed by many others in this important field of investigation.

D. L. J. Bilbey

A Bibliography for the International Geophysical Year

National Science Foundation. Pp. vi+51. (Washington, D.C.: Government Printing Office, 1957.) 25 cents.

The foreword to this bibliography states that it is neither definitive nor selective, is imperfect in many respects, and consists, for the most part, of discrete articles, the majority of which are of a non-technical nature. The reviewer can only emphasize the fact, implicit in the quoted description, that this bibliography is inadequate for the needs of the scientist professionally concerned with the International Geophysical Year. A large number of the 600 or so articles listed consist of popular articles in American magazines.

Thirteen of the 37 bibliographical pages are devoted to Earth satellites, but even in this subject it was easy to think of a scientific article, one published in *Tellus* in 1956, which was not included. Articles in the scientific press of the U.S.S.R. are not listed, reports of Russian work being almost entirely limited to press releases from the Soviet Embassy in Washington.

Besides the bibliography there is a general account of the administration of the International Geophysical Year, and a comprehensive list of members of the U.S. committees concerned with it.

G. A. Bull

Forest Fungi

By Margaret E. Lancaster. Pp. 96. (Wellington: Government Printer, 1955.) 9s. 6d.

This attractively produced book, designed as a fairly elementary manual on forest mycology for use of the field staff of the New Zealand Forest Service, is disappointing in several respects. With such a title and so few pages, one does not expect a third or so of the text to be devoted to an account of elementary botany and an outline classification of the plant kingdom.

In the preface, the statement that "It is apparent that a basic understanding of the broad essentials of growth and reproduction of all plants is a prerequisite for even a cursory study of such a specialized group as the fungi" is, broadly speaking, true, but it was unwise here to waste space in attempting the impossible. The remainder of the book deals with the classification of fungi generally and gives a summary of the individual families with special attention to those including representatives pathogenic to trees. This is a fairly good text-book outline, well illustrated, but, in spite of a full glossary, much beyond the comprehension of the type of student for whom it is apparently intended. In compiling it the author has occasionally nodded through making generalizations. A few minor errors have been corrected in an inserted errata slip. One of a kind which haunts proof-readers, *Dictyota* for *Dictyophora*, should be added—and *Eurotium* is the perfect stage of *Aspergillus*, not of *Penicillium*.

J. Ramsbottom

Species Studies in the British Flora

Edited by J. E. Lousley. (Botanical Society of the British Isles Conference Report No. 4.) Pp. 188. (London: Botanical Society of the British Isles, c/o Department of Botany, British Museum (Natural History), 1955.) 20s.

This volume is the report of the fourth conference of the Botanical Society of the British Isles, held in London in 1954. These biennial conferences have become an important feature of the activities of the Society, providing an opportunity for the presentation and discussion of work on all aspects of the British flora. The present report contains twenty-six contributions, mostly of high scientific merit. It is unusual in including a number of valuable papers upon the problems of bryophytes and thallophytes, since the work of the Society is traditionally limited to vascular plants with a minor descent to embrace the orphan charophytes. The contributions are from botanists both amateur and professional, for the Botanical Society is one of the few remaining scientific societies in which amateurs and professionals continue to work actively and amicably together with mutual comprehension and profit. While productions as informative as this report continue to emerge, one is moved to hope the collaboration will long continue.

WETTING AND SPREADING OF LIQUID METALS ON SOLID METAL SURFACES

DEVELOPMENTS in modern science which open up new fields of academic and industrial activity also have a direct impact on the older, established applied sciences. These generally undergo a transition from empiricism to the development of the scientific basis of the subject. In most cases this transition has already taken place or is well under way, but it is only just beginning in the heterogeneous group of subjects, soldering, brazing, welding and the gas-cutting of metals, which comprises one aspect of the science of metallurgy. The demand of modern industry to be able to join an ever-increasing variety of metals and alloys by a multitude of techniques has resulted in a considerable expansion of research activity in industry, research associations and the universities. One hundred and forty representatives of these bodies attended a conference on "The Wetting and Spreading of Liquid Metals on Solid Metal Surfaces" held at the University of Birmingham on September 25 under the chairmanship of Prof. E. C. Rollason, head of the Department of Industrial Metallurgy. In his opening address, Prof. Rollason explained that it was planned to hold occasional conferences on various aspects of the joining of metals, of which this was the first. In this way the practical experience of industrialists could aid the University in deciding the direction of its efforts and further the formation of general principles which are important in the teaching of the undergraduate. In turn, the University hoped to provide a useful stimulus to industry by contributing another point of view. Four papers, by Mr. D. R. Milner, of the Department of Industrial Metallurgy; Mr. E. V. Beatson, of Joseph Lucas, Ltd.; Dr. J. C. Chaston and Mr. M. H. Sloboda, of Johnson Matthey, Ltd.; and Mr. A. Cibula, of the British Non-Ferrous Metals Research Association, were then presented and discussed.

The phenomena of wetting and spreading are of prime importance in the formation of brazed and soldered joints, and in practice often present considerable difficulties, while scientifically they require an interesting extension of classical physical and chemical principles to take account of the complexities and interactions which occur in practical systems. Thus, the well-known equilibrium surface tension theory which relates, first, the surface free energies to the interfacial energy and contact angle; and secondly, the pressure difference across a curved liquid surface to its radii of curvature and surface free energy, implicitly assumes no interaction between the solid and liquid and that the solid surface is plane and clean. In all soldering and brazing systems, however, there is some interaction which cannot be ignored. Mr. Cibula's paper was largely concerned with one of the most important of these, namely, alloying between the liquid and solid metal, which can become of over-riding importance at high temperatures. Thus, a liquid drop when placed on the solid surface takes up a shape dependent on the surface and interfacial free energies and then spreads out as alloying takes place, the rate of spread depending on the solubility of the liquid in the solid metal. However, marked alloying results in erosion of the solid metal and a considerable change in the properties of the liquid. Erosion is generally undesirable and may be controlled by using a mixture consisting of a liquid which has limited intersolubility with the solid and a small proportion of a more soluble metal. Increasing the superheat has a marked effect on the rate of spread as it increases the rate of alloying. A particularly important case of this kind occurs when the liquid flows over the solid and interacts to form an intermetallic compound layer at the solid surface greatly reducing its free energy, with the result that the liquid layer becomes unstable and 'dewets' by retracting into an array of isolated drops.

There are other forms of interaction and it has been shown, for example, that the surface tension of solid copper is reduced to less than half its 'clean' value in the presence of lead due to the absorption of lead vapour. When a flux is used, further interactions are possible; metal can be transferred from the liquid metal on to the solid surface by an electrochemical mechanism; surface energies can be altered by electro-capillarity forces and chemical reactions can take place between the flux and the metal. The latter is made use of in the so-called 'reaction fluxes' for the soldering and brazing of aluminium; these fluxes contain zinc chloride, the zinc being replaced by the aluminium and deposited as a liquid layer on the aluminium surface. Since zinc is much less readily oxidized than aluminium, wetting and spreading are promoted.

Oxide films are present on the majority of metals and have to be removed before satisfactory wetting can occur. Fluxes are often used for this purpose, but the exact mechanism by which they act is obscured by the lack of knowledge of the behaviour of molten salts. One thing is becoming clear, however: although fluxes may remove the initial oxide film, oxygen can still diffuse through to reoxidize the underlying metal and retard spreading and flow. An account of the particularly interesting case of the fluxing of stainless steel was given by Dr. Chaston and Mr. Sloboda. In this case the interaction with oxygen appears to be more complex than usual, as in some fluoride-containing fluxes the chromium is preferentially oxidized out of the surface layers, leaving a deposit of iron fluoride, which, having the relatively low surface energy associated with ionic compounds, gives rise to a large contact angle and poor flow of liquid brazing metal.

Mr. Beatson dealt with the two other common methods of removing oxide films, heating in a reducing atmosphere and heating *in vacuo*. The reduction of oxides by hydrogen or carbon monoxide has a sound thermodynamic basis and it is not difficult to derive the critical value for the dryness of hydrogen or critical carbon dioxide/carbon monoxide ratio above which the oxide cannot be reduced. Below this value, however, the kinetics of the system must be considered and no generalizations are as yet possible, other than that above 1,000° C. thermodynamically favourable reductions appear to take place within a reasonable period of time, while below this temperature an answer can only be given by resort to experiment. Perhaps the major limitation of the thermodynamic approach is that at present it can only be applied to pure metals, whereas in practice it is generally necessary to consider alloys, which are sometimes very complex and often contain a proportion of a metal which forms a highly stable oxide. The use of atomic hydrogen for oxide reduction appears to offer interesting potentialities, as thermodynamically it is considerably more favourable. Since dissociation of molecular hydrogen at the metal surface may constitute a major part of the activation energy involved in oxide reduction, the kinetics may also be more favourable. In this connexion there is an interesting process which is finding increasing application to the frequently occurring problem of the construction of fine thermocouples. The thermocouple wires are twisted together and made the cathode of an electrolytic cell in which the electrolyte is 15 per cent aqueous sodium carbonate solution contained in an iron vessel which is the anode. A potential of 80–220 volts is applied to give a high current density and atomic hydrogen is freely liberated at the cathode, reducing any oxide, while the heat of recombination suffices to fuse the ends of the wires together.

The developing use of vacuum brazing illustrates the advanced techniques necessary in modern metal-joining practice. The use of vacuum or an inert atmosphere, generally argon in Britain and helium in the United States, is essential for the brazing of the highly reactive metals such as titanium, zirconium and molybdenum. The 'Nimonic' alloys, which are so important in the development of the gas turbine, are also frequently brazed in a vacuum. The manner in which a metal surface is freed from oxide by heating *in vacuo* is open to conjecture and various opinions were expressed at the Conference, such as solution of the oxide into the metal, or vaporization of the oxide film.

The analysis of the flow of the liquid metal into a joint under the influence of capillary forces presents considerable difficulty. A simple model has been set up in which laminar flow is assumed to take place, but although the size of the capillary passages and the velocity of flow are well within the limits for laminar flow under steady-state conditions, it is doubtful whether this applies to the 'once and for all' filling of a joint. Experiments made on the flow of solder into capillary passages between copper sheet and tinplate give an actual time of flow about twice that predicted theoretically. Mr. Cibula showed that at high temperature, unless special care is taken, the whole analysis becomes meaningless, because temperature gradients enable the liquid to flow all around the relatively hot periphery of a joint, giving a satisfactory-looking fillet but leaving the colder inner portion unfilled. Alternatively, alloying can occur, increasing the melting point of the liquid before it has time to enter far into the capillary.

The points raised during the discussion clearly reflected the preoccupation of those engaged in solving current problems. Thus the difficulty of maintaining the desired purity of hydrogen and predrying techniques when using production heating furnaces received some discussion; removal of water vapour and oxygen by zirconium or magnesium turnings within the furnace, and the use of the gases boron trifluoride and silicon tetrafluoride were all mentioned. There was considerable discussion of the problem of voids, which may occupy from 5 per cent to as much as 50 per cent of the total area in brazed joints, and in addition to non-uniform heating it was claimed that shrinkage or gas evolution on cooling, and incomplete oxide removal were all significant. The problem of the wetting of stainless steel and the 'Nimonic' alloys was raised by several speakers; the former can be solved by ensuring the use of adequately dry hydrogen and the latter by the use of a vacuum better than one micron. Difficulties associated with the other less widely used metals such as tungsten and molybdenum were also mentioned, but the range of applications and problems which are now confronting workers in this field was perhaps best illustrated by the representative of a firm manufacturing transistors, who stated that when 'brazing' germanium with indium, wetting and spreading were determined by the dislocation density and indices of the crystal face being brazed.

D. R. MILNER

NUCLEAR ENERGY AND THE GROWTH OF MAN*

By DR. ARTHUR H. COMPTON
Distinguished Service Professor of Natural Philosophy, Washington University, St. Louis

MY prime concern is the urgency that availability of nuclear energy gives to world-wide co-operation in the cause of humanity. It is toward such co-operation that we must now look for the growth of man.

In the programme of 'Atoms for Peace', emphasis has been laid on the usefulness of the energy of the nucleus. This is as it should be. We are using this energy in the form of radiation for diagnosis and healing of disease. We are using isotopes as tools in science and industry. With the important steps already made, we see electric power from nuclear furnaces ready to meet a great human need for a long time to come.

Consider as an example the use of nuclear radiations in the art of healing. Such use began with the discovery of X-rays and radium at about the turn of the century. Estimates have been made of the effectiveness of these rays in diagnosis and therapy. These estimates are necessarily only approximate; but they do show this, that by the use of these rays throughout the world some tens of millions of lives have been saved. This number is roughly the same as that of the lives destroyed in all the world's wars fought since their discovery. In this way alone our concern with atoms and nuclei has opened to a great multitude of men and women more complete physical health and life.

But important as it is, here is not our prime point of emphasis when we think of nuclear energy and the growth of man.

---

* Substance of an address during ceremonies marking the presentation of the Atoms for Peace Award (*Nature*, 179, 698; 1957) to Prof. Niels Bohr at the National Academy of Sciences, Washington, on October 24.

The prime point is rather this: science and technology have provided us with unprecedented new powers. We are acutely aware that these powers can bring us either greater opportunity, or destruction and death. In this regard, nuclear energy is only one dramatic example of the new possibilities that science holds before us, possibilities for good or ill in truly startling measure; and the rate at which science is presenting man with these unprecedented powers is increasing at enormous speed. Furthermore, each such technical development multiplies the effectiveness of those that went before. This is a condition similar to that recognized in science as dynamic instability. We must expect the balance of world-power to be continually shifting as new technical advances, occurring in different parts of the world, make more effective the use of the strength already in men's hands. The stability of civilization itself is thus at stake.

Immersed in the immediate task of protecting freedom, we must not fail to look to the future. For a limited period we may hope to prevent war by keeping a strong and sure defence; and never was an alert defence more needed than to-day. But to bring stability among sovereign nations only one way is open. They must be united by some human goal worthy of their strength. There is no other hope for a peace that will endure.

If mankind is to prosper, if civilization is even to survive, it is necessary that steps be taken which will ensure that our new powers will not be used for destruction. We must turn them toward enabling men and women to grow. The time when we need the assurance of the human use of technical strength is now. Every day we delay constitutes a statistically significant lessening of mankind's chance for survival. I am not exaggerating. The seriousness of the dangers and the greatness of the corresponding opportunities are evident to all who have examined the changing situation of man.

What can be done that man's new-found strength will be used for building, not destroying, our civilization? This is the all-important question. Let me repeat: if co-operation is to replace antagonism among nations, it will come only as they agree upon some common objective which will inspire the whole-hearted support of their people. Such an objective cannot be one which places the interests of one nation above those of another. To be affirmed by all nations it must relate to the needs of all men and women.

There exists such an objective that during the past half-century has arisen throughout the world as a hope in the hearts of men. In the United States we have known this hope since before our nation was founded. We call it "the American Dream". Our vision is of a place where every man and every woman can grow to the best that is in them and be recognized for what they do to help others share this opportunity. Some years ago I showed to Mme. Pandit a description of this vision as written by our late historian, James Truslow Adams. "You call that the American Dream," she exclaimed. "It has become the dream of the world."

Let us examine the answer to our central question that this dream suggests. To state the proposal specifically, it is this. Let every nation affirm, as basic to its policy, this principle: that it will do all in its power towards opening the way for everyone under its jurisdiction to grow to his full human stature, and will co-operate with nations affirming and adhering to this principle in helping each other provide such opportunity for their people.

In accord with this principle, each nation that thus commits itself will endeavour to direct its own actions so as not to interfere with those of other co-operating nations in their efforts on behalf of their people. It will consult in advance before taking action that might affect adversely the plans of another co-operating nation. It will join with other such nations in defence against threats to any of them regarding its internal actions on behalf of its citizens.

The intent of the proposal is to turn the world's resources toward enabling men and women to become able and responsible citizens of their respective nations. Each nation co-operating to this end retains its sovereign right to choose its own method for providing its citizens with increased opportunity. Each can also count on the help of the others in providing and defending these opportunities. Can a government, the prime responsibility of which is the safety and welfare of its citizens, agree to a policy that has in it so much of altruistic content?

In answer we note that every nation's safety and welfare require assurance of co-operation by other nations. On no lesser objective than opening the way for all men and women to grow more fully can one nation expect to win the co-operation of other nations that are free. With acceptance of this objective as the alternative to national aggrandizement, both the safety and the well-being of a nation's citizens will be as firmly assured as is possible under present world conditions.

Powerful support of such a policy can be counted on. Thus a nation's leaders must recognize that only as its citizens grow in health and understanding and have their heart in its objectives can the nation's strength be fully realized. Such growth is, however, at its best only through co-operation on an international as well as a national level.

Every organization to which men look for inspiration is concerned that each person shall have open to him a life of meaning. Whether one's first loyalty is to his eternal God, or to the principle of right-dealing with his fellows, or to his system of government, the highest expression of that loyalty lies in promoting the health and human growth of men and women. Commitment to such a great human goal is precisely what is needed to give incentive to a person's best effort and meaning to his life.

To an increasing degree, society is giving its rewards to those who are opening new opportunities which all can enjoy. The Atoms for Peace Award is an example of this trend in public acclaim. Economic pressures and public opinion are encouraging every effort that would provide men and women with wider opportunities for growth as human beings.

In the autumn of 1945, Niels Bohr made an appointment to talk with me as we were journeying together toward Washington. Six months before, at Los Alamos, we had spent hours discussing how use of the atomic bomb, newly developed but not yet tried, might be turned toward establishing a harmonious and enduring peace. Following these discussions, one great question was now on his mind. "Is it not possible," he asked, "for the United States to perform some great moral act that will give hope to the world?" I suggested an action similar to what became the Marshall Plan, of economic help to the nations where help was needed. "Good," was his answer, "but this is not the basic thing we need." In our discussion we failed to pinpoint what great moral act by our nation could accomplish what Bohr had in mind. Perhaps the time was not yet ripe.

The experiences of the past decade have opened our eyes. The American dream has grown to be the dream of the world. This dream must now become the world's united, all-compelling purpose.

The era of nuclear power began fifteen years ago as a result of unprecedented international co-operation. Those whose efforts were responsible for the birth of the era, and especially the scientists, were inspired by the hope that this new-found power would bring fuller life to all mankind. The Atoms for Peace Award is a symbol that our nation shares and cherishes this hope. Niels Bohr has called on America to lead the world in another great co-operative venture. This venture is that of committing the united efforts of the nations to the human growth of man. If in earnest we undertake to direct our own nation's prime efforts to this end, if we can bring the world thus to use to the full the powers of science and technology, the bright hopes inspired by nuclear energy will bear their full fruit.

Let us, the United States of America, proclaim boldly that what in our hearts has long been a precious dream is henceforth the corner-stone of our national policy. Let us call on all nations to share this policy with us, that the world may work as one toward giving every man and every woman the opportunity to grow to his full human stature. Let us put our policy into practice by assuring all nations who will share this commitment that we will counsel with them regarding our proposed actions of international concern, and will co-operate with them in providing their people and ours with means for healthy growth.

With such leadership in our present anxious world we can count confidently on a strong following. We may hope that our first steps will bring co-operation on an ever broader basis. It is a reasonable expectation that antagonisms will thus gradually be displaced by mutual confidence, and that peace based on harmony will grow.

No, competition and rivalry will not decline, but it will be with a new spirit. As the dream of the world is transformed into one united purpose, men and nations will seek to outdo each other in advancing the human worth of man. Because life then takes on meaning, our civilization itself will stir with new strength.

With such powers as nuclear energy in our hands, the need for affirming this united purpose is immediate and is vital to mankind. Failure by the United States to make this commitment and to call on all nations to do likewise will leave the world in jeopardy. Acceptance of this leadership will give new hope. It will put new life into the world. If we are unwilling to take the lead, to whom shall we look?

UNIVERSITY OF BERGEN

NEW LABORATORY BUILDINGS OF THE BIOLOGICAL STATION

By PROF. HANS BRATTSTRÖM

Director

ON September 10, 1957, the new laboratory building of the Biological Station, Espegrend, was officially taken over by the University of Bergen (Fig. 1).

The Biological Station at Espegrend has had two predecessors. The first Station, inaugurated on September 10, 1892, was situated in Bergen. In the beginning it was mainly devoted to fisheries investigations, but after the Fisheries Directorate had been established in 1900, fundamental research in the marine sciences became the main task of the Station. Besides, it played an important part in the international courses in marine research which were arranged by the Bergens Museum. In 1917, the new Geophysical Institute took over the physical oceanographical programme of the Station, and in 1921 the biochemical investigations were transferred to a new Biochemical Institute. From then on the Station became a purely biological station, mainly devoted to fundamental marine biological research and education.

For various reasons the Station had to be closed down in 1921; but in 1922 a new and better Station was opened on the island of Herdla, north-west of Bergen. After almost twenty years of intense activity Station number two also had to be abandoned a short while after Norway entered the Second World War. For ten years the Station was on the move, until in 1949–50 staff and equipment were transferred to Espegrend, where the Bergens Museum (now the University of Bergen) had acquired new premises. Here the Station has worked under provisional conditions until the new laboratory building was ready in September this year.

The new Station is situated in one of the most charming parts of western Norway. It lies at the eastern shore of the Raunefjord, 20 km. south-southwest of Bergen, and it has road connexion with this town. The location is well suited for all kinds of marine research. Many different types of biotopes can be reached within a short time, from the extremely exposed rocky shores of the North Sea with high salinity, to sheltered fjords, bays and pools with more or less brackish water. Of special interest are the great deeps of the fjords, the current-swept shallow sounds with rich epifaunal communities, the *Lophelia* reefs and areas with shell sand (*Amphioxus*-bottom). Depths of 200–300 m. are found off the Station and depths of 700 m. can be reached in one hour. Also for intertidal studies the conditions are very advantageous. Several small ponds and lakes are found in the vicinity of the Station, and the landscape is very varying, providing good opportunities for terrestrial and limnological studies.

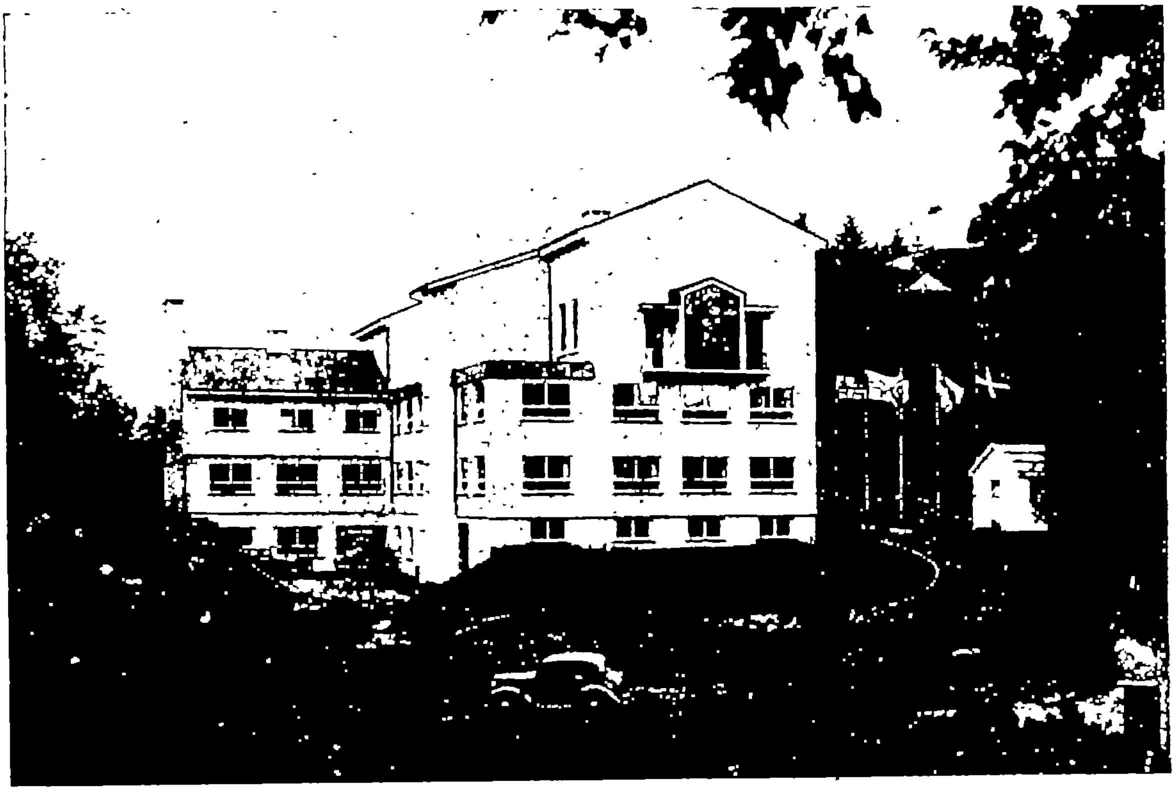

Fig. 1. The Biological Station, Espegrend

The Station has a new 63-ft. research vessel, *Fridtjof Nansen* (Fig. 2), well equipped for research down to the greatest depths in the Norwegian fjords (about 1,200 m.). The old R.V. *Herman Friele* is at present lent to the Biological Station at Trondheim. The Station also has a 30-ft. motor-boat, several rowing boats and an outboard motor. All types of gear for collecting bottom animals, fish, plankton and water samples are at hand, and also equipment for terrestrial ecological investigations.

The combined laboratory and boarding-house building is four stories high with a ground area of 575 sq. m. The fitting up of the building is being carried out in two stages. The basement, the ground floor and the first floor, containing laboratories and other service rooms, represent stage 1. This stage is complete. It is hoped that stage 2, comprising the two upper floors with accommodation for visitors, will follow shortly. In the meantime, visitors will be accommodated in other rooms and in other buildings belonging to the Station.

In addition to rooms for the scientific and technical staff the laboratory at present has available twelve rooms for visiting research workers, one bigger room for physiological and chemical investigations, and one for botanical work. The botanical laboratory has a study herbarium of marine algæ.

The Station has a small library of handbooks, marine biological journals and reprints. It exchanges publications with about two hundred other stations and institutes. Books not kept in the library can be borrowed from the University Library in Bergen.

Of other service rooms the basement contains a room for sorting material, three controlled environment rooms, storage rooms and a big aquarium hall. In the laboratory stories are two rooms for aquaria, a room for microtome work, a photographic dark room, a balance room and a room for storage of chemicals. An area of about 150 sq. m. is reserved for future work.

For educational purposes there is a teaching laboratory for 12–20 students. In this laboratory a study collection of marine animals is available. The room can be divided by curtains into five research laboratories. As additional tables are also in several of the above-mentioned rooms, the Station can accommodate about twenty research workers and 12–20 students (or twenty-five research workers). However, accommodation facilities are at present limited, and until stage 2 has been completed, the laboratory capacity cannot be used to the full.

From the Norwegian Research Council for Science and the Humanities the Station has received a sum

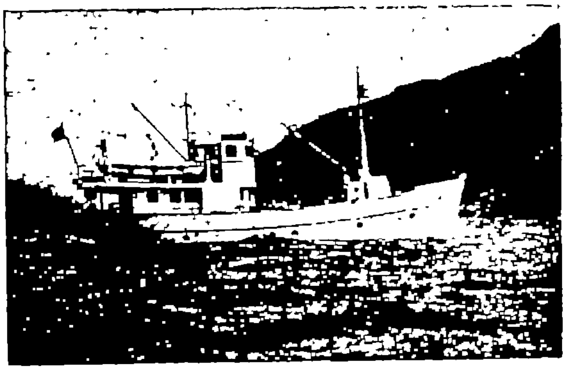

Fig. 2. R.V. *Fridtjof Nansen*

of £15,000 for equipment. Within a short time it will therefore be well equipped with standard instruments, glassware, etc., for botanical, zoological, physiological, biochemical and hydrographical investigations and for educational purposes, whereas visitors must be prepared to bring special instruments and microscopes as well as special or rare chemicals and personal laboratory equipment.

All laboratories have running cold and hot fresh-water as well as circulating sea-water. Gas, compressed air, etc., are provided by small transportable units. 220-V. alternating current is available. When furnishing the laboratories stress has been laid on great elasticity, permitting a rapid change from one type of laboratory to another.

The scientific staff is small. The Station is mainly a visitors' research laboratory, open all the year round for research workers from all countries. The visitors will get a laboratory or a table, material, instruments, chemicals and all the service that the Station can afford, all free of charge on condition that they publish their results in one of the publications of the University, unless dispensation has been given. The material collected belongs to the Station, and all types and duplicates of rare species have to be handed over to the Station after description. Furthermore, visitors must be prepared to pay for particularly expensive collecting trips and costly chemicals. Board and lodging will be available at a low price.

Application for a table should be sent to the director, if possible one month in advance (for the months June–August not later than May 1). Exceptionally the Station can send material for investigation in other laboratories on the same conditions as those mentioned above.

The Station will give courses in botany, zoology and marine biology for students from the Universities in Bergen and Oslo, and also for students from the other Scandinavian countries. The last-named courses are part of a joint Scandinavian programme for education and research recently started. The Scandinavian countries also exchange scholarship holders.

BIOLOGY OF YEAST

During the British Association meeting at Dublin, Sections B (Chemistry) and K (Botany) held a joint session on September 9, at which "The Biology of Yeast" was discussed. Prof. D. G. Catcheside read the first paper, which was on "The Genetics of Yeast". He said that although regular transmission of genetic traits to daughter cells shows that an orderly process of chromosome division exists in yeasts, the details of the mitotic process, and even the identification of nuclei and other cellular organelles, have not yet been satisfactorily settled. Yeast has a simple life cycle with an alternation of haploid (sexual) and diploid (asexual) generations. The haploid cells belong to one or other of two opposite mating types, determined by Mendelizing genes, and possessing some of the attributes of different sexes. When haploid cells of opposite mating type are mixed, they become associated in pairs and fuse to form zygotes, within which the two haploid nuclei fuse. Under conditions favouring growth the zygotes germinate to produce the diploid phase which can later be caused to sporulate by starvation. The mating types segregate characteristically in sporulation. The main difference between this process and the genetical cycle common to most higher plants and animals is that the segregation products of any one event of meiosis are kept as a group of four ascospores in the yeast ascus, and if these ascospores are isolated they reproduce vegetatively. This results in a substantial gain in genetical information, so that genetical analysis may be applied to discovering details in the life-history of yeast which have so far eluded the cytologist who studies these problems with a microscope.

Complexities may be introduced into inheritance patterns because, first, the mating types are able to mutate, though rarely, from one to the other, and, secondly, the haploids can undergo chromosome doubling by an unexplained process to produce diploids of either mating type. When the latter take part in sexual reproduction, triploids or tetraploids are formed, and these show complicated genetic segregations at sporulation, and this has in the past led to difficulty in interpretation of results. When sporulation occurs in triploids or tetraploids, mating type segregates in a trisomic or tetrasomic manner, and in either case the frequency of each type of ascus depends upon the position of the gene in the chromosome with respect to the centromere. The extreme cases are when crossing-over between the locus and the centromere of its chromosome is either zero or limiting; any particular case is likely to be intermediate between these two limits. This obviously leads to situations which cannot be recognized and distinguished without careful genetic analysis, lack of which has led to confusion in yeast genetics.

The number of chromosomes in yeast can be determined by two distinct genetical methods. The first method depends on the determination of how many linkage groups there are, while the second depends on the formation and analysis of an aneuploid zygote which is trisomic for one chromosome and disomic for the rest, so that, on sporulation, characteristic trisomic and disomic ratios may be obtained for genes located on the respective chromosomes; a disomic ratio for one factor occurring with a trisomic ratio for a second factor shows that the two factors must be in different chromosomes. At least eight linkage groups have been recognized so far by these methods, putting a lower limit of eight to the chromosome number. The recent discovery and use of linear asci should give valuable information on reduction division and the frequency with which reduction occurs at the first and second division of meiosis. By a detailed discussion of one group of inherited characters (adenine dependence, red colour) some of the techniques and results of genetic analysis were illustrated.

Prof. E. J. Conway then read a paper on "Cell Structure and Function in Yeast". Having outlined the principal structural features of the yeast cell, he pointed out that the cell membrane and its functions had been subjected to intensive investigation, and that this was not surprising as one of the most interesting features of the internal environment of this organism is its very high osmotic pressure. It is clear that there must be some mechanism which allows ions to reach the interior of the cell but prevents them from coming out again, and at least three explanations of this mechanism have been suggested: passage through pores in the membrane; solution in a lipid layer of the cell membrane; and active transport which involves temporary combination with a chemical entity at one side of the membrane and with consequent liberation at the other side. The 'cylindrical pore' theory has been investigated by finding the selective permeability of the membrane in terms of the relative sizes of the ions, due regard being had to the facts that hydration may alter the relative sizes of ions and that electrical forces depending on membrane potential difference and ion valency may affect rate of penetration of ions. It is generally true that larger ions pass through membranes only with difficulty, but no quantitative relations have been established. Danielli's theory of a double lipid layer with protein monolayers has been investigated by comparing rates of penetration of substances with their lipid solubility, and, although there is a general proportionality, no exact relation holds.

The active transport theory was then discussed by Prof. Conway with reference to studies made in his laboratory on the mechanism of acid production by yeast, on the nature of the acid produced, on the effect of acid production on the environment of the cell, and on the transport of cations across the yeast cell wall. During the fermentation of unbuffered glucose solution, yeast produces acid by two processes: liberation of succinic acid (in the absence of salts) and exchange of hydrogen ions formed internally for potassium ions (when potassium is present in the medium). The latter process, which is accompanied by a quantitative increase in bicarbonate ions in the cell, results in an accumulation of potassium ions in the yeast and an outside pH falling as low as 1·4. The experimental results are best explained on the basis of a redox system—the so-called redox pump mechanism. This hypothesis requires the existence of a mobile redox system within the cell membrane which, having been reduced, say by metabolic hydrogen, would complex with a cation at the internal boundary of the membrane; this complex would then orient itself to the external boundary, where on transferring its electrons to an acceptor system it would release the cation to the medium. It is possible to replace the internal potassium of the yeast cell by sodium or ammonium and so make the interesting 'sodium yeasts' and 'ammonium yeasts'; these interchanges are readily reversed. Although we have gained some insight into how the cell membrane functions, a description of the complete pattern of organization within the yeast cell must await further knowledge of the functioning of its subcellular components.

The third paper, on "The Biochemistry of Alcoholic Fermentation", was read by Dr. R. Davies. He referred to the fact that it was just one hundred years since Louis Pasteur published his first paper on alcoholic fermentation, in which fermentation was defined as life without air. Since then it has been found that fermentation depends on a series of internal oxidations and reductions in which energy is released in a form in which the organism can use it for synthesis of cell material. The energy is stored principally in high-energy phosphates of which a typical member is adenosine triphosphate. Because of the high energy of the terminal phosphate bond, this can act as a link between the energy-liberating metabolic reactions and the energy-requiring synthetic reactions. The fermentation of sugar by yeasts involves four phases: first the passage of the sugar across the outer cell membrane into the cell; second, the preparation of the sugar for entry into the energy-yielding mechanism proper; third, degradation to ethanol and carbon dioxide; and fourth, synthesis of cell materials. Two molecules of adenosine triphosphate are used up in phase two (this is the energy required to set the process going); four are released in phase three, so that there is an overall gain of two molecules of adenosine triphosphate per molecule of glucose fermented; these high-energy phosphates are then available for synthetic work in phase four. The series of reactions in phases two and three, which are known as the Embden–Myerhof–Parnas glycolysis system, involve the chain glucose, glucose-6-phosphate, fructose-6-phosphate, fructose-1 : 6-diphosphate, phosphoglyceraldehyde (and dihydroxyacetone phosphate), 1 : 3-diphosphoglyceric acid, 3-phosphoglyceric acid, 2-phosphoglyceric acid, 2-phosphoenolpyruvic acid, pyruvic acid, acetaldehyde (and carbon dioxide), and finally ethyl alcohol. The interconversion of each pair of these intermediates requires its own enzyme and frequently a coenzyme. The action of these enzymes accounts for alcoholic fermentation of glucose or fructose, but for the fermentation of galactose at least three further enzymes are required, and these enzymes may correspond with three dominant genes shown by genetical investigations to be involved in galactose fermentation. In the passage of sugar into the cell (phase one) it has been found that the cell membranes exhibit highly specific permeabilities and that some ions pass into the cell only by active transport, which takes place while the cell is metabolizing. The uptake of amino-acids, and of certain β-galactosides, by *Escherichia coli* involves active transport but also appears to be mediated by substances having all the properties of enzymes which have been called permeases. For yeast, only the uptake of α-methylglucoside has so far been shown to involve permease action. It may be that the formation of permeases is genetically controlled and it is possible that if rate of fermentation of a sugar is limited by permease activity, this may provide an explanation of cases in which an oligosaccharide ferments at a higher rate than its component hexoses.

The fourth paper, on "Yeast Biology in Relation to Fermentation Techniques", was read by Mr. R. B. Gilliland. He first mentioned the many industries interested either in yeast production or in the products of fermentation, and went on to say that studies of the genetics, biochemistry, cytology and physiology of yeast have contributed to the improvement of industrial techniques and the solution of industrial problems. As examples of this, the improvement of yeast strains, the production of strains with new properties, the control of the balance between flocculated and dispersed yeast, and the control of the balance between aerobic respiration and anaerobic fermentation, were discussed. Considerable improvements in the performance of yeasts have been made by strain selection and, more recently, by the production of new hybrid strains. Yeast appears to have an advantage over other organisms in that its haploid generation can have a free existence, and may be tested, so that a selection of the best haploids may be used for hybrid production. This apparent advantage is largely illusory, as any character except the very simplest may be governed by many genes, so that the ability of a diploid cannot be judged by the separate abilities of its haploid components. The best method of finding better strains may therefore be to screen large numbers of randomly produced hybrids. Several producers of baking yeast have already found artificially produced yeast hybrids which are superior to naturally occurring strains, but apparently no other industry has yet used yeast hybrids commercially. Nor have polyploid yeasts been used commercially, though they have attractive qualities in that they are larger, ferment faster, and give higher yields than diploid yeasts.

The fermentation of various sugars, such as maltose, sucrose, raffinose and galactose, is under simple genetical control in yeasts, and this has recently been found to extend to the fermentation of maltotriose, dextrin and starch. Practically any selection of carbohydrate-fermenting abilities could be combined in one yeast, with possible applications both in industry and also for isolation of the individual enzymes.

It is very disconcerting if an industrial yeast changes its properties; fortunately this is very rare, but brewing yeast does occasionally change its flocculation characteristics. The ability to flocculate is controlled by from one to three pairs of dominant genes which are more than ordinarily subject to mutation. Flocculation generally requires calcium ions, sometimes alcohol, is inhibited by mannose, maltose or glucose, but not by mannitol, raffinose or fructose, is dependent on pH and on surface tension, and sometimes is achieved only when another mutually flocculent yeast is present. All this is known, but there is much that is not known about the phenomenon and we have not yet got complete control of the balance between too intense and too weak flocculation, either of which may cause technical difficulties. A recent innovation is the deliberate use of two yeast cultures, one flocculent and one dispersed, in a brewery, with control by adjustment of the percentage of each in the mixture used for brewing.

The balance between respiration and fermentation is of importance both to producers of yeast and to industries dependent on the products of fermentation. For the former, intense exponential aeration and exponential feeding give the maximum production of yeast for the amount of carbohydrate used, with no alcohol in the residue. For the latter, aeration is necessary to keep the yeast healthy and vigorous, but too much aeration would lead to loss of alcohol production, so that just the correct amount of aeration is essential.

In a short but lively discussion the comparative values of protein extract from grass and of food yeast were questioned. The flavour of the former was stated to be sickly and unpleasant and the texture of the latter did not compare favourably with roast beef, so that in communities which enjoyed a good mixed diet neither was likely to appeal; but where dietary protein was low either might form a valuable additive, if not a main course. The function of glycogen in the yeast cell was admitted to be still a mystery, while the aerobic fermentation of glucose by osmophilic yeasts was probably due to a shunt from the main system into one of the many alternative pathways.

R. B. GILLILAND

UNIVERSITY APARTHEID IN SOUTH AFRICA

THE proposals of the South African Government to enforce racial segregation at the university-level and to exercise rigid control over projected colleges for non-whites has caused concern and indignation in university circles throughout the Commonwealth and beyond. Some of this concern found expression in a well-attended meeting held at the Caxton Hall in London on November 2 under the sponsorship of the International Committee on Science and Freedom in co-operation with the Association of University Teachers. Dr. J. W. Cook, vice-chancellor of the University of Exeter, presided at the meeting, which by an overwhelming majority passed a resolution expressing admiration and support for those South African universities which are resisting their Government's policy and calling upon the South African Government to heed the cruel and disastrous consequences of its policy and to abstain from its further pursuit. Messages of support for the protest against university apartheid had been received from a number of organizations, including the Senatus of the University of Aberdeen, University of British Columbia, University of the Philippines, University of the Punjab, University of Delhi, the University College of North Staffordshire, various branches of the Association of University Teachers and the National Union of South African Students.

In his introductory address, Prof. M. Polanyi, chairman of the Committee on Science and Freedom, outlined the Committee's activities during the past three years. He described the apartheid issue as one in a chain of campaigns "always the same in different form". As in other cases, the claim was made that this issue had nothing to do with academic freedom; but if it had, then academic freedom must yield to higher considerations of social interest. Prof. Polanyi suggested that it is an obligation on universities to teach young people those ideas which it is the duty of society to maintain; that any violation of these ideas within the universities cannot be tolerated; and that to demand the participation of universities in a programme of inhumanity, oppression and intellectual dishonesty is a violation of academic freedom. The general philosophy of apartheid, against the background of the racial composition of South Africa, was discussed by Rev. Michael Scott, honorary director of the Africa Bureau and spokesman for the African tribes in the United Nations. Apartheid, he said, has two faces: with one it looks out on the world at large, and with the other it confronts its own non-European people. To the outside world it is represented as a solution to the problem of race relationships, whereby each race is thought of as developing separately and along its own traditional lines, and within its own separate socio-economic system. To the peoples of South Africa, apartheid means White supremacy, which in practice means Afrikaaner domination over all other peoples for the foreseeable future. During the ten years in which the Nationalist Government has been in power, the repressive aspect of apartheid has found expression in legislation for tightening of control over both physical and political movements. As several later speakers recognized, university apartheid is a natural and general development of this repressive policy.

The two main principles of this policy which emerge from the Separate University Education Bill were referred to by the next three speakers, Prof. Kenneth Kirkwood, Dr. J. W. Cook and Lord Chorley. The first new principle is the proposed creation of a system of university colleges for non-whites (that is, Asians, Africans and coloured people of mixed origin). The colleges are to be established on a tribal basis, and the most notable feature is the very strict measure of control which the Government intends to exercise. Moreover, whereas in previous university legislation in South Africa it has been possible to dismiss the matter of misconduct by university staff in a couple of lines, in the proposed new law some 300 lines are devoted to this question. By a provision which, as Lord Chorley said, must be unique in the history of any civilized community, the staff are made retrospectively liable for misconduct committed before the date of transfer to the new regime. The position of teachers in the new institutions would be one of legal rightlessness which has scarcely been known in any free community since the serfdom of the Middle Ages. The second main principle of the Bill is the ministerial determination of the composition of the student bodies of the existing universities and the exclusion of non-white students in the future. These two principles are indeed supported by the majority of the academic staff of the four universities using the Afrikaans medium, but Prof. Kirkwood stressed that it is a majority and that there is no complete unanimity even in these universities. In the other four South African universities opinion is, of course, overwhelmingly against the Bill. This Bill, which received its second reading on May 27, was on the following day referred to a Select Committee.

Prof. Kirkwood, while acknowledging that there is the apartheid tradition in the Union, pointed out that there is an equally valid non-racial tradition which found its expression chiefly during the long years of British Colonial administration in South Africa, in the Cape Colony, in the Colony of Natal and elsewhere. The practice of non-racialism has been by no means confined to the English-speaking group, and it is a practice which in the universities originated more than half a century ago. Contrary to what has sometimes been suggested, it is not at the mixed universities that friction has arisen; it is in the segregated institutions that there is a sense of grievance at the denial of opportunities and facilities that are available elsewhere. Dr. Cook recalled some of the principles of self-government of the universities of the United Kingdom which are violated by the provisions of the South African University Bill, and contrasted the proposals to enforce racial segregation with the conditions which obtain at the newer university colleges in some of the British overseas territories. Of particular significance is the multi-racial character of the University College of Rhodesia and Nyasaland. The Federation adjoins the Union and has a somewhat similar racial distribution with similar social conventions.

Perhaps partly because of the ties of common ancestry with the Afrikaans-speaking population of South Africa, the Netherlands Association of University Professors and Lecturers was not officially represented, and Prof. W. T. Koiter, of Delft, emphasized that he was present in a personal capacity. But he left no doubt about the general feeling in the Netherlands universities in favour of academic freedom; and he concluded a forceful speech against the policy of apartheid with a plea to those in the South African universities who have so far supported their Government to join forces with their colleagues in the 'open' universities, and not to indulge in the illusion that academic freedom can be retained when all students are segregated according to their race.

The audience gave a polite but sceptical hearing to Prof. L. J. du Plessis, of the Potchefstroom University, who had come over from South Africa to present the case in favour of university apartheid. The principle of the scheme for compulsory separate university education, he said, has already been accepted by the Union Parliament. The matter still open for discussion in the light of the evidence to be submitted to the Commission would seem to be mainly the intensity of the Ministerial control over the non-European university colleges and the stages to be observed in the exclusion of non-European students from the existing residential universities. The new university institutions are to complete the educational structure already developed for the non-white groups from the elementary school stage upwards. They are meant to supply intellectual leaders for the several racial groups, and such leaders can only be satisfactorily educated in racially homogeneous institutions. Provision will be made in the near future to transfer control of Fort Hare University College and the Durban Medical School to the Government. The present situation does not give the same scope for development of non-whites as would be given in separate institutions. Prof. du Plessis conceded that the measures proposed would constitute some limitation of university autonomy, but this the State was entitled to do on behalf of over-riding national interests. In any event, control of the new institutions by Government departments is rendered necessary by the fact that the Government initially supplies all the funds, and that a responsible authority is needed to prevent undesirable ideological and other developments. Quality will be guaranteed by the University of South Africa, he said, so there is no validity in the argument that the standard of the separate institutions will be inferior. The principle of racially segregated university institutions will open the way for the employment of non-whites on an ever-widening scale in the highest university positions.

In his brief reply to the ensuing general discussion, Prof. du Plessis said: "If I were in England, I would be an integrationist too, because it is not a danger to English national character, and if I were in America I would be an integrationist too; the negroes in America are in no danger of destroying that great nation of America in its identity. But the Bantus and Indians and Coloureds of South Africa, if they are integrated more fully than they are now, would undoubtedly destroy our great South African nation".

The general discussion, in which Prof. J. L. Montrose, Prof. A. J. Ayer, Mr. L. Behrens and others took part, was largely concerned with what steps could be taken to assist the South African universities and the non-European students. Mr. T. D. Smith outlined what was being done in Oxford by the Joint Action Committee against Racial Intolerance, now a university society with more than two thousand undergraduate members, which is raising a fund to provide a scholarship for a non-white from South Africa. Dr. H. J. Grenville-Wells, who was brought up in South Africa and attended for five years a South African university, deplored the fact that she had had to come to England and go to America to meet Africans of university standard, and to find out what Africans and other coloured people want for themselves. At a meeting where plain speaking was not spared, this seemed to some the most telling indictment of apartheid.

THE CHEMICAL SOCIETY OF FRANCE, 1857–1957

The centenary of the Société Chimique de France was celebrated in the Sorbonne on July 16, the President of the Republic, the Minister of Education, and the Secretaries of State for Agriculture and Public Health being present. An address was given by the president of the Society, Prof. R. Delaby, who reviewed the history of the foundation and development of the senior association of French chemists. It was founded on June 4, 1857, on the initiative of three young chemists, Arnaudon, Collinet and Ubaldini, who, with a few other young colleagues, decided to meet weekly for the purpose of keeping in touch with all branches of the science by reading memoirs, extracts, and abstracts of work published in French and foreign journals. At that time the younger chemists of France included Wurtz, Sainte-Claire Deville, Pasteur and Berthelot. Dumas was president in 1859, Wurtz being secretary and Pasteur and Cahours vice-presidents. In 1864, the publications of the Society were united under the title of *Bulletin de la Société chimique de Paris*; in the same year a decree of Napoleon recognized the Society as of public utility. By the creation of the *Bulletin* the Society acquired a growing influence, the enthusiasm of Wurtz being especially influential, so that he was regarded as the true founder of the Society.

When the Society was founded, the chemists of France were divided into three rival schools. That of Sainte-Claire Deville at the École Normale Supérieure continued the older traditions of Berthollet and Gay-Lussac, who were mainly interested in physical chemistry, and it continued to use the dualistic notation of Berzelius. In the École de Pharmacie, Berthelot used the equivalent formulæ (as he did for long after Cannizzaro's atomic weights were accepted by other chemists). In the École de Médecine, Wurtz was a protagonist of the new school, based on the atomic theory, and with his collaborators, including Friedel, Ladenburg, Salet, Crafts, Grimaux, and Beilstein, used structural formulæ and the idea of chemical bonds. On account of Wurtz's influence, the new Society became the centre of interest in atomistic ideas in France. Delaby quotes what was said by Gautier on the occasion when the Society had reached its fiftieth year, to the effect that in passing from one school to another in the earlier times, a young chemist had to learn to speak a different chemical language as well as to make profound adjustments in his outlook on chemical theory.

In 1884, it was proposed that the name of the Society should be changed to Société Chimique de France, but authorization for this was not given by the Council of State until 1906, the statutes being amended accordingly. Among past presidents were three permanent secretaries of the Académie des Sciences, Dumas, Pasteur, and Berthelot, and three recipients of a Nobel Prize, Moissan, Grignard, and Sabatier. Delaby in his lecture gave brief accounts of the careers of several presidents of the Society. Dumas is best known for his discovery of substitution and homology; he was the author of a large "Traité de Chimie appliquées aux arts" and the famous "Leçons de philosophie chimique". Pasteur, a great experimenter, founded stereochemistry, and later in his researches in the fields of biochemistry and biology made important contributions to medicine. Berthelot contributed to the fields of organic synthesis, thermochemistry, the physical chemistry of the detonation wave, and the chemistry of agriculture, as well as to the history of Greek alchemy and the alchemy of the Middle Ages by the publication of texts. He also occupied important positions in the State—senator, Minister of Public Instruction, and Foreign Secretary. Moissan worked mainly in the field of inorganic chemistry; he discovered fluorine and invented the electric furnace, with which he studied the carbides, borides and silicides of metals. Grignard is well known as the discoverer of the organomagnesium compounds and of their applications in organic synthesis. Sabatier was a pupil of Berthelot and was associated with him in many researches, but is best remembered for his process of catalytic hydrogenation, partly worked out with Senderens. Later notable names are Moureu, Urbain, Delepine, Matignon, and Jolibois, whose work was briefly reviewed.

Prof. Delaby's lecture gave an interesting survey of the development of chemistry in France from about 1850 to the present day. It shows how the Société Chimique de France participated in this and how the most famous members of the Society advanced the various branches of the science. It is a record of which the French nation is justifiably proud.

J. R. Partington

OBITUARIES

Prof. C.-G. Rossby

Prof. Carl-Gustav Rossby, director of the Institute of Meteorology, University of Stockholm, died suddenly on August 19, at the age of fifty-nine. With his untimely death, meteorology has lost its most colourful, stimulating and provocative exponent of the past twenty years or so. Rossby was a native of Stockholm and graduated from its University in 1918. Geophysical science was 'quite the rage' in Scandinavia in those days and Rossby was immediately attracted to its 'Mecca', the Geophysical Institute at Bergen, where for the next two years he worked under Prof. V. Bjerknes, and with the several exponents of the famous air-mass and frontal school of meteorology. He continued his geophysical studies for a year at Leipzig, where V. Bjerknes had formerly occupied a chair, and then entered in 1932 the Swedish Meteorological and Hydrographic Service. In 1926, he was awarded a fellowship, by the Swedish-American Foundation, to propagate the gospel of the Bergen school among meteorologists in the United States, and this led, a year later, to his appointment under the Guggenheim Fund for Promotion of Aeronautics to apply meteorological knowledge more effectively to aviation. The role was exacting and, apparently, often exciting; but it failed to satisfy the scholar that lay somewhat hidden behind the many other qualities that made up Rossby.

In 1928, the Massachusetts Institute of Technology invited Rossby to become its first head of a department of meteorology. When he left it, in 1939, academic meteorology was well founded in the United States. For the next two years Rossby was assistant chief of research to the U.S. Weather Bureau, but on America's entry into the War he was appointed to a new chair of meteorology at the University of Chicago and directed a large effort on the rapid training of meteorologists to satisfy the needs of the Armed Services. He retained his chair at Chicago, where he became distinguished service professor, until 1950, but from 1947 onwards he spent about half his time in the University of Stockholm where he created yet another department of meteorology, this time of an avowedly international flavour. Stockholm was indeed his home from about 1949, but he continued to make occasional extended visits to the United States, mainly for work at Woods Hole Oceanographic Institution.

Rossby's direct contributions to meteorology and oceanography were rather closely phased to his various academic appointments. During the period when he was at the Massachusetts Institute of Technology, Rossby was largely concerned with the theory of atmospheric and oceanic turbulence and with meteorological thermodynamics. He developed the latter as a tool in air-mass analysis and sought the workings of large-scale atmospheric processes in isentropic analysis, that is, by the charting of the contours of isentropic surfaces. Others failed to advance the subject significantly by its aid, and the technique lapsed. But it led Rossby on to his major work, the form and behaviour of atmospheric flow on the planetary scale. Earlier work in this field had been almost entirely climatological, but Rossby dealt with the instantaneous pattern, a circumpolar system of 'long' waves most in evidence in the westerlies of the middle and upper troposphere, and its evolution. Well enough aware that all atmospheric motion is essentially thermally driven, Rossby sought to find how far a purely inertial model of the atmosphere would take him in the description of the large-scale flow-field. This was characteristic of Rossby: not to attempt to solve the problem of atmospheric motion in all its bewildering complexity but to see whether major features could be accounted for in relatively simple terms. By about the end of his period at the Massachusetts Institute of Technology he had on the basis of the conservation of absolute vorticity developed the famous Rossby equation

$$C = U - \beta\left(\frac{L}{2\pi}\right)^2$$

where C is the speed of propagation of long waves of length L in a zonal air current of speed U, and β is the variation of the Coriolis parameter with latitude. For large wind speeds or low wave-lengths the waves are propagated downstream at relatively high speed, whereas for low wind speeds or large wave-lengths the waves may retrogress.

The Chicago period was one of elaboration and application of these ideas. Upper-air data on pressure and wind fields were accumulating rapidly and the long-waves could be mapped with some thoroughness over a large part of the northern hemisphere on a day-to-day basis. The 'jet stream' was identified as the fast-moving core of air embedded in the upper long-waves and Rossby sought an explanation, not quite successful, in terms of conservation of vorticity and large-scale mixing.

I well remember a hot August day in Chicago in 1947 when I was privileged to attend the daily conference on the current large-scale synoptic situation at which the long-wave and jet ideas were under discussion and application. This was a period too when Rossby, with others, began to see the possibility of applying the hydrodynamical equations of his or other model atmospheres for numerical weather prediction, using the new high-speed, electronic computers. That research is still very active.

Dynamical problems were by no means dropped during the final Stockholm period, but Rossby was looking for new interests and found them in the study of atmospheric micro-chemistry. He organized a network of stations in Western Europe at which the concentration of various radicals, such as sulphate, chloride, etc., in the air and in precipitation, was measured on a routine basis to provide their distribution in space and time. Such information, Rossby believed, would lead to important advances in meteorology, oceanography and agricultural science. He leaves in Sweden workers who can be expected to continue this research from the point now reached.

An account of Rossby's interests and original work shows only a part of the great character he was. Probing, puckish, kindly, cultured, a great European and a great American, he was much honoured, both formally and by the many who could call him friend. A light has gone out and the world is in debt to Scandinavia for one of her great sons of geophysics.

P. A. Sheppard

Dr. Robert Chambers

ROBERT CHAMBERS, perhaps the most distinguished figure in the field of experimental cytology, died recently at the age of seventy-five. Of Canadian parentage, he was born in Turkey, where his early years were spent in fascinating and, at times, exciting surroundings. As a young man he graduated at Queen's University, Ontario, and after a period spent in Richard Hertwig's laboratory at Munich, he held teaching and research posts at Cornell and elsewhere. In 1928, he was elected to a research professorship at New York University, Washington Square; this post he held until his retirement.

Chambers was largely responsible for the development of micro-dissection as a means of investigating the properties of living cells. He was a brilliant technician; to watch his control of a needle or pipette was an inspiration in itself, and much of our knowledge of the processes of fertilization and cleavage of an egg we owe either directly to him or to the enthusiasm which he inspired in others. Not the least of the lessons which he taught was modesty when an experiment went well, and absence of impatience or depression when things went wrong. He was the author of a very large number of papers, all characterized by their conciseness and clarity of style. Nearly—but perhaps not quite—all his conclusions have been substantiated by the use of techniques much more elaborate than his own.

During the inter-War years Chambers travelled extensively in Europe and made many friends. His handsome features, lit by a characteristically jovial smile, made him a welcome visitor to any laboratory; within a few days, he became "Robert" and remained so to young and old alike. For the best part of a generation he and his wife, Bertha, kept open house at their home in Woods Hole or New York. They had the supreme gift of welding a heterogeneous mixture of individuals into a happy gathering free from the strain of scientific research and the troubles of the outside world.

Superficially casual in the affairs of everyday life, Robert's scientific vision was remarkably acute and he pursued his ends tenaciously and unselfishly. He founded and was editor of a journal (*Protoplasma*), and he started centres of informal discussion which grew into well-organized and successful societies. He received many honours, but among these the affection of his friends and their respect for his scientific work must have ranked highly. Perhaps his most endearing and characteristic quality was his ability to remain young and—superficially at least—carefree. There can be few biologists of his own generation to whom his death did not bring a sense of personal loss, and younger cytologists will be among the first to acknowledge the lasting value of his scientific work.

J. GRAY

Prof. Jean Giaja

BIOLOGISTS everywhere will learn with regret of the sudden death in Belgrade on October 1 of Prof. Jean Giaja, otherwise Ivan Djaja, which occurred during a symposium on hypothermia, of which he was president. The symposium was being held in connexion with the fifteenth International Congress of Military Medicine and Pharmacy. Physiologists and medical men from many lands had gathered to honour Prof. Giaja and to discuss recent advances in the study of hypothermia, a subject in which he was an authority and had been a pioneer.

Giaja was born in Dubrovnik on August 21, 1884. His father was the skipper of a four-masted barque which sailed the oceans, so that young Giaja was often left with his mother, who was a Frenchwoman and who influenced him greatly and provided a rich cultural background. He graduated from the University of Belgrade and, after a year at Rouen, moved to Paris, where he spent six years doing physiological research under Prof. Dastré. He was awarded the degree of doctor of biological sciences at the Sorbonne. Then, in 1910, he was appointed professor of physiology in the University of Belgrade. There he remained until his death.

During the past fifty-two years Prof. Giaja had published many original articles and reviews. Between 1906 and 1920 he studied the enzymic breakdown of glucosides and carbohydrates in mammals, birds, fish, invertebrate marine animals and yeasts. This led to investigations of energy intake and expenditure by yeasts, and by poikilothermic, homoeothermic and hibernating animals. His results enabled him to draw important conclusions about the regulation of heat production and maintenance of body temperature in birds and mammals. As long ago as 1930 Giaja began to study mammals with reduced body temperatures. He was the first to use the rat for this purpose and to show the protective action of hypothermia in a variety of adverse conditions including lack of oxygen. Twenty years passed before the subject of hypothermia became fashionable as a result of its application to cardiac surgery in 1950. By then a firm physiological basis for its use had been laid by Prof. Giaja.

Although nominally he retired three years ago, Prof. Giaja continued active research until the last. One of his recent articles on "Survival of the Heart following Deep Hypothermia" was recently published in *Nature* (178, 1286; 1956). He was a member of the Serbian and French Academies of Sciences, of several Yugoslavian and French scientific societies and of the Légion d'Honneur. Among his hobbies were gardening, boats, music, reading and travel.

Prof. Giaja had a charming personality and inspired admiration and affection in his students, his colleagues and his numerous friends among scientists overseas. He is survived by a daughter and by his second wife, who had worked with him for many years.

AUDREY SMITH

Prof. Antonino Mura

THE untimely death of Antonino Mura, which occurred on July 24, near Milan, deprived physics of a dedicated student. He was born in Florence on March 19, 1916, and after attending the Scuola Normale Superiore in Pisa, obtained his doctor's degree in physics in 1938. Of the nineteen years since then, five were spent with the army during the War, and eight were clouded by the disease that eventually killed him. The remaining years were wholly dedicated to teaching and research at the University of Milan, where Mura contributed so much to re-establishing the academic and scientific activities of the Department of Physics after the Second World War.

Notwithstanding the odds against him, Mura continued to perform remarkable research work in the field of cosmic-ray physics. He started in 1945 studying the extensive (Auger) showers, and the properties of their penetrating component. Soon afterwards, he developed the cloud chambers which were to be successfully operated at the Alpine laboratory of Testa Grigia to investigate the characteristics of the nuclear disintegrations induced by cosmic rays: Mura and his co-workers determined the strong nuclear properties of the 'shower' particles emitted from the disintegrations. This research, and later work on the production of neutral pions and on the development of the nucleon cascade, shared with other investigations carried out in the same years in different countries the merit of bringing about the present understanding of the phenomenological aspects of the cosmic radiation: namely, that the extensive, the penetrating and the mixed showers are but different offspring of the high-energy nucleon–nucleon collision, the most catastrophic phenomenon of Nature.

It was with the intention of collecting information relevant to the behaviour of high-energy particles that he and his colleagues engaged in the study of phenomena underground. They demonstrated the groundlessness of reports from other investigators suggesting that the muons might give rise to previously unknown sub-atomic particles: the assumption of non-electromagnetic interaction properties of the muons could thus be discarded.

After this work, Mura was no longer able to participate directly in the experimental activity: in his last years his ailing body prevented him from contributing more than advice, criticism and interpretation of results. His interest in physics remained, however, unabated; and to the very end of his life he continued to discuss scientific subjects either in letters or with gatherings of his collaborators around his hospital bed.

The association of most of Mura's work with such an exacting and delicate instrument as the cloud chamber was not casual. He was at heart a respectful student of Nature, and elected to depend on a research tool presenting a straightforward kind of evidence of Nature's ways. His particular excellence as a physicist lay in his relentlessly critical mind, striving to uncover whatever truth, if any, might be hidden under uncritically accepted, misleading or exaggerated statements.

This earnest approach to the object of scientific research did not prevent him from being good-humoured and witty; and this indeed was his prevailing mood in performing his duties and in his contacts with people. He made an ideal partner in team-work, because he sincerely believed that everyone tries always to do his best. He never complained of his fate, of which he must have been deeply aware.

GIORGIO SALVINI

NEWS and VIEWS

Artificial Meteors

IT is reported from the United States that in an experiment devised by the U.S. Air Force Research Station at Cambridge, Massachusetts, artificial meteors in the form of aluminium pellets were released by an Aerobee rocket at an altitude of 54 miles over New Mexico on October 16. It is probable that some of the meteors, which were ejected from the rocket by means of shaped charges of explosive, may have achieved speeds in excess of the velocity of escape from the Earth's gravitational field. A photograph taken with a Baker Super-Schmidt meteor camera is said to have shown one of these meteors travelling at a speed greater than 33,000 miles per hour, with a brightness of stellar magnitude −2. Observations of the temperature (luminosity) and rate of vaporization of artificial meteors, the composition and mass of which are known, are likely to be of use for determining the density of the Earth's atmosphere at great heights. Radar observations of the ionized trail of such meteors may also be expected to throw light on processes occurring in the ionosphere.

Electrical Engineering at The Queen's University, Belfast: Prof. P. L. Burns

PROF. P. L. BURNS, who retires from the chair of electrical engineering in The Queen's University of Belfast at the close of the present session, received his engineering education at the University of Manchester, where, during the First World War, he was associated with Lord Rutherford in the problem of the detection of submarines. His practical training was obtained in the then British Westinghouse Co. at Trafford Park, Manchester. He entered the teaching profession in 1918, being successively in charge of the electrical engineering departments at Hull Technical College and at Rutherford College, Newcastle upon Tyne, before being appointed in 1924 to the position of head of the Department of Electrical Engineering and Physics of the Belfast College of Technology and extra-mural professor of electrical engineering in The Queen's University of Belfast. This position he held until 1955 when, with the formation of the Joint Authority for Higher Technological Studies, he became the first holder of the university chair in his subject, being still associated with the Belfast College of Technology as director of higher studies in electrical engineering.

Prof. Burns's tenure of the chair has been marked by steady developments in both the University and the Technical College sides of the department, in all of which his skill as a teacher found full scope. His interest in the students has not, however, been confined to their academic studies, for he has interested himself in all their activities. For a considerable period during and after the War he commanded the Signals Unit of the Senior Training Corps, for the formation of which he had been responsible. He was elected president of the University Rugby Club, and his cheerful and enthusiastic figure is a familiar sight on the touch-line at all university matches. Prof. Burns carries into his retirement the best wishes of his colleagues and of the long line of students who came under his influence, many of whom now hold positions of high responsibility in industry.

Dr. J. C. West

DR. J. C. WEST, who has been appointed to succeed Prof. P. L. Burns, entered the Department of Electrical Engineering at the University of Manchester in October 1940, and graduated with first-class honours in 1943. He then joined the Royal Navy as midshipman and successively became sub-lieutenant and lieutenant, his main concern being with anti-submarine warfare. He returned to the staff of the Department in 1946, and was appointed senior lecturer in 1953. His first researches were in the field of electron optics, but in 1947 he began to take an interest in servo-mechanisms. During the ten years that have elapsed since then he has built up an active research group specializing mainly in non-linear servo-mechanisms. Dr. West has become a well-known authority in this difficult field, to which he, and his group, have contributed a considerable body of published work. Arising out of this work he was awarded the degrees of Ph.D. in 1952 and D.Sc. in 1957. Alongside this research activity he has built up an excellent third-year undergraduate course. In connexion with this course he has published a very successful text-book and he has a further book in course of publication. Dr. West's activities extend well beyond purely academic circles: he is a member of several committees concerned with automatic control and is in close touch with industry through his consulting activities. He has taken an active part in the work of the Institution of Electrical Engineers and received a Premium of the Institution in 1956 for his work on non-linear control systems. He has been a member of the North-Western Centre Measurement and Control Section Committee, of which he was chairman during 1955–56, and has been an invited speaker at several international conferences on automatic control.

Biohistorical Institute of the University of Utrecht: Dr. Frans Verdoorn

Dr. Frans Verdoorn, managing editor of the Chronica Botanica Co. and secretary of the International Biohistorical Commission, has been appointed director of the new Biohistorical Institute of the University of Utrecht, The Netherlands. This Institute, now being set up in conjunction with Prof. Lanjouw's Botanical Museum and Herbarium, will concern itself with the cultural, historical, other humanistic and related aspects of the pure and applied sciences of life, with special reference to the plant species. Born in The Netherlands and originally a cryptogamic botanist, Dr. Verdoorn later engaged mainly in editorial and international relations work. After moving to the United States in 1940, his main interests turned gradually to the borderlands between the natural sciences and the humanities and he collected a great deal of information on botanical biography ("Index Botanicorum"), the history of biology, the history of botanic gardens, the Linnean period, etc., which will now form the nucleus of the new Institute at Utrecht.

Centenary of the British Ornithologists' Union

As part of its centenary celebrations the British Ornithologists' Union (founded 1858–59) is placing two scientific expeditions in the field. The main expedition is to Ascension Island, where a party of four will undertake a thorough examination of the general biology and breeding behaviour of the ten species of sea birds present. Particular attention will be paid to the following points: investigation of the factors influencing the timing of the breeding seasons (known to fall every nine months in one species); comparisons of the feeding, growth, maturation and survival-rates of the young; comparative studies of behaviour patterns in closely related species; population counts and surveys of breeding sites, as a basis for conservation measures and possible future studies; an extensive programme of ringing adults and young. The party left England recently and expects to remain in the field for eighteen months. It will be joined from time to time by visiting scientists, who will work on independent problems. The expedition, which is led by Bernard Stonehouse, of the Edward Grey Institute, Oxford, who has had long experience of biological and meteorological work in Antarctica and Grahamland, will also be taking hydrographic observations. A second expedition is planned to investigate problems of taxonomics and speciation in the Comoro Islands.

Scientific and Technical Man-power in Britain

Several questions relating to scientific man-power were raised in the House of Commons during November 18–19. The Paymaster-General gave the number of scientists now employed in his Department as 162 and his expenditure on scientific research in the current financial year as £1,045,000. Asked whether he would arrange for one Government department to be responsible for maintaining records of the numbers, qualifications and types of appointment held by professional engineers and technologists, the Prime Minister said that the Minister of Labour is already responsible for collecting information about the employment of persons in Great Britain, including engineers and technologists, and that the expense of keeping records as full as those suggested would be disproportionate to the value. Asked if he would arrange for one Government department to be responsible for maintaining records of all emigration of highly qualified scientists and engineers, the Prime Minister referred to an earlier reply of the Home Secretary which stated that in view of admitted deficiencies in the available statistics of emigration to and from the United Kingdom, Government departments interested are making a special review of the information required for official purposes about migration and the means for obtaining it. In reply to a further question as to the accuracy and fullness of the records of emigration, the Prime Minister emphasized the difficulty of obtaining the records, which are undoubtedly desirable, without resorting to compulsory registration, for example; he said he is ready to seek all possible information short of reverting to compulsory powers. On November 20, the Minister of Labour said, in answer to a question whether he would now grant exemption from National Service to science and engineering graduates with second-class honours degrees entering establishments of further education, that he had asked his Technical Personnel Committee to study the proposal.

Russian Scientific Literature

The Department of Scientific and Industrial Research Lending Library Unit is building up a comprehensive collection of Russian scientific and technological literature. At present it is receiving some 220 periodicals regularly from the U.S.S.R. In addition it has received parts of a number of irregular serials, and has catalogued more than 500 Russian books. In all it is probably receiving something over half the current Russian output of scientific and technical literature. The rest is in the main available only on exchange terms from a number of organizations scattered throughout the U.S.S.R. These exchanges are being developed as rapidly as possible. The main difficulty is to track down what is available and the addresses of producing organizations. The Unit will welcome any assistance in this task. Although the bulk of the Russian literature held is very recent, a service for it is being started. Further information can be obtained from the D.S.I.R. Lending Library Unit, 20 Chester Terrace, London, N.W.1.

Scientific Translation and Languages

A report on "Scientific and Technical Translating and other Aspects of the Language Problem" (pp. 282: Paris: Unesco, 1957) is the result of collaboration between the Secretariat and 219 persons from twenty-one countries, arising out of a resolution adopted at the seventh and eighth sessions of the Organization's General Conference in 1952 and 1954. This authorized the Director-General "to advise and encourage international organizations concerned with the development and improvement of scientific documentation, standardization of terminology, compilation of multilingual dictionaries, and the improvement of terminology". In the first chapter the magnitude of the problem is appraised and the qualitative aspects of translating are reviewed in the second. Two chapters on methods and organizations for translation and distribution follow and the problems of increasing scientists' knowledge of languages are then discussed. In this connexion there is appended to the report a useful bibliography of books for technical language study. The concluding two chapters deal with the possible use of languages which are internationally understood so as to minimize the need for translation, and with terminology and lexicography. The latter is in continuation of activities initiated in response to a recommendation of the International Conference on Science Abstracting in 1949. There is a general bibliography and also a list of proposals regarding which further expressions of opinion are invited. No decisions have yet been taken by Unesco upon these proposals and the report is to be regarded as a statement of progress put forward in the hope that proposals may be reached for positive action which could be undertaken if funds permit.

Some interesting figures are given in the first chapter of the report. From a random sample of 1,000 scientific periodicals, English appears to be the dominant language, accounting for 436, compared with 144 in German, 126 in French, 53 in Spanish, 93 in other Latin script, 81 in Russian and other Cyrillic, and 36 in Italian. Except in geology and mining, meteorology and palæontology, in which English accounted for only 25 out of 96, this proportion held in all the main subject groups: for example, 32 out of 88 for pure and applied sciences in general; 24 out of 59 in mathematics and physics; 23 out of 54 in pure and applied chemistry; 43 out of 100 in biology, bacteriology, etc.; 78 out of 193 in medicine, pharmacy, dentistry; 65 out of 122 in engineering, transport, building, architecture; 91 out of 185 in agriculture, forestry, fisheries; and 25 out of 48 in leather, plastics, rubber, textiles, etc. It is also estimated that out of some 4,624,000 scientists and technologists, 1,643,000 can read German, 361,000 Spanish, 2,650,000 English, 1,206,000 French, and 1,131,000 Russian.

Acta Virologica

An increasing effort is being made to render the Iron Curtain permeable to scientific knowledge. Much of interest is reported in the first number of *Acta Virologica* (Vol. 1, No. 1 (January–March, 1957). Pp. 64. English edition. Annual subscription 30 Kčs. Orders to ARTIA, 30 Ve smečkách, Prague). This journal is edited by D. Blaškovič of Bratislava in Czechoslovakia with A. A. Smorodintseff of Leningrad as sub-editor, and is published quarterly under the auspices of the Czechoslovak Academy of Sciences. It is to appear in two editions, in English and Russian respectively. The articles in the first number, which come from Bratislava (three), Leningrad (two), Warsaw, Peking and Sofia (one each), represent serious contributions to virology. The English is good, as are the illustrations, some of which are in colour, and the journal is well produced. If the standard is maintained, *Acta Virologica* should prove a very worthwhile venture, of much benefit to the subject.

The Woollen Industry

Throughout the world, the woollen industry has an incomparable record in its efforts to find more and more uses for this natural fibre. These efforts are matched by the exertions the industry has made to improve the wearing quality of the fibre and to find more people who wish to use it. All those concerned must be gratified with the results achieved. The review of the International Wool Secretariat and Wool Bureau Incorporated for 1956–57 shows that wool had a remarkable resurgence during the year, particularly in the United States; it is still the most popular clothing fibre throughout the world. The United Kingdom remains as the largest wool-producing country in Europe. The work of the education, publicity, trade promotion, economics, and science and technology branches of the International Wool Secretariat and Wool Bureau are described in the review, which is most attractively illustrated. Copies may be obtained from the International Wool Secretariat, 18–20 Regent Street, London, S.W.1, or from the Wool Bureau, 16 West 46th Street, New York 36.

Food Additives

The use of food additives—with all their attendant dangers—is now so widespread that the World Health Organization and the Food and Agriculture Organization have felt it necessary to set up a joint expert committee to examine the position and advise on the measures needed to safeguard the health of the consumers. Its first report has recently been published (General Principles governing the Use of Food Additives. W.H.O. Tech. Rep. Ser. No. 129. Geneva, 1957. 1*s*. 9*d*.), dealing with the use and abuse of "non-nutritive substances added intentionally to food . . . to improve its appearance, flavour, texture or storage properties". While allowing that such additives may, in certain circumstances, reduce the wastage of food or provide essential aids in food processing, it is clear that without close legal control their use may result in a substantial reduction in the nutritive value of common foods, they may disguise faulty processing and handling techniques, and they may expose the consumers to unknown risks—not only from the intake of substances abnormal in themselves but also from the further possibility that the combined effect of a number of additives in different foods used in the diet may produce an undesirable summation of reactions. This small report should prove of very great help to medical officers, administrators and teachers concerned with problems of public health.

High-Level Beach Lines in Morocco

The study of the high-level beaches occurring along the North African coast has long occupied quaternary geologists. The term 'high-level' rather than 'raised' is used deliberately as it is believed that they are the result of a rising and falling of the sea-level during interglacial and glacial periods rather than of earth movements. During glacial maxima vast quantities of water were locked up in the form of ice sheets and the level of the sea sank; when the warm conditions of interglacial times supervened the ice melted and the level of the sea rose. High-level beaches, therefore, indicate an interglacial period. A number of savants have been concerned with this study and among them must be mentioned M. Georges Choubert, who has contributed an interesting paper (*C.R. Acad. Sci., Paris*, 245, Sept. 23, 1957) on the correlation between the marine and continental cycles of the Pleistocene period in Morocco. One fact his article shows clearly, and it is a problem which has not yet been satisfactorily explained. The earliest terrace (Sicilian) lies at 90 metres above present sea-level. There was then a fall of the sea with the oncoming of glacial conditions. When the water rose again it only reached 60 metres above present sea-level; and this phenomenon of general lowering continued. As well as the up and down movements of the sea-level, there seems to have been at the same time a steady depletion of the available sea water. Possibly considerable earth movements caused large underwater deeps which had to be filled, but the explanation of this steady fall in sea-level throughout Pleistocene times, apart from the up and down due to glacial and interglacial phases, is a mystery. The phenomenon is not confined to the Mediterranean. M. Choubert also claims to have discovered pre-Günz climatic changes back in the Villafranchian. He equates the latest of these with the pebble culture of Arbaoua. But are any of these so-called early pebble tools really artefacts? A number of workers have recently come to the conclusion that there are no man-made objects prior to the early Oldoway culture.

Griseofulvin in Horticulture

Griseofulvin, a new antibiotic, has now been released by the Government for use in horticulture. Trials have shown it to be highly effective in controlling *Botrytis* (grey mould) in the lettuce crop grown under glass: as a 3 per cent dust, used at approximately 1 oz. per 20 sq. yd., *Botrytis* infection was reduced by some 40–50 per cent, treatment both before and after planting-out giving the best control. Application in the form of a 3 per cent atomizing spray was also successful. The cost of the treatment, where the full value of the crop is assessed at £1,500, would lie between £35 and £52, while the gain to the grower is estimated at £190 per acre. There would also be an increase in size of marketable lettuces from the reduction in infected leaves, and a substantial saving in time and labour spent on trimming. Trials are now in progress on the effect of griseofulvin on other diseases of lettuce, such as downy mildew and damping-off, and will shortly be extended to other crops, including strawberries, raspberries and tomatoes. Griseofulvin is not yet available for sale to growers, but the Murphy Chemical Co., Ltd., Wheathampstead, Herts, is marketing a substance, 'Grisovin', containing the antibiotic, and has issued an illustrated leaflet dealing with the control of *Botrytis* in lettuce under glass with this product. Limited quantities of griseofulvin are available, however, from G. L. Hey at the above address, for research workers in Britain or overseas who are interested in trying the material against species of *Botrytis* or *Mycosphaerella* on a range of crops.

Committee of Inquiry into the Fishing Industry

A Committee of Inquiry into the Fishing Industry has recently been formed by the Ministry of Agriculture, Fisheries and Food and the Scottish Home Department "To assess, in relation to developments in fishing and the marketing of fish, the size and pattern, and implications, of an economic fishing industry in the U.K., and to report". Members of the Committee are: Sir Alexander Fleck (*chairman*), Mr. H. W. Clements, Rear Admiral R. A. Currie, Sir Alister Hardy, Sir Graham Larmor, Mr. I. W. Macdonald, Mr. George Middleton, Mr. W. B. Reddaway. The secretaries are Miss M. E. Vince, Ministry of Agriculture, Fisheries and Food, and Mr. I. L. Sharp, Scottish Home Department.

Royal Agricultural Society of England Research Medal

The Royal Agricultural Society of England offers annually a medal together with an award of one hundred guineas for research work of outstanding merit carried out in the United Kingdom which has proved, or is likely to prove, of benefit to agriculture. Recommendations for this award can be made by the heads of university departments, research stations and institutes and other research establishments. No direct application by candidates will be considered. Recommendations for the next award must be submitted to the Secretary, Royal Agricultural Society of England, 35 Belgrave Square, London, S.W.1, before January 31, 1958.

Micro- and Semi-Microchemical Methods

Commencing on January 11, a course of twelve lectures and appropriate practical work will be held on Saturday mornings at the Norwood Technical College from 9.15 a.m. to 12.30 p.m. The course is designed to survey the principal branches of chemistry in which small-scale methods have been successfully applied and is particularly suitable for teachers wishing to introduce modern techniques into advanced and scholarship level and degree courses. Further information can be obtained from the Secretary, Norwood Technical College, London, S.E.27.

University News: Bristol

The following appointments in the University of Bristol have been announced: Dr. D. W. Barritt, as lecturer in medicine; I. W. Cameron, as lecturer in dental surgery (prosthetics); Dr. L. C. Frost, as lecturer in genetics in the Department of Botany; N. St. G. Hyslop, as lecturer in clinical veterinary pathology; Dr. P. M. Llewellyn, as lecturer in physics; Barbara M. Q. Weaver, as lecturer in veterinary surgery.

Among the grants, gifts and bequests received by the University are the following: from the Department of Scientific and Industrial Research to the Department of Physics, £4,000 for experimental research in nuclear physics and cosmic radiation, £3,600 for experimental research into flights with free balloons of long duration at 100,000 ft., and £3,100 for work on measurement in relativistic quantum theory; from the National Coal Board to the Department of Physical and Inorganic Chemistry, £1,000 and £750 for the study of the reactivity of carbon surfaces with oxygen and a study of the structure of active carbons, respectively; a bequest from the late Miss Nebendahl of £1,000 to the University's Cancer Research Fund; from the Department of Scientific and Industrial Research to the Department of Organic Chemistry, £866 for research on chlorogenic acid and closely related compounds, and £600 for continuation of research on cell-wall carbohydrates of plums. The University is also to receive a bequest from Mrs. A. M. Fertel of an estate valued at more than £5,000 to found one or more studentships for the furtherance of experimental research in physics, preferably in nuclear physics, to be known as Geoffrey E. Fertel Studentships, in memory of her son, who was a member of staff of the Department of Physics.

Glasgow

Dr. D. C. Gillies has been appointed director of the Electronic Computer Laboratory and is now in residence at Glasgow. He will have charge of the Scottish mercury computer, delivery of which may be expected next year, when it is to be housed in the Chemistry Department.

Drs. R. Hodges and A. I. Scott have been appointed lecturers in chemistry, and Dr. D. H. Watson to an Imperial Chemical Industries fellowship in chemistry.

The Wellcome Trustees have made a grant, of up to £50,000, for the building of a Small Animals Experimental Research Unit at the Veterinary Hospital, Garscube. Work has begun on the second stage of development of the extensions to the Natural Philosophy building.

For the present session four hundred new students (304 men and 96 women) have been admitted to the science departments. Over the University as a whole, the total number of matriculated students now stands at 6,090, compared with about 5,920 a year ago.

London

The title of professor emeritus in biometry in the University of London has been conferred on Prof. J. B. S. Haldane.

Dr. Stephen Dyonis Elek has been appointed to the chair of bacteriology, tenable at St. George's Hospital Medical School, from October 1, 1957.

The Night Sky in December

Full moon occurs on Dec. 7d. 06h. 16m. U.T., and new moon on Dec. 21d. 06h. 12m. The following conjunctions with the Moon take place: Dec. 16d. 18h., Jupiter 2° N.; Dec. 18d. 21h., Mars 1° S.; Dec. 24d. 18h., Venus 6° S. Mercury is visible at the beginning of the month as an evening star low in the west after sunset, but conditions are unfavourable for observation. Venus sets at 18h. 55m., 19h. 10m. and 19h. 10m. at the beginning, middle and end of the month, respectively; during this time its distance from the Earth decreases from 53 to 34 million miles, the visible portion of the apparent disk from 0·428 to 0·201, and its stellar magnitude is about − 4·3. It is a brilliant object in the south-west after sunset; greatest brightness is on December 23. Mars rises at about 5h. 35m. throughout the month; it is in Libra until December 25, when it enters Scorpius, being near β Scorpii at the end of the month. Jupiter rises at 3h. 30m., 2h. 50m. and 2h. 00m. at the beginning, middle and end of the month, respectively, and is east of Spica. The stellar magnitude of Jupiter is − 1·4, its distance from the Earth on December 15 being 550 million miles. Saturn is too close to the Sun for observation. Occultations of stars brighter than magnitude 6 are as follows, observations being made at Greenwich: Dec. 12h. 0h. 23·5m., ω Leo. *m.* (*R*); Dec. 26d. 20h. 33·7m., κ Aqr. (*D*). *R* and *D* refer to reappearance and disappearance, respectively. The Geminid meteors are active during December 9–14, but conditions are not very favourable. The Ursids are active during December 21–22, and conditions are very favourable; the radiant is at R.A. 14h. 28m., Dec. + 76° N. The winter solstice occurs on Dec. 22d. 03h.

Announcements

A House of Scientific Technique, which will accommodate more than twenty scientific bodies under the same roof, is to be built in Budapest at a cost of £600,000, to be paid by a government grant. Several stories high, the House, which is due to be completed in 1960, will have club rooms, lecture halls, libraries, a modern theatre, a gymnasium and a restaurant.

The Royal Society is prepared to consider applications from scientific societies for grants towards the travelling expenses of scientists (particularly young scientists in the United Kingdom) attending ordinary or special meetings, or congresses, held in the United Kingdom. Further information can be obtained from the Assistant Secretary, Royal Society, Burlington House, Piccadilly, London, W.1.

The complete proceedings of the International Symposium on Macromolecular Chemistry, held in Prague during September 9–15, will be published in the spring of 1958 as two or three special numbers of the *Journal of Polymer Sciences*.

A Physical Society conference on "Band Theory of Metals and the Structure of the Fermi Surface" will be held in the Imperial College Union, Prince Consort Road, London, S.W.7, on December 19 and 20.

An international colloquium on "Optics in Metrology" will be held in Brussels during May 6–9, 1958, under the auspices of the International Commission for Optics. Further information can be obtained from M. P. Mollet, Comité Belge d'Optique, 128 Rue du Sport, Gand, Belgium.

The Third International Congress on Rheology will be held in Bad Oeynhausen, Germany, during September 23–30, 1958. Contributions are invited for this Congress and a 100–200 word abstract of any proposed paper should be sent by January 1, 1958, to the Congress secretary, Dr. W. Meskat, Bahnhofstrasse 9, Dormagen, Near Cologne.

Erratum. In the communication entitled "Further Radio Observations of the First Satellite" by Norman Lea in *Nature* of November 9, p. 943, the lower figure on the vertical axis of Fig. 1 should read 1,600 [c./s. above 40 Mc./s.], and not 1,500 as printed.

RECENT SOLAR ACTIVITY

By Dr. M. A. ELLISON

Royal Observatory, Edinburgh

THE present maximum phase of the sunspot cycle is outstanding in many respects. The Zurich relative sunspot numbers (provisional) for the first ten months of 1957 were: 152, 117, 157, 175, 165, 206, 194, 163, 244, 263. These high values for September (244) and October (263) are quite exceptional. If we look back to the beginning of the series in 1749, the only other monthly means which have exceeded the 200 level were those of May 1778 (239), December 1836 (206), May 1947 (201) and November 1956 (203). We may thus regard the timing of the opening months of the International Geophysical Year as particularly fortunate: to have caught so great a peak of solar activity within its net was a considerable achievement of planning.

The high sunspot numbers of 1957 have been contributed mainly by the occurrence of large numbers of small and medium-sized spot groups. On many days in September and October there have been upwards of twenty such groups present on the disk at one time. On the other hand, the giant *F*-type sunspots which were such a characteristic feature of the last cycle, in the years 1946–51, have been noticeably few. It is spots of this type, possessing complex magnetic fields (βγ and γ), which give rise to the most intense (3+) solar flares, and these have likewise been less frequent than the high sunspot numbers would lead one to expect.

Another unusual feature has been the continued appearances of occasional spots in high latitudes, such as are characteristic of the early years of the cycle. One of these groups, in latitude 46° S., crossed the central meridian on September 15 and lasted for at least seven days.

September also provided something like a record in magnetic activity: there were, in all, six great storms with sudden commencements, beginning on September 2, 4, 13, 21, 22 and 29. Two regions showing high flare activity (one in 20° N. and the other in 30° S. latitude) crossed the Sun's central meridian on August 31, and to these must be attributed the great geomagnetic disturbances during September 2–5. One of the few *F*-type sunspots developed rapidly from September 14 onwards, crossing the central meridian on September 19. This region generated a high level of activity—at least a dozen flares were observed here in the class 2 and 3 categories—and was undoubtedly responsible for the magnetic storms on September 21 and 22. Another active group, with central meridian passage on September 27, was the probable cause of the storm on September 29.

Prof. J. Bartels reports that, for September, the monthly average of the daily planetary magnetic amplitudes, *Ap*, in the usual unit of 2 gamma, was 49. The next highest monthly averages in the available series (1932–33, and 1937 to date) were 40 (September 1951) and 37 (March 1940). September had three days with *Cp* = 2·0 and five days with *Cp* = 1·9.

Some thirty-six sudden ionospheric disturbances (cases of *D*-layer absorption due to solar flares) were recorded in Britain during daylight hours in September. Many of these produced severe fade-outs on 18 Mc./s. and lower frequencies, such as are usually associated with flares of classes 2 and 3. *F*-layer radio reception with North America was particularly disturbed, especially at the times of the large magnetic storms referred to above.

Although the sunspot number for October exceeded the high value in September, active solar regions were less pronounced and their terrestrial effects were on a considerably smaller scale. A 3+ flare, observed at the McMath-Hulbert Observatory, reached its peak intensity at about 17h. 00m. on October 20. This outburst would appear, on a provisional view, to have been the most likely source of the magnetic storm particles which began to affect the ionosphere on the afternoon of October 21.

ECOLOGY OF GRASSLANDS

ON September 11 in Dublin, Section K (Botany) and Section M (Agriculture) of the British Association held a joint session under the chairmanship of Prof. J. Doyle on "The Ecology of Grasslands". Mr. C. E. Hubbard opened with a paper on "Genetical and Ecological Variation of the Components of Grasslands in the British Isles". Speaking as a taxonomist, Mr. Hubbard pointed out that while the botanist was primarily interested in characters distinguishing taxa and especially those indicative of relationship, the agriculturist was essentially concerned with characteristics likely to be of value for grassland improvement and only those varieties likely to be of economic importance were of prime interest to him. Variability in grass populations had long been recognized. A. F. Gray in 1821 recorded seventy-five varieties of wild British grasses, while nowadays the number of intraspecific variants recorded exceeded four hundred. Mr. Hubbard then presented a classification of grass variants and distinguished between those of some taxonomic significance and others of a more trivial nature. Diseased or abnormal states were seldom of any ecological or genetical significance. Colour variants, however, might be due to ecological or genetical factors: the colour-spikeleted forms of *Deschampsia caespitosa*, for example, were definitely genetical in character. Albinism, on the other hand, when almost complete, usually led to early death. Partial albinism producing variation, however, was often an unstable condition, and reversion was not unusual. Anatomical variation included the pruinose and glaucous condition due to a waxy surface layer or a thick cuticle, and the rigidity or otherwise of a grass depending on the amount and arrangement of sclerenchymatous tissue. This last condition was probably of ecological significance only. The degree of hairiness of a grass was a very variable factor. Some genetically fixed hairy variants existed, but the range of hairiness of the spikelets found, for example, in a population of the microspecies of the *Bromus mollis* complex was doubtless due to hybridization. A number of trivial modifications in the spikelets, such as extra florets or the presence or absence of awns, appeared in some instances to be due to edaphic factors.

There were many variants distinguished by differences in vigour and size which occurred in a number of polyploid complexes. The collective species—*Agrostis stolonifera*, *Phleum nodosum* and *Dactylis glomerata*—provided examples of paired genetical variants with distinct ecological requirements and size differences. Differences in spikelet size might be due either to genetical or ecological factors.

In a closely grazed grassland the constituent grasses under cultivation as spaced plants showed obvious distinctions in growth form. These had arisen as a result of different forms of managements and maintained their special characteristics under cultivation. Differences in growth-rate and flowering time of geographical races of herbage plants provided grazing over a longer period than single strains when sown together.

The question of self- and cross-fertility was then considered by Mr. Hubbard. It had been noted that most annuals were self-fertile, whereas many perennials were cross-pollinated and often self-sterile. Annuals, as might be expected, tended to have fewer outstanding variants. The polymorphism seen in perennials might arise from intraspecific cross-pollination, interspecific hybridization and some intergeneric crossing. Of interspecific hybrids, thirty-one were known in the British flora, occurring in fourteen genera, six of them annuals and twenty-five perennials. The outstanding polymorphism of *Molinia coerulea* was probably due to ancient hybridization. Cytological investigation here was highly desirable. In the British Isles nine intergeneric hybrids were known involving five or six pairs of genera. Most of them were rare, but one of them, *Festulolium loliaceum*, was widely distributed.

The cause of some outstanding examples of variability might be due to the presence of two or more members of a polyploid series in a taxon. For example, *Holcus mollis* included strains with twenty-eight, thirty-five and forty-two chromosomes; and it was possible that polyploidy might account for other species exhibiting well-marked morphological differences associated with special habit preferences.

The phenomenon of apomixis demonstrated in Scandinavia for *Poa pratensis* did not appear to have been proved experimentally in Britain, but it was probable that the position was similar. It appeared feasible that variation in species of *Calamagrostis*, *Deschampsia*, *Sieglingia* and *Puccinellia* might also be due to apomixis.

Finally, Mr. Hubbard outlined the possible development of natural grassland in the British Isles. Grasses from south and east following retreating ice-sheets of the last Ice Age produced a genetically mixed basic stock which became augmented by accidental introductions and later by intentional additions by man. Plant-breeding stations continued to distribute improved strains which were gradually replacing the indigenous strains in ancient pastures and meadows. Whether it was desirable to replace such strains, selected naturally through a long period of time, by a few selected strains was a debatable point. Mr. Hubbard contended that native strains in Britain should be preserved in as many regions as possible as a reserve from which to make selections for the grasslands of the future.

Prof. M. J. Gorman then followed with his paper on "The Influences of Biotic Factors on Natural and Semi-natural Grassland". He dealt specifically with the permanent grasslands of Ireland and opened by referring to the extent of pasture, old meadows and rough grazings which had remained undisturbed for long periods. The character of herbage was primarily dependent on the nature of the soils, but was ultimately determined by management. What the ecologist called the biotic factor was in a general way what a farmer described as management. The grazing animal, mowing, harrowing and all differential treatments were contributing factors. The intensity of grazing in the Curragh, for example, kept the heather under control and it was seen only at the margins. In Ireland, grass grew readily in response to a sufficiency of rain uniformly distributed. The soil varied and with it the primary vegetation. On poor soils the plants were of poor stature and adapted to poverty conditions. On the richer soils the plants were of good stature, such as perennial rye grass, meadow fescue, tall fescue and tall oat grass.

However, it was the management, or the biotic factors, that ultimately determined the botanical composition of the sward. The actual quantity of fodder produced was dependent on the soil and rain, but the botanical composition of the sward depended ultimately on the grazing animal. The animal operated in response to the relative palatability of the species present, and this was the more important factor in determining the balance of plants in the community. Linnæus's experiments, more than two hundred years ago, on palatability were unfortunately conducted on plucked plants which were then offered to the animals. It was known that animals would eat almost any plant that was offered to them, even poisonous species. They would devour ragwort in hay, yew clippings, and poisonous roots thrown up by drainage operations. In the growing condition such plants rarely caused casualties. The most palatable of grasses appeared to be timothy grass and red fescue, whereas the bents seemed to be less appetizing and for that reason tended to dominate very old pastures. The grazing animal, in fact, had left its imprint on the entire countryside. In recent years the dearth of rabbits had meant the disappearance of ragwort in certain areas, since grasses such as red fescue had been able to develop and crowd it out.

Prof. Gorman then showed colour slides of what he described as typical grasslands and some showing biotic factors at work. Many in the audience were horrified at the various shots of herbage which appeared to be dominated by such weedy species as the bulbous buttercup, ragwort, *Centaurea scabiosa*, *Leontodon*, thistles, *Ulex gallii* and others. Prof. Gorman conceded, however, that grasslands of high quality existed in various parts of Ireland, but at the same time gave the impression that such weed-infested areas were not uncommon. The unsatisfactory state of such grasslands had apparently been due to overgrazing by different animals at different times, with the consequent domination of ungrazable and unpalatable species. Although much could be done by liming and the use of fertilizers, only improved management and effective weed control could successfully deal with the problem, though long years of neglect had added to the difficulty. Much expense and labour would be necessary to carry out what must inevitably prove to be a long-term project.

The Weeds and Seeds (Ireland) Act passed by Parliament in 1908 endeavoured to cope with the problem, but in spite of heroic efforts the success of the Act as a 'biotic factor' had been strikingly unspectacular.

Dr. R. F. Hunter, of the Hill Farming Association, was unable to deliver in person his paper on "The Pasture–Animal Relationship on Hill Grazings", and Mr. A. R. Wannop, director of the Association, read it for him. The paper dealt with hill sheep farming, and in particular the management system known as the border hefting system. This prevailed wherever the stocking intensity lay between one and a little less than two and a half acres per sheep. The flocks were maintained throughout the year on the hill ground, with perhaps a little hay in severe weather. A representative heft included about 150 ewes, and on the particular heft selected for study there were about 130 ewes plus hoggets on an area of about 250 acres. The plant communities included *Nardus*, *Calluna*, *Molinia* and *Agrostis–Festuca* combined with bracken. Experiments were carried out to determine the relative grazing values of these communities. The attention given by the sheep to a particular community was assumed to be a measure of its value. The work was carried out at Sourhope in the Cheviot Hills on a heft sloping up from 900 ft. altitude to approximately 1,750 ft. The sheep were observed from a hut in which was arranged a piece of apparatus designed by Dr. Hunter and christened a 'sheeposcope'. This consisted of a powerful telescope, covering most of the heft, with which was coupled a mechanism capable of plotting the exact position of any animal on a map of the area. It was possible to plot with great accuracy the exact position of all the 150 or so sheep in 10–15 min. Observations, started in September 1956, were made once every hour from dawn until dusk at approximately weekly intervals. Meteorological data were also assembled to determine whether or not sheep behaviour had any connexion with meteorological events.

A number of graphs illustrating the results of the observations on particular plant associations were then shown. It was seen that on the *Nardus* areas, 5 per cent of the total heft, 16 per cent of the sheep were observed. As an index of grazing intensity, the figure of 100 was allotted to a community which was neither favoured nor disfavoured. A figure less than this indicated an avoidance; one greater showed a preference. The grazing of grass below bracken was generally high, since bracken was only about 2 ft. tall and not particularly dense. Variation in grazing intensity was seasonal, being high during September–October and again during March–April. The graph for Molinetum showed a low grazing intensity with some degree of seasonal variation and was definitely not favoured by sheep. Another community consisting of a mixture of *Molinia*, *Juncus squarrosus* and heather, the latter being dominant, also showed a low grazing intensity. The Nardetum curve demonstrated a consistently low grazing intensity, being favoured by the sheep only in the winter. On the other hand, the *Agrostis–Festuca* community had a high intensity throughout the year.

Dr. Hunter had compared his results with similar observations carried out during 1950–52 in the Lammermuir Hills, and, in general, results showed a fair correspondence. Such discrepancies as occurred were explained by the differences in percentage composition of the communities of the corresponding hefts. It was concluded that variation in grazing intensity was modified according to the types of communities and the varying proportions they bore to the heft as a whole. Two broad generalizations arose from the results. First, wide differences existed between the grazing intensities of different communities. Secondly, the seasonal variation in intensity appeared to be a characteristic of the community whenever it occurred in association with others.

Dr. Hunter's paper then discussed the connexion between these conclusions and the work of the ecologist and those concerned with the improvement of hill pasture. The botanical composition of the pastures would obviously be affected by wide differences in grazing intensities. The improvement of these hill pastures, however, presented a number of problems. Should one tackle the heavily grazed communities or those which under free grazing conditions are little utilized? It was Dr. Hunter's opinion that an improvement of the *Molinia* and *Nardus* areas would be advantageous. Nevertheless, in improving pastures there would be difficulties in fencing off improved areas to control the grazing. Many questions remained unanswered. It was concluded, however, that an understanding of the grazing preferences of sheep under free-ranging conditions might help to predict whether the improvement brought about would be utilized in such a way as to lead to an improvement of overall utilization of the pasture as a whole.

The session ended with a long and spirited discussion on many of the points raised by the speakers.

F. Ballard

FUNDAMENTAL RESEARCH ON PAPER-MAKING FIBRES

The activities of the Technical Section of the British Paper and Board Makers' Association are usually deliberately organized so as to appeal to all classes of members. The symposium entitled "Fundamental Aspects of Fibres and their Treatment for Papermaking", held at Cambridge during September 23–27, was therefore a unique departure from custom. Its object was to assemble together prominent workers in this field from all parts of the world, for the purpose of presenting papers for discussion at the highest possible academic level.

The success of the experiment may be judged from the fact that of some two hundred persons attending, about one half were from overseas, and these included many well known for their work in specialized fields of fibre research. Seventeen overseas nations were represented.

Social features were provided in the form of evening conversaziones, a theatre visit, and an excursion to Ely and Norwich. These, however, appeared to supplement opportunities for discussion on the more serious business of the symposium rather than to provide a relaxation, and this despite the full official programme. To many of the overseas visitors the atmosphere of Cambridge, despite the bad weather, was an attraction in itself; and the lecture hall and residential facilities made available by the University authorities were greatly appreciated.

After Sir Geoffrey Taylor had welcomed the participants, Session 1, dealing with the morphology of pulp fibres, was opened under the chairmanship of Dr. W. Holzer. Prof. A. Frey-Wyssling (Switzerland), in discussing the general structure of fibres, pointed out that the young differentiating fibre has a very thin cell wall consisting of an amorphous matrix of pectic and hemicellulosic material reinforced by about 5 per cent by volume of cellulosic microfibrils (diameter about 250 A.) arranged in a dispersed interwoven texture. This may be described as the primary wall. As growth proceeds, more of the microfibrils are produced, and the character of the wall changes. Indeed, it is possibly then identical with the outer layer of the secondary wall, a lamellated structure in which the microfibrils are closely packed, touching laterally and forming characteristic fasciations. The elementary fibrils appear to be ideally crystallized, the space between them being filled partly with paracrystalline cellulose and partly with alkali-soluble non-cellulosic material. Throughout fibre growth a tertiary lamella exists at the boundary between the living cytoplasm and the fully differentiated secondary wall.

This overall picture of fibre structure provided a background for the following more detailed treatment of the subject. Dr. H. Bucher (Switzerland) was concerned with discontinuities in the microscopic structure of wood fibres, as disclosed when they are allowed to swell in dilute alkali and then crushed. Such work indicates an actual discontinuity in the constitution of the secondary wall of coniferous wood fibres; a concept which existed at one time but which has been abandoned in recent years. The presence of a tertiary wall having a distinct microscopic structure is an important concept, since it appears to influence such important papermaking considerations as stability, elasticity and water sorption. H. W. Emerton (British Paper and Board Industry Research Association) then dealt with the structure of the outer secondary wall. Differences in the terminology of cell structure became apparent from time to time during the symposium, but many speakers, including Emerton, regarded the secondary wall as the series of coaxial layers characterized by close lateral packing and parallel alignment of their fibres within the primary wall. The polarizing light microscope shows that in the outermost ($S1$) and innermost ($S3$) layers of the secondary wall the fibres have an almost transverse direction; while in the middle layer ($S2$) they are almost longitudinal. Some excellent micrographs were used for showing that when pine tracheids are pulped by the kraft process there is a tendency for an outer wall to part cleanly and readily from the rest of the wall over a wide area. This wall (believed to be $S1$) consists of two counter-rotating sets of striations, symmetrically disposed about the axial direction. There is experimental support for the hypothesis that the two helices are in distinct layers. Markings in the axial direction which occur chiefly at the edges of the cells were a striking feature of the micrographs. However, it is not yet certain whether they are bundles of fibrils or creases resulting from the drying of the specimen.

The fine structure of the cellulose fibrils was discussed by Dr. B. Rånby (United States), starting with the concept (based on X-ray diffraction data for crystalline cellulose) that the cellulose chains form fairly straight and flat ribbons in the cellulose lattices. The flexibility of cellulose chains is thus limited mainly to the glycosidic bonds between the glucose units, where rotation is easier. The electron microscope provides evidence that hemicellulose is dispersed between the cellulose fibrils throughout the whole cell wall, and the ease of dispersion of pulp fibrils rich in hemicellulose into fibrils suggests that there are few cellulose chains linking one fibril to another—a conclusion which Rånby felt should be treated with caution. He also discussed the crystallinity of native cellulose, pointing out that it can be assessed from the regions of low order (that is, those most accessible to chemical reagents), the average width of the crystalline regions, and the lattice order, which varies according to the biological origin of the material.

The discussion on this session produced general confirmation of Emerton's work. The important point was made that elementary fibrils cannot be disintegrated solely by mechanical means, but that the hydrogen bonds must first be destroyed by solvent action. Moreover, fibrils of the same dimensions in the primary and secondary walls do not necessarily appear to be otherwise identical. There is insufficient difference in chemical composition between the secondary and tertiary walls to account for the differences in their behaviour.

Session 2 (chairman, Dr. J. Grant) dealt with the chemistry of pulp fibres and was introduced by Prof. E. L. Hirst (Edinburgh) with a concise survey of existing knowledge of the chemical structure of the hemicellulose group. Dr. L. Jörgensen (Sweden) then presented data for the carbohydrate compositions of spruce pulps prepared by a variety of processes over a wide field range. It was then possible to relate the hemicellulose content with the strength values of the pulps. Dr. P. Lange (Norway) discussed his work on the distribution of cellulose, hemicellulose and lignin in the cell walls of spruce, birch and cotton. His paper introduced some elegant techniques; notably the use of interference microscopy, histo-radiography and absorption microphotometry in the visible and ultra-violet regions. The results show that the compound middle lamella and the secondary wall are the main locations for the lignin and carbohydrate constituents, respectively. The most rapid change in lignin concentration occurs in the outer secondary wall, where it falls from 60–90 to 10–20 per cent in the lumen (for spruce). Thus, in general, the cell wall of wood is highly ordered around the lumen and becomes more amorphous as the middle lamella is reached. Dr. G. N. Christensen presented a paper by H. E. Dadswell, A. B. Wardrop and A. J. Watson (Australia) on what is known as reaction wood, that is, wood which is anatomically different from normal wood, having developed in leaning or crooked trunks and in branches. In the softwoods such wood (compression wood) has a relatively high lignin, and a low cellulose content. The reverse applies to reaction hardwood (tension wood) and in addition its pentosan content is very low; hence its poor papermaking properties. Strangely enough, the mechanical pulps from tension and compression woods are superior and inferior, respectively, to those obtained from the corresponding normal woods.

The discussion on this session emphasized the importance of the acid hydrolysis of cellulose as a guide to the degree of crystallinity. Such work shows that the interfibrillar material is accessible to hydrolysis and therefore amorphous, and that it consists mainly of mixed hemicellulose. There is also evidence that attack by hydrolysis is assisted by slip-planes introduced by tension-wood. While self-contained in a chemical sense, the discussion gave the impression that it is not yet possible to link up the physical and chemical evidence on cell-wall structure.

In Session 3, which, under the chairmanship of Dr. H. F. Rance, dealt with bonded-fibre assemblages, the contributions took a more practical form in that they dealt with paper as distinct from fibres. Prof. B. Steenberg (Sweden) presented a critical review of the relationship between beating and the mechanical properties of paper. He indicated that the ultimate strength properties are determined essentially by the less-damaged fibres and the contacts they make with one another. Prof. W. Brecht (German Federal Republic) dealt with the effect of beating on the important practical property of hygrostability of paper, and the influence of paper composition, thickness and density. It was concluded that inter-fibre shrinking, which is a consequence of surface tension effects between individual structural elements, is promoted by beating since this produces suppleness. Single fibre shrinkage, on the other hand, is practically independent of beating, but its effect is transferred to the final sheet to a degree which depends on the extent to which the fibres are in contact.

A paper by Dr. H. Corte (German Federal Republic) dealt with the measurement of the porous structure of paper and its modification by beating; and L. Nordman (Finland) discussed strength of bonding in paper in terms of the energy required to break the bonds in an area of unit size. For such measurements the optical method based on the theory of Kubelka and Monk is preferred, the bond-strength being determined from the slope of the line relating the increase in scattering coefficient and the irrecoverable energy loss in a straining/destraining cycle. The results are similar to those deduced from the work of Nissan on strained hydrogen-bonded materials.

The stepwise pattern of Nordman's curves relating increase in reflectance and strain was related by C. R. G. Maynard, during the discussion, to the formation of opaque patches made up of criss-cross lines when transparent paper is subjected to strain.

Session 4, on the process of beating (chairman, Prof. B. Steenberg), comprised six papers which were intended, so far as possible, to collate the conclusions of the preceding sessions. Dr. W. Gallay (Canada) introduced it with a review of aspects of the theory of beating, and Emerton provided a short sequel to his paper in Session 1 when dealing with the significance for paper-making of the outer secondary wall (or primary wall as a number of speakers felt it should now be called). Prof. H. W. Giertz (Norway), in a study of the effects of beating on individual fibres, dealt primarily with swelling and fibrillation phenomena. Although it is difficult to measure the degree of swelling, it has been shown that it increases with beating. While, therefore, swelling is a necessary condition to obtain paper strength, it has not been possible to correlate these two properties. In general, similar conclusions apply to external fibrillation. A combined swelling and staining technique was used to render the primary wall visible, and thence to show that removal of the primary wall has a drastic influence on the bonding capacity of the fibre.

Prof. G. Centola and Dr. D. Borruso (Italy) then discussed the influence on beating of certain electrolytes and substantive azo-dyes. As a rule, electrolytes reduce the beating rate (as compared with distilled water). On the other hand, benzidine type azo-dyes greatly accelerate beating and the development of mechanical properties, and when added to the beaten pulp produce an increase in wetness without appreciable change in strength. Extraction of the dye from the beaten pulp reduces the wetness.

Dr. J. A. Van den Akker (United States) applied energy considerations to the beating process under idealized conditions. He found an energy requirement of 0·01 kWh. per ton of pulp for the production of 'sub-microscopic fuzz' (fibrillation), that is, only 0·0025 per cent of the total energy expended in a typical beater or refiner. For the loosening of the internal structure of the fibres (swelling) and for cutting, the respective energy requirements are only 0·4 and $2 \cdot 7 \times 10^{-3}$ kWh. per ton. The wastage of energy in the form of heat during beating has always been regarded as inevitable; these figures should, however, shake the complacency with which it has been accepted.

The concluding paper, by O. L. Forgass, A. A. Robertson and Dr. S. G. Mason, read by Dr. S. G. Mason (Canada), dealt in a masterly way with the hydrodynamic behaviour of paper-making fibres, under the headings of flow of pulp suspensions, coherent fibre networks, and the flexibility of single fibres. The study of flexibility is of particular interest because of its relationship to fibre entanglement and wet-web properties. The method of measurement adopted makes use of the characteristic rotational orbits described by fibres suspended in a liquid subjected to laminar shear. The flexibility was found to increase as the lignin was removed; with increase in the length of fibre; and on beating.

A point raised in the discussion (which indeed is applicable to the whole of the symposium) is the importance of making clear when the term 'fibre' is used in a general sense—and when used for describing wood fibres only, as was usually the case. It was pointed out, for example, that the conclusions regarding the relative unimportance of external fibrillation in producing strength is most unlikely to apply to well-fibrillated rag fibres.

A brief summing-up by Dr. H. F. Rance brought this highly successful event to a close.

Julius Grant

THE BRITISH SCIENTIFIC INSTRUMENT RESEARCH ASSOCIATION

THE Association opened its doors to eight hundred visitors from member-firms, academic and government agencies, and non-member organizations during the week beginning October 7. Each day a distinguished scientist gave a lecture to the visitors after luncheon in a marquee on the lawn. Fortunately for all concerned, the weather remained uniformly good over the period. The chairman of the Association, Mr. J. E. C. Bailey, entertained the speakers and other distinguished guests at a dinner held in London on the evening of October 9.

The main research programme of the Association, as approved by the Research Advisory Committee, was exemplified by exhibits of the investigation of the structure and control of thin films, ultrasonic and electromagnetic flowmeters, applications of semiconductors, and the design of a specific microscope objective. These formed but a part of the seventy-seven exhibits, covering many aspects of the Association's work. Of particular interest, as indicating the importance of giving as much freedom as possible to the individual scientist, was the demonstration of a chemical balance which used flexure pivots in place of knife-edges. This development had no place in the research programme, but although the investigation is still in its early stages, a promising degree of robustness and sensitivity has been achieved. Another exhibit of potential value was the moisture-sensitive ceramic element. This was demonstrated, measuring humidities in the 0–1 per cent region to about 0·02 per cent. The instrumental applications of graticules, devices which started as scales and now form an essential part of certain automatic control processes, are becoming more numerous every day. The exhibits concerned with graticules covered the whole field of their manufacture and application. British thermometer manufacturers now have at their command a method of making permanent markings on many of their products. The process for doing this, developed by the Association, was the subject of another exhibit. Pneumatic gauging, as developed by the Mechanical Department, excited considerable interest.

The extent of the services provided by the Information Department came as a surprise to many visitors, particularly the range of technical inquiries handled by the scientific staff of the Department. Working models of flexure pivots, illustrating devices described in one of the Department's publications, aroused much interest.

The speaker on October 7, Dr. T. E. Allibone, took as his subject "Black and White Elephants at Aldermaston". In the course of his lecture he described many discoveries and inventions made in his own laboratories which were apparently of little use, but had afterwards turned out to have considerable value. On October 8, Sir John Cockcroft spoke about "Nuclear Instrumentation" and directed attention to the enormous field for instruments which was being created by the planned reactor programme. On October 9, Prof. Casimir, from Holland, gave his audience a peep into the future by discussing "Atoms as Units", describing how atomic properties could be used as standards of length, time, electric charge and magnetic induction. Dr. Ponte, of Paris, gave a more detailed account of a particular branch of instrumentation on October 10. His subject, "Quartz Oscillators and their Limitations", was illustrated by slides of modern time-measuring equipment. He showed that an accuracy of 1 part in 10^8 was now feasible with small, robust equipment. On October 11, Prof. S. Tolansky demonstrated the power of phase-contrast microscopy by means of many photographs of the detail of crystal structure in metals, convincingly illustrating that for the detection and measurement of the contours of a surface the optical method is comparable with the electron microscope.

A noteworthy feature of the open days was the exhibition of members' products to which the Research Association had made some contribution. It was a kind gesture on the part of the members and one which is bound to have a good effect on the morale of the staff thus to acknowledge some of the benefits which have accrued as a result of the Association's work.

CONTROL OF ADMINISTRATIVE TRIBUNALS

IN opening a debate in the House of Commons on October 31, in which the House took note of the report of the Franks Committee on Administrative Tribunals and Enquiries, Mr. R. A. Butler said that the Government is concerned to accept as many of the recommendations of the report as possible. Nevertheless, it wishes to obtain the views of members on certain of the findings and particularly in the light of the three guiding principles of openness, fairness and impartiality. The Government believes it would be possible to accept wholly or substantially the majority of the detailed recommendations, while striking a just balance between the rights of the citizen and the efficient discharge of the country's business. The Government proposes to set up a single Council on Tribunals which will be appointed jointly by the Lord Chancellor and by the Secretary of State for Scotland, with a special committee or panel of the Council to deal with matters of special concern to Scotland. The Council would be consulted before establishing any new tribunal and the Government would refer to the Council various recommendations made by the Franks Committee.

It is also proposed that, in general, chairmen should be appointed by the Lord Chancellor in England and Wales, and by the Lord President of the Court of Session in Scotland, and the Government agrees that for the most part it is desirable that chairmen of tribunals should have legal qualifications. The opinion of the House of Commons is to be obtained regarding the proposal to entrust adjudicating functions of county agricultural executive committees to new independent tribunals, with appeal to the Land Tribunal or to the Scottish Land Court. In future, it is proposed to appoint inspectors only after consultation with the Lord Chancellor, and the Minister would be free to dismiss chairmen only with the Lord Chancellor's consent. Mr. Butler said that the Government is also prepared to arrange for publication of inspector's reports and promised that in future responsible Ministers would ensure that more is done to make the policies for which they are responsible more widely understood, that people are told where they can find the information which may help them, and that authorities will be required in future to see that their case is properly set out before an inquiry opens. The statement was generally welcomed, and in replying on the debate the Attorney-General stressed the advisory functions of the proposed Council.

EFFECT OF RADIATION ON HUMAN HEREDITY

A STUDY group, set up by the World Health Organization in Geneva to consider the effect of radiation on human heredity, has presented its report to the United Nations Scientific Committee on Atomic Radiation; in shortened form, the report has been prepared as a special feature of the *Chronicle of the World Health Organization* (11, No. 8; August 1957).

Each member of the group was acutely aware of the existing gaps in knowledge and drew up an inventory of problems which will need to be investigated by geneticists, nationally or internationally.

Spontaneous and artificially induced mutations, particularly the kinds of mutation produced by various doses and types of radiation, applied at different stages of the life-cycle under a variety of conditions and utilizing different kinds of organisms, need further examination. The role of changes in the hereditary material of somatic cells in the genesis of leukæmia and various neoplasms could be elucidated. This is now possible owing to the recent developments in tissue-culture techniques. The means of protection against mutagenic agents needs attention. New and improved techniques for the identification of mutants, many of which remain unrecognized at the present time, need development. The manner of gene action is of importance. Dominance, synergism and other forms of gene interaction, including the role of the environment, are important in appraising the effects of radiation and should be further studied in both man and animal.

Factors such as natural selection in populations through the collection of demographic and experimental data should be studied. This type of research is indispensable if the genetic structure of past and present human communities is to be understood and future trends are to be predicted.

Patterns of mating in human populations, such as inbreeding and their genetic implications, are important problems which need solving.

Twin studies in man which are known to be helpful for the understanding of many problems of human heredity offer a large field for research.

The frequency of diseases with a significant genetic component, with particular reference to their epidemiology, needs to be determined. Central registration of data on human inbreeding and hereditary diseases is believed to be of the utmost importance.

Populations of special genetic interest, such as relatively stable, primitive communities, long isolated by geography or culture, and communities exposed to unusually high background radiation should be studied.

The genetic mapping of human chromosomes is also of importance. Cytochemistry and human cytology, particularly investigation of the ultramicroscopic structure and chemical composition of the hereditary material and of the manner in which this is altered by irradiation and other mutagens, and the development of new statistical methods for analysing the results obtained from research in human and experimental population genetics are also valuable fields for further research.

Investigations capable of throwing fresh light on all these problems will involve great effort in many countries and a great expansion of general and *ad hoc* research in genetics and other fields of biology with the closest possible collaboration between those working in the experimental and human fields. The report of the study group emphasizes that "there is at present an insufficient number of institutions where an adequate training in genetics, particularly in human genetics, can be given". The group believes that "medical undergraduates should all receive training in genetics and teaching should be co-ordinated with that in radiology and in the use of radioactive substances in medicine, so that the genetic hazards of diagnostic and therapeutic procedures are thoroughly understood. Medical men training as radiologists should have specific, more advanced, instruction in genetics. Health physicists, radiological physicists and radiological technicians should also receive instructions in genetics as part of their technical training".

The study group was particularly concerned about the genetic hazards of radiation from sources used in medicine, industry, commerce and experimental science. As the report puts it: "Both as an approach to control and as providing basic background information for relating quantitatively radiation exposure and effects on man, it is essential that methods be found of recording exposures to individuals and populations however difficult this may prove.

"There is reason to believe that radiation exposure can be much reduced; those in charge of sources of ionizing radiations should always ensure that there is adequate justification for exposing individuals to doses, however small. On account of the danger to offspring resulting from irradiation of the gonads by X-rays, consideration should be given to determining what efficient means of shielding the gonads could be devised and brought into general use. In addition, in every exposure, the X-ray beam ought as far as practicable to be directed so that a minimum of radiation reaches the gonads."

MEASUREMENT OF SMALL QUANTITIES OF FLUORIDE WITH THE HELP OF FLUORINE-18

By Dr. J. H. FREMLIN, Dr. J. L. HARDWICK and J. SUTHERS

Department of Physics and Department of Dental Surgery, University of Birmingham

IN the course of investigations of the uptake of fluoride ions by teeth, we wish to measure the concentration of fluorine in small samples of enamel and of various aqueous solutions. Colorimetric methods will work at low concentrations (down to less than one part per million) but need samples of at least several millilitres. The more convenient methods may be upset by the presence of phosphates and other salts.

We have developed an isotope-dilution adsorption method which we can use with samples of a milligram or less of solution at the lowest available concentrations. The method is based on the adsorption of fluoride from acid solution by glass. The procedure is as follows. To the solution for analysis is added a small known quantity of fluorine-18 as fluoride, as nearly carrier-free as possible. N nitric acid is then added to give a pH close to 2. The mixed solution is applied to a defined area of a glass surface. (We have found good-quality microscope slides satisfactory; these are cleaned for a few seconds with dilute nitric acid followed by distilled water.) Fluoride ions are then taken up by the glass, 80 per cent of equilibrium being reached in two or three minutes. After an adequate time, the active solution is washed off for 1 min. in a fast stream of tap-water (pH about 6).

At this pH the adsorbed material does not leave the surface at a significant rate. The amount of fluorine-18 adsorbed can then be measured by means of a Geiger counter.

The total quantity of fluorine adsorbed from solution varies only slowly with concentration. The stable and the radioactive isotopes compete for the adsorption sites available. Consequently, the stronger the mixed solution is in stable fluorine, the less fluorine-18 activity there will be in the adsorbed layer.

The method is obviously not an absolute one and is calibrated by the use of a set of standard fluorine solutions of known strength, each containing exactly the same concentration of fluorine-18 and having the same pH. In Fig. 1 is shown a calibration curve obtained using 4 ml. samples and 1 cm.^{2} of glass for each sample. It has clearly the form of an adsorption isotherm. The divergence from linearity at the beginning probably indicates a trace of fluorine in the nitric acid or distilled water used. Above 100 p.p.m. there is a divergence at the other end due to etching of the glass by hydrofluoric acid which increases markedly the effective surface area of the glass. The arrows represent the count given by samples of laboratory tap water and distilled water; the 0·05 p.p.m. of fluorine indicated for the tap water is in good agreement with colorimetric measurements.

In Fig. 2 is shown a calibration curve obtained using 1 mgm. samples of the standard solutions, to each of which was added 1 mgm. of N nitric acid and 1 mgm. of distilled water containing cyclotron-produced fluorine-18. The strength of this was in the region of 10 µc. per ml. In this particular case the material to be investigated, and hence also the calibrating solutions, were in a standard lactic-acid lactate buffer having a pH of 4·6. At the higher fluoride concentration this gives the same result as pure water, but the percentage sensitivity falls away a little at the lowest concentrations. This is almost certainly due to the contamination of our original materials with traces of fluorine.

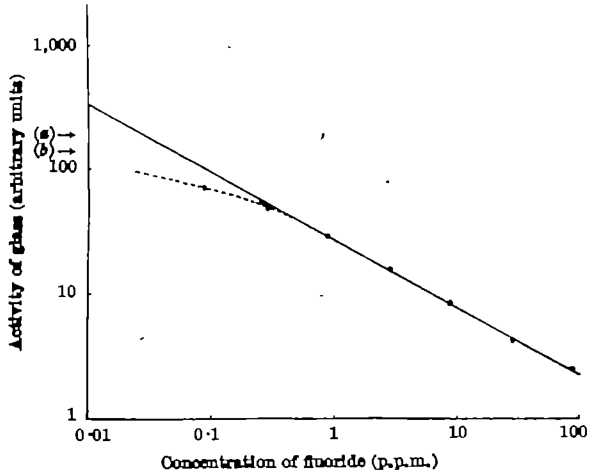

Fig. 1. (a) Activity of slide in distilled water; (b) activity of slide in tap water

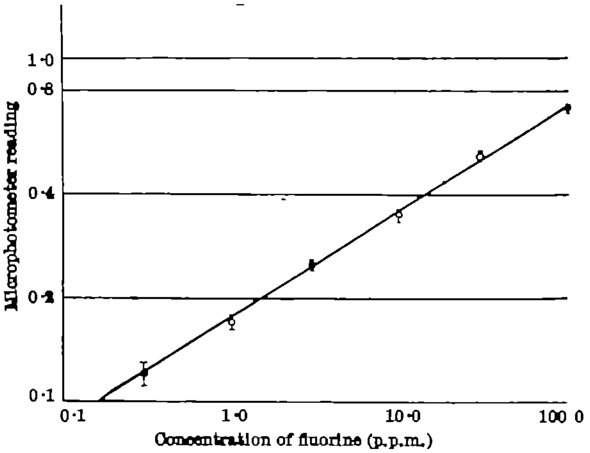

Fig. 2. Calibration curve for 1 mgm. samples in lactic acid–lactate buffer solution

In this example, a Geiger counter was not used for the measurement of the samples. Instead, all the active areas of glass (which were each about 2 mm. diameter) were placed against a single piece of X-ray film and left overnight. The developed autoradiographs were then measured by means of a microphotometer. The results of this measurement can be translated into terms of fluorine-18 activity by means of calibrated exposures to a standard source. For our purposes it is, however, convenient to plot the microphotometer readings direct.

It can be seen that at the lower concentrations an added concentration of one or two tenths of a part per million can be detected in spite of the contamination already mentioned. In one milligram of solution this corresponds to one or two ten-thousandths of a microgram of fluorine. The percentage error is fairly large, but it is not serious for our immediate purpose. Much of it is due to microphotometer errors which could be considerably reduced.

The handling of these small quantities of liquid must be done carefully to avoid evaporation. We made up several micropipettes, of about 5 per cent accuracy, of glass and 'Polythene' tubing. The latter had always been used for the acidified solutions to avoid loss of fluorine. The glass areas were defined by waxing on to the clean slide a series of 8 *BA* washers. As each sample was deposited on the slide inside the washer, a drop of liquid paraffin was placed over it, which isolated it effectively until required.

Subsidiary experiments have shown that acid, sample and radioactive solution may be added mixed or separately in any order, without any significant difference in the results, so long as the fluid mixture is left long enough to allow complete mixing (and so long as the pH is not raised after addition of the fluorine-18). It is evident that at a low pH there is a continuous rapid exchange of fluorine ions between the glass surface and the solution.

Another subsidiary experiment has shown that there is little change in take-up between a pH of 1 and a pH of 3·5, but that above 4·5 the take-up falls off very rapidly. We are investigating the effects of the presence of various other ions, but the main discovery made so far is that most materials contain a number of parts per million of fluorine and that this is quite difficult to remove.

Finally, it has been shown that, as would be expected, the variation with temperature is not large enough for a thermostat to be necessary. To give a change of 10 per cent would require a temperature difference of 4° C., which is unlikely to occur between different parts of the same microscope slide.

The principle used in this method should be applicable to many other elements and, we believe, may be of enough general interest to justify this preliminary report, although it may be some time before the results of our main research are complete.

When radioisotopes of high specific activity are obtainable, the ultimate sensitivity has been by no means reached. The limiting difficulties are probably the handling of very small quantities of liquids rather than the determination of concentration.

We would like to express our gratitude to Mrs. June Mathieson for her help with the later and more exacting stages of this work.

PHOSPHODIESTERASE FROM RATTLE-SNAKE VENOM

In a recent communication, Boman and Kaletta[1] concluded that venom of *Crotalus adamanteus* contained two phosphodiesterases, both of which digested deoxyribonucleic acid. The evidence consisted of chromatography of venom on diethylaminoethyl-cellulose[2], resulting in two active peaks containing phosphodiesterase and deoxyribonuclease in an almost constant ratio. The ratio remained constant after about 20 per cent of each activity was destroyed by exposure to elevated temperatures. The conclusion of Boman and Kaletta[1] was not in agreement with that of Privat de Garilhe and Laskowski[3], who claimed that phosphodiesterase can be separated from deoxyribonuclease.

Phosphodiesterase was determined by the same method[3] in both laboratories, but deoxyribonuclease was determined in Upsala by the liberation of material showing absorption (E_{260}) after precipitation of the non-digested deoxyribonucleic acid with lanthanum salt in acid solution, whereas in Milwaukee it was determined viscosimetrically[4]. Clearly, viscosity will be strongly influenced if a diester bond, located in the middle of the molecule of deoxyribonucleic acid, is split, but only a little change in viscosity will be expected if a terminal mononucleotide is cleaved off. On the contrary, a cleavage occurring in the middle of the chain will produce no 'lanthanum-soluble' material; but if the terminal mononucleotide is split, it will become soluble. The two methods, therefore, do not measure the same phenomenon.

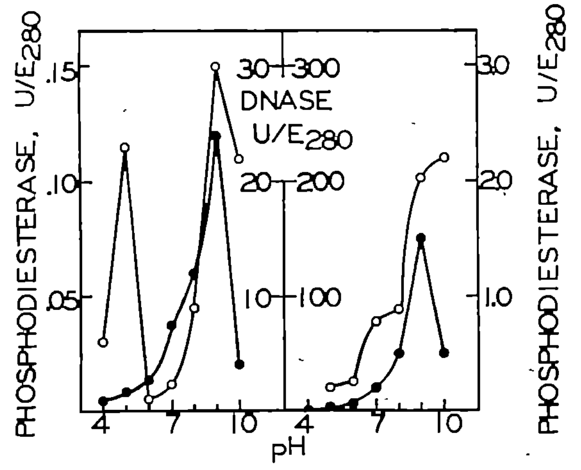

Fig. 1. Effect of pH on activity. Left side, crude venom; right side, preparation of phosphodiesterase purified by chromatography on diethylaminoethyl-cellulose and carboxymethyl-cellulose. Left and right ordinates represent phosphodiesterase activity (●—●) expressed in units (ref. 3) E_{280}. Central ordinates represent deoxyribonuclease activity (○—○) measured by viscosimetric method and expressed in units (ref. 4) E_{280}

Table 1. SEPARATION OF PHOSPHODIESTERASE FROM DEOXYRIBONUCLEASE

	Phosphodiesterase* U/E_{280}	Deoxyribonuclease† U/E_{280}	Ratio × 10^3
Crude venom	0·08	10	8
Ppt. after dialysis, *p*H 5·5, 0·05 *M* acetate	0·008	5·3	1·5
Ppt. after a second dialysis of the previous	<0·00008	2·7	<0·3
Tube 5, chromatography of venom on diethylaminoethyl-cellulose, *p*H 8·9, 0·05 *M* *tris* buffer	4·3	70	60
Tube 32, chromatography of venom on diethylaminoethyl-cellulose, *p*H 7·5, 0·05 *M* *tris* buffer	2·9	16·2	180

* Expressed in units as defined in ref. 3.

† Measured at *p*H 8·9, *tris* buffer, expressed in units as defined in ref. 4.

The following results may be quoted in support of the contention that, besides phosphodiesterase, venom contains one (or more) deoxyribonuclease(s). Fig. 1 indicates that crude venom has two pronounced optima for the action of deoxyribonuclease (viscosity), but one for phosphodiesterase. The existence of an optimum at *p*H 5 was previously observed by Haessler and Cunningham[5]. With a partially purified preparation of phosphodiesterase, the optimum at *p*H 5 practically disappears. The optimum on the alkaline side is broader for deoxyribonuclease than for phosphodiesterase; the difference is particularly pronounced with a purified preparation. Even when both activities are measured at *p*H 8·9, they do not parallel each other during the fractionation procedure (Table 1).

This confirmation of our previous claim does not, however, contradict those results of Boman and Kaletta[1] which relate to the appearance of 'lanthanum-soluble' material as a result of the action of phosphodiesterase. On the basis of our previous work[6,7] on the action of phosphodiesterase on different fragments of deoxyribonucleic acid, it was postulated[6] that phosphodiesterase is an exonuclease and that it acts by a consecutive splitting of the 5′-terminal mononucleotide from the chain, regardless of the length of chain. The only fact difficult to reconcile with this view was our own observation[6] that an 'intact' deoxyribonucleic acid was resistant to purified phosphodiesterase. The negative conclusion drawn from this experiment is now retracted.

The following results provide additional evidence favouring the exonuclease mechanism. In agreement with Boman and Kaletta[1], phosphodiesterase obtained by chromatography of venom on '*IRC 50*' [8], carboxymethyl-cellulose[2], or on diethylaminoethyl-cellulose[1], was active on both calcium [*bis* (*p*-nitrophenyl) phosphate]$_2$ and deoxyribonucleic acid, when tested by the 'lanthanum-soluble' method.

In agreement with the postulation[4], the high viscosity of the digestion mixture persisted (at least until 10 per cent of the deoxyribonucleic acid became 'lanthanum-soluble'). The 'lanthanum-soluble' fraction was composed almost entirely of mononucleotides, the sum of which accounted for about 90 per cent of the optical density of the whole fraction. Fig. 2 illustrates the results of one of these experiments. Small amounts of nucleosides (peak 1) resulted from traces of contaminating 5′-nucleotidase. Peaks 6 and 7 contained some fragments higher than mononucleotides; however, they were heavily contaminated (more than 80 per cent) with the material extracted from the resin itself, since they had abnormal spectra without maxima between 250 and 290 mμ. After the pooled peaks 6 and 7 were hydrolysed with formic acid, all four bases were identified, but the total absorption (E_{260}) of the recovered bases accounted for less than 20 per cent of the value prior to hydrolysis. It was concluded that the small amounts of unidentified oligonucleotides (peaks 6, 7) were formed as a result of action of contaminating deoxyribonuclease.

The contention that the 'lanthanum-soluble' method of Boman and Kaletta[1] reflects the activities of both phosphodiesterase and deoxyribonuclease is further strengthened by the results shown in Fig. 3. The most plausible explanation is that a slow reaction, representing the consecutive cleavage of mononucleotides from the already existing terminal, changes into a rapid one, after additional terminals have been produced as a result of the action of deoxyribonuclease.

Finally, when deoxyribonucleic acid was incubated with a crude venom at *p*H 5·0, viscosity decreased fairly rapidly. However, the majority of the digest was composed of large oligonucleotides requiring[2] for elution buffers stronger than 1 *M*. The sum of nucleosides and mononucleotides accounted for less than 10 per cent; there were virtually no dinucleotides. It is interesting that a small amount of thymidine 3′,5′-diphosphate was identified among the products. Such a compound could not have been formed in a detectable quantity from deoxyribonucleic acid by the action of phosphodiesterase alone. The appearance of such a compound, however, would be expected as a result of a combined action of deoxyribonuclease (with a specificity of the deoxyribonuclease II) and phosphodiesterase[7,8].

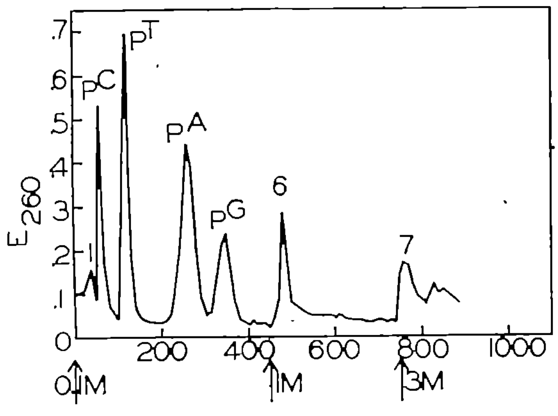

Fig. 2. Digest of 10 mgm. of deoxyribonucleic acid with 0 04 unit of purified phosphodiesterase (ref. 3), 0 05 *M tris* buffer, *p*H 8 9, 37°, 24 hr. Non-digested deoxyribonucleic acid removed with 'acid-lanthanum', lanthanum removed with oxalate. Column, 'Dowex 1-2X', 1 cm. × 10 cm Peaks 2–5 are labelled *pC*, *pT*, *pA*, *pG*, respectively, and represent mononucleotides which were identified by the position, spectrum, ionophoresis and chromatography on paper. Peaks 6 and 7 contain some unidentified oligonucleotides and a heavy contaminant from the resin

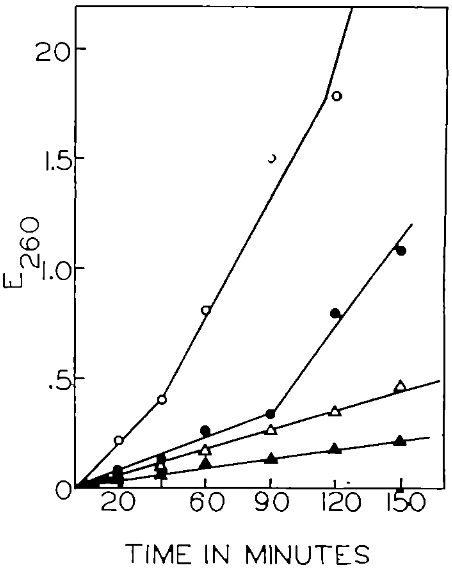

Fig. 3. Activity by the 'lanthanum-soluble' method plotted versus time. Open triangles, dialysed venom, with a ratio of phosphodiesterase/deoxyribonuclease (*p*H 8 9) = 8 × 10⁴; closed circles, preparation with a ratio 40 × 10⁴; open circles, preparation with a ratio 70 × 10⁴; closed triangles, the same as previous, diluted 1 : 5

THE need for knowledge of the specificity of the phosphodiesterases is related to the use of these enzymes as tools in structure work on, for example, nucleic acids and phosphoproteins. It is therefore of great interest that Laskowski and co-workers have been able to verify our earlier conclusion that the phosphodiesterases from *Crotalus adamanteus* hydrolyse macromolecular deoxyribonucleic acid[1]. It appears also very likely that the differences in the 'deoxyribonuclease activity' obtained by the viscosimetric[2] and the 'lanthanum-acid-soluble' methods[1] are due to the fact that the phosphodiesterase has an exonucleotidase activity.

It is a separate problem if the venom, in addition to the phosphodiesterases, contains another enzyme which can decrease the viscosity of deoxyribonucleic acid (a 'deoxyribonucleic acid depolymerase') but would not act on calcium(*bis*(*p*-nitrophenyl)phosphate)$_2$. We have, at this Institute, at present no definite opinion whether or not such an enzyme exists in our batches of venom. This uncertainty is due to the following difficulties we have had in obtaining conclusive experimental results: (1) the commercially available rattle-snake venom does not appear to be a reproducible and well-defined product, probably depending on an enzymic autodigestion occurring during the collection of the venom: (2) the optimum metal-ion concentration for the enzymes does not seem to be known for the different substrates; (3) inhibition of the phosphodiesterase by small amounts of inorganic phosphate; (4) the differences in the salt concentration of the enzyme fractions from a chromatographic experiment[3], a factor which is of some relevance for activity determinations by the viscosimetric method[2].

LIQUID-CRYSTALLINE STRUCTURES IN POLYPEPTIDES

By DR. CONMAR ROBINSON and J. C. WARD

Research Laboratory, Courtaulds, Ltd., Maidenhead

IN a previous communication[1], a liquid crystalline structure which occurs in solutions of certain polypeptides (for example, poly-γ-benzyl-L-glutamate) has been described. This structure is characterized by the presence of a helical twist of very large and uniform pitch which gives rise to equidistant lines (3–100μ apart, depending on the solvent and concentration) which are visible if the structure is observed at right angles to the axis of the macrohelix and to a very high form-optical rotatory power for light travelling parallel to this axis. (This form-optical rotatory power which arises from the helical nature of the multimolecular structure is distinct from, and greater by several powers of ten than, the form-optical rotatory power arising from the α-helical configurations[2,3] of the individual molecules.) These and other properties of the solutions are also found in so-called cholesteric liquid crystals[4] which are formed chiefly by esters and ethers of cholesterol, although the latter are one-component rather than two-component systems. De Vries[5] has deduced a theoretical expression for the optical rotatory power of cholesteric liquid crystals, of which a simplified form in terms of observable quantities is

$$\theta = -\frac{n^2 P}{\lambda^2} \times 4\cdot5 \times 10^4 \qquad (1)$$

where θ is the optical rotation observed parallel to the axis of the macrohelix in degrees per millimetre, n is the birefringence of what we may refer to as the untwisted medium, λ is the vacuum wave-length of light in microns, and P is the pitch of the helix in microns. The negative sign indicates that the optical rotation is in the opposite sense to the twist of the helix. No data were available to de Vries which would have allowed him to verify his relationship, but the polypeptide solutions with their large spacings, which can conveniently be varied by altering the concentrations or the solvent, are suitable for providing such data. We have measured the optical rotatory power at various wave-lengths for fourteen different solutions, covering a range both of concentration and solvents. In all cases the proportionality to λ^{-2} was found to hold over the visible spectrum. The pitch of the helix, which is equal to twice the microscopic spacing, could also be measured, but unfortunately difficulties were found in measuring the birefringence and only its order of magnitude was determined. However, by assuming the equation to hold, the birefringence of the untwisted medium could be calculated. In all but one of the fourteen cases the calculated value divided by the volume fraction concentration was found to fall within ± 20 per cent of a mean value of 0·0248, although the specific rotation, $[\alpha]_{5461}$, varied from 20,000° to 140,000° and the microscopic spacing from 5 to 100μ. These results suggested that the equation probably held, at least as a first approximation.

In deriving the simple form of the relationship certain approximations were made by de Vries, but we have shown by comparing numerical values of θ obtained from equation 1 with values obtained from de Vries's exact expression that the error introduced is substantially less than 4 per cent for all our experimental values of n, P and λ, and is less than 1 per cent in most cases.

Stronger evidence for the validity of the equation has been obtained in a different way. A solution was made up which contained equal quantities of the L and D enantiomorphs of poly-γ-benzyl glutamate in dioxan. This solution, instead of showing the visible periodicities and other characteristics of the helical structure, behaves as a typical nematic liquid-crystalline system. After such a solution has been allowed to flow into a suitable flat cell, a number of discrete regions develop, each of which extends throughout the thickness of the cell and in each of which the orientation is uniform. The major refractive index of each of the regions is found to lie parallel or nearly parallel to the glass, although its orientation in the plane of the glass varies from region to region, but the birefringence has a constant value for all the areas. Even more remarkable is the behaviour of this solution in the 1-mm. glass capillary. Although the solution is birefringent, shortly after filling the capillary no regular orientation can be observed with the polarization microscope, but after a short time orientation appears near the walls of the capillary

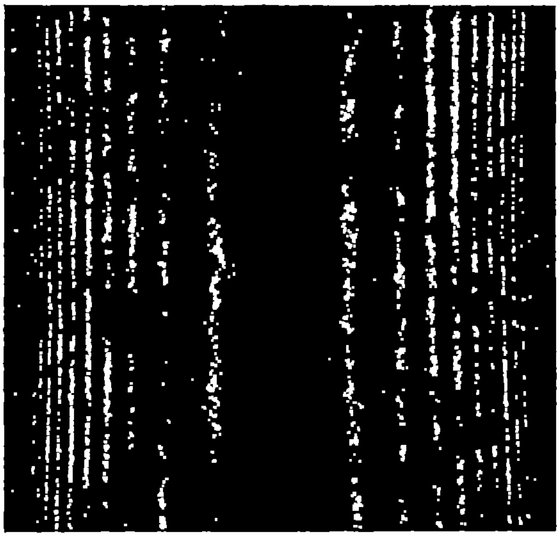

Fig. 1. The single liquid crystal of the racemic mixture of D and L polymers seen between crossed polarizers (diameter of capillary, 1·06 mm.)

and spreads gradually towards the centre. Eventually a very regular orientation is reached, as is shown in Fig. 1, which was taken in monochromatic light (λ = 5461 A.). The retardation increased continuously from the circumference of the tube to the centre. The birefringence corresponding to each fringe (assumed constant along the light path) was calculated and was found to be independent of which fringe was selected. The magnitude and sign of the infra-red dichroism (which was measured by Dr. B. R. Malcolm, of this Laboratory, using the band at 4,850 cm.$^{-1}$) is in accordance with the molecules having a high degree of orientation and lying with their long axes parallel to the length of the capillary. It would seem as if the contents of the capillary were arranged to form a single uni-axial liquid-crystal. The observed birefringence divided by the concentration was 0·029 ± 0·0015, while that in the discrete areas in the flat cell was 0·026. This compares with a value of 0·025 which was calculated from the optical rotation and helical pitch of a solution of the D enantiomorph of the same polypeptide concentration. This good agreement (the experimental error was perhaps as large as 10 per cent) leaves little doubt of the validity of the de Vries equation, and further indicates that the nematic structure in the solution containing equal quantities of both enantiomorphs may be looked upon as the untwisted counterpart of the helical structure which arises in solutions of the single enantiomorphs.

The verification of the approximate de Vries equation for the polypeptide solution in this way not only strengthens our belief in the correctness of the model of the structure that was previously put forward[1], but also provides for the first time quantitative evidence for the correctness of the conception that cholesteric liquid crystals constitute a special twisted case of nematic liquid crystals which arises when the molecules have the left- or right-handedness which is indicated by their optical activity.

The molecules of both the L and the D enantiomorphs of poly-γ-benzyl glutamate are in the α-helical configuration, the intramolecular hydrogen bonding of which gives them considerable rigidity. This rigidity no doubt is an important factor in allowing the liquid crystalline properties, whether 'cholesteric' or nematic, to persist over a considerable range of dilution.

Our thanks are due to Mr. W. E. Hanby for synthesizing the polypeptides used in this investigation.

STRUCTURE OF GRAPHITES

Interlayer Spacings of Graphitic Carbons

BASED upon the X-ray diffraction studies of Nelson and Riley[1] on Ceylon natural graphite, Franklin[2] assigned an interlayer spacing of 3·3538 A. (15° C.) to a carbon of 100 per cent graphite structure. Any carbon having a spacing of greater than this value is said to contain less than 100 per cent graphite structure—the amount less being given by the Franklin relationship[2]. We have looked at many graphitized carbons heat treated between 2,500 and 3,000° C. which have been produced from petroleum coke and coal-tar pitch coke materials. The lowest interlayer spacing found is 3·3569 ± 0·0004 A. (15° C.), indicating, according to the Franklin correlation, that the best artificial 'graphite' obtainable under usual graphitization conditions contains about 10 per cent turbostratic structure[3].

In this work, four commercial graphitized carbons have been further heated in argon in the vicinity of 3,600° C. under a pressure of 10 atm. to investigate the possibility of lowering the interlayer spacing of the carbon down to or below that of Ceylon natural graphite. The above pressure prevented any significant sublimation of the carbon. The X-ray procedures used have been thoroughly described in a previous publication[4].

Table 1 presents the X-ray diffraction data and other pertinent information on the samples. The interlayer spacing for the Ceylon graphite used is in close agreement with the value found by Nelson and Riley, particularly considering the probability that the two samples were not exposed to precisely similar geological conditions. The change in interlayer spacing of the carbons upon heat treatment is seen to be in qualitative agreement with the amount of impurities evolved. It is of further interest to note the parallel between the decrease in interlayer spacing and the irreversible change in thermal expansion above 2,200° C. during the first heating.

Even though increasing the graphitization temperatures of the carbons to 3,600° C. did produce some additional decrease in interlayer spacing, the lowest spacing obtainable still is indicative of a carbon containing only 90 per cent graphite structure. It is

Table 1. INTERLAYER SPACINGS OF CARBONS

Sample	*d*-Spacing (A.) (15° C.)	Relative amount of impurities evolved on heat treatment*	Per cent irreversible decrease in thermal expansion above 2,200° C. during first heating†
Ceylon natural graphite	3·3544 ± 0·0001

3,600	3·3585 ± 0·0003		
Type 2,			
< 3,000° C.	3·3660 ± 0·0003	Large	0·25
3,600	3·3584 ± 0·0003		

* The impurities consisted of lacy, white material appearing in the cooler regions of the furnace.

† The irreversible effects were only noticed in the direction normal to the extrusion axis or parallel to the moulding axis, that is, along the preferred *c*-axis orientation in both cases.

‡ There was somewhat less impurity for sample *B* than for *A*.

felt that the higher interlayer spacing values found for the artificial 'graphites' in comparison with that for Ceylon graphite is a result of the inability of the crystallites to grow as large in artificial 'graphites'. As Bacon[5] and Pinnick[6] have discussed, the interlayer spacing decreases as crystallite diameter increases. This variation in interlayer spacing is due to the competition between the aligning forces between planes and the 'pinning' forces at their edges, the competition being a function of crystallite size. It is thought that the factor restricting crystallite growth in the graphitized carbons is the porosity developed previously during the coking cycle. These pores within the coke particles act as boundaries across which crystallite growth cannot occur. In comparison with this, Ceylon natural graphite particles are dense and non-porous, crystallite growth not having been restricted. Coking under a high static pressure would probably produce a better-ordered, lower porosity material, which upon subsequent graphitization would yield a carbon with an interlayer spacing more closely approaching that of Ceylon natural graphite.

We thank the Atomic Energy Commission, Contract No. *AT*(30–1)—1710, for support, in part, of this work. We express particular appreciation to N. S. Rasor, of Atomics International, for heat-treating the samples, supplying the data on impurity release and thermal expansion, and offering many constructive criticisms on the manuscript.

Graphitic Character of Kish

KISH is a waste product which forms on the surface of molten iron of high carbon content during the manufacture of steel. It is carbon which has been taken into solid solution with the iron and is afterwards evolved when the iron cools. Kish particles are shiny and flaky, resembling large particles of natural graphite. It is of interest to compare the graphitic character of kish with Ceylon natural graphite by interlayer spacing measurements. X-ray procedures used have been thoroughly described in a previous publication[1].

Table 1. INTERLAYER SPACINGS OF KISH AND CEYLON NATURAL GRAPHITE BEFORE AND AFTER VARIOUS TREATMENTS

Sample	Treatment	*d*-Spacing (A.) (15° C.)	Ash content (per cent)
Kish	None	3·3528 ± 0·0002	48·4*
Kish	HCl	3·3544 ± 0 0001	23·2
Kish	HCl + HF	3·3540 ± 0 0001	2·9
Kish	2,800° C.	3·3543 ± 0·0003	0·6
Ceylon natural graphite	None	3·3543 ± 0·0001	2·1
Ceylon natural graphite	2,800° C.	3·3543 ± 0 0001	0·0

* The main constituents were iron and silicon.

Table 1 presents interlayer spacing data for kish and Ceylon natural graphite before and after various treatments. It is noted that the raw kish has an interlayer spacing significantly less than that of the Ceylon natural graphite. However, after acid treatment or graphitization at 2,800° C. the spacing is found to increase to the same value as Ceylon natural graphite.

The increase in interlayer spacing upon purification suggests that the carbon in the raw kish is subjected to considerable internal pressure because of the contraction of the molten iron. Assuming a volume compressibility of $4 \cdot 4 \times 10^{-6}$ cm.^{2}/kgm. for carbon[2], an internal pressure of *ca.* 100 kgm./cm.^{2} is calculated for this particular kish sample. It is significant that acid treatment with only hydrochloric acid, which would remove the iron but not the silicon, increases the interlayer spacing to the Ceylon natural graphite value. This suggests that iron alone is subjecting the carbon to the high internal pressure.

It is suggested[3] that Ceylon natural graphite was crystallized from an iron melt in the same manner as kish. However, in the case of Ceylon graphite, it is not clear what happened to the iron which had to be originally present to produce the high internal pressure. Thus it is seen in the present work, since the interlayer spacing of Ceylon graphite does not change after graphitization, that the carbon (after mining) is not under an internal pressure. In the formation of Ceylon graphite, it would seem that the pressure necessary to produce good ordering and consequent large growth of the carbon crystallites, with an attendant small interlayer spacing, could be produced by the depth of the deposit. Assuming a density of 3·0 gm./c.c. for the Earth, a material at a depth of *ca.* 330 m. would be under a pressure of 100 kgm./cm.^{2}.

We thank the Atomic Energy Commission, Contract No. *AT*(30–1)—1710, for support, in part, of the above work.

The Geomagnetic Field in Upper Triassic Times in the United States

It is commonly assumed[1] that magnetically stable rocks have a remanent magnetization in the direction of the geomagnetic field at the time of formation, and that the mean direction determined from samples collected through a considerable thickness of one rock formation is that of a dipole field orientated along the axis of rotation of the Earth at that time.

Mean directions of magnetization of Upper Triassic formations from the United States, specified by declination D reckoned eastwards from geographical north and the inclination I positive downwards. α is the angle of confidence at the 95 per cent probability-level. The semi-axes of the ovals of confidence of the poles, $d\psi$ and $d\chi$, in the direction of and perpendicular to the great circle joining the pole and the site are given. The significance of α, $d\psi$ and $d\chi$ have been discussed previously (ref. 1).

Because of the possibility of special effects, such as magnetostriction, the view has been taken[2] that these assumptions are likely to be in error and that in consequence the inferences which have recently been drawn from palæomagnetic studies[1] concerning the occurrence of polar wandering and continental drift in the geological past are based on no substantial grounds. A test relevant to this discussion is to determine whether rocks of the same age within one continent give pole positions in agreement, although it must be remembered that the geological age of those rocks which are most strongly magnetized, lavas and red sandstones, cannot usually be established with precision because diagnostic fossils are often scarce or lacking.

Measurements on rocks of Upper Triassic age collected in the United States have recently been made in Newcastle, Cambridge and Canberra, as shown in Table 1. In all cases the number of samples was small but they were well spread stratigraphically. The Springdale Sandstone[3] was collected from Zion National Park, Utah, and those from the eastern United States from the lower Connecticut Valley, from the upper Connecticut Valley and from New Jersey. The pole positions calculated on the assumption of an average dipole field are given in Table 1 and are plotted in Fig. 1. The ovals of confidence of the pole positions overlap.

The pole based on measurements of the Upper Triassic Keuper Marls of England[4] and its oval of confidence is also given for comparison—it is believed that this discrepancy results from post-Triassic continental drift.

From these results three points of interest arise. (1) They show that results from small numbers of samples can be quite reliable and provide a practical demonstration of the validity of the sampling methods advocated by Irving and Watson[5] and by Runcorn[6].

(2) Results from both igneous and sedimentary rocks laid down at approximately the same geological time but at points thousands of miles apart within the same continent are in agreement, and indicate the high degree of certainty with which these 'fossil' directions may be identified with the Earth's magnetic field during the Upper Triassic so that in these red sandstones and lavas it seems that the special effects mentioned above are of negligible importance.

(3) It seems reasonably certain that during this time the geomagnetic field over the region of the United States approximated on average to that of a dipole as it is known to have done since the Miocene[7,8].

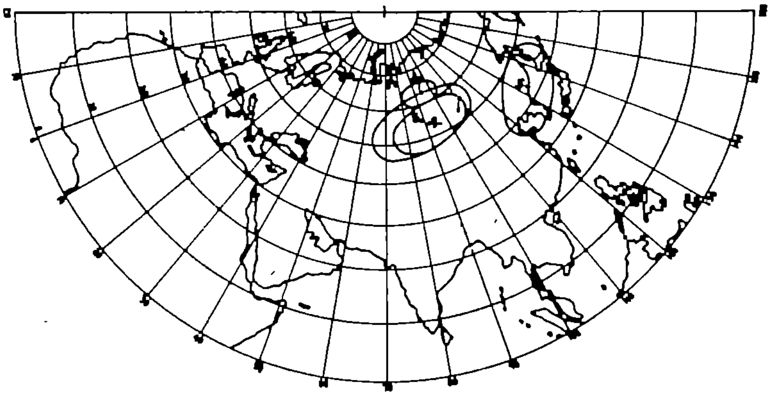

Fig. 1. Position of the geomagnetic pole in Upper Triassic times relative to the United States and Europe. The determinations from rock formation in the United States are numbered as in Table 1. The equivalent pole determined from England is numbered 5

The axis of this dipole intersected the Earth's surface in the regions of what are now central Siberia and southern South America.

Charged Particles in a Non-uniform Radio-frequency Field

An analysis of the motion of a charged particle in a non-uniform radio-frequency field has been made and has shown that under certain conditions particles of either sign will experience an acceleration towards the position of least electric field strength.

Considering the Lorentz forces upon free electrons, a second-order force arises due to spatial variation of the electric field-strength, which is of the same order as the conventional forces due to motion in the magnetic field and charge density fluctuations. In a continuous but not necessarily homogeneous electron distribution, such as we suppose to exist in a collision-free and neutral plasma, a small-signal theory shows that the time-averaged force per unit volume upon the electrons is, $f = -\frac{1}{4}(\rho e/\omega^2 m)\nabla(\overline{E\cdot E})$, where ρ is the average electron charge density, $\omega = 2\pi \times$ frequency, $\overline{E\cdot E}$ is time-averaged square of electric field, in rationalized M.K.S. units.

The total force upon an isolated body of electrons is the same as that given by conventional theory[1] from the field equations; the force is therefore consistent with the concept of radiation pressure. The internal stresses, or pressure in a fluid, differ, however, from the conventional theory, and appear to enhance the possibility of containing a heated plasma within a resonant cavity by radiation pressure[2].

It is hoped that it will shortly be possible to publish the details of the calculations which we have quoted.

The existence of such a force on electrons has been demonstrated in a 10-cm. slotted anode magnetron having no magnetic field and a cold cathode. Pulses of 10-cm. radio-frequency power were fed into this magnetron and set up electromagnetic fields which decreased towards the cathode. The multipactor effect produced a copious supply of electrons within the slots and limited the radio-frequency voltage there to about 5 kV.

Pulses of electrons arrived at the cathode with energies up to 250 volts, and current of up to 0·1 amp. per cm. length of cathode could be drawn with anode and cathode at the same potential. The anode and cathode diameters were 1·25 and 0·59 in. respectively. A small increase in cathode temperature was observed with a thermocouple, which proves that the current was due to negative particles bombarding the cathode.

Acknowledgment is made to the Admiralty for permission to publish this communication.

Some Observations of the Infra-red Solar Spectrum from a High-flying Aircraft

The strong absorption bands of water vapour and carbon dioxide in the infra-red obscure much of the solar spectrum from observation on the ground. By working at high altitude, however, it is possible to use measurements of absorption in these bands for obtaining data about the concentration of water vapour and other atmospheric constituents in the upper atmosphere. To make such measurements, an infra-red grating spectrometer with a resolution ~ 2 cm.$^{-1}$ has been installed in a Canberra aircraft. A heliostat maintains a steady image of the sun on the input slit of the spectrometer. The spectrometer and heliostat are installed in the unpressurized part of the aircraft necessitating an elaborate system of remote control for its operation.

Successful ascents have been made in which the spectral region 1·8–2·1μ has been observed using a

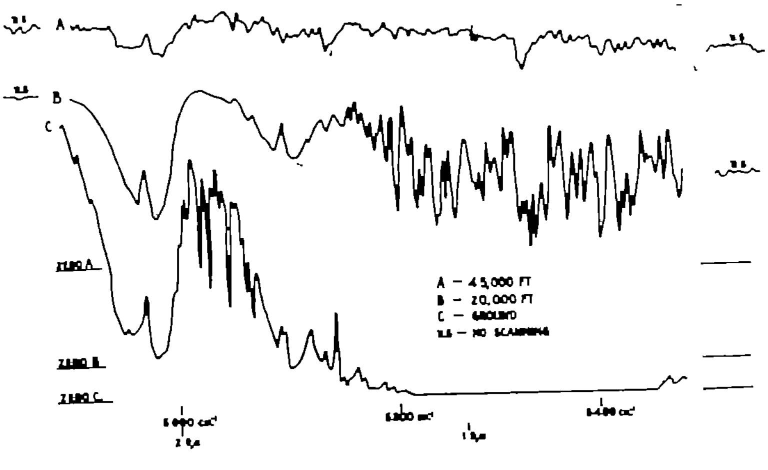

Fig. 1. Solar spectra

lead-sulphide detector. The absorption in this region at different heights is shown in Fig. 1. The good performance of the heliostat is demonstrated by the steadiness of the trace at each end of the spectral region where the spectrometer is not scanning. The 1·9μ water vapour absorption band and the 2μ absorption bands of carbon dioxide are clearly shown. It is clear that the water-vapour absorption is rapidly disappearing at the higher altitudes. A path-length of laboratory air containing only 7 microns of precipitable water vapour would give the same absorption as that shown on the record at 45,000 ft. Since this trace was taken at a solar elevation of 47°, the amount of water vapour in a vertical column of atmosphere above 45,000 ft. would be equivalent to a path of laboratory air containing approximately 5 microns of precipitable water. This is the first time an estimate of this important meteorological parameter has been made.

More extensive measurements over the spectral region 1–8μ are planned for the future.

Luminescence produced in Air by Polonium-210 α-Particles

A KNOWLEDGE of the spectral composition of the feeble luminosity arising from the passage of energetic ions through gases is essential to the complete understanding of the processes by which the ions lose energy along their tracks. It also has important applications to the physics of the aurora (part of which is excited by traversal through the high atmosphere of solar protons), and in the efficient use of gas scintillators in nuclear physics.

Following studies of the luminosities produced by 2–4 keV. lithium ions in atmospheric gases[1] (which have recently been extended) the present communication deals with observations upon the luminosity maintained in air at atmospheric pressure by high-energy (5·3 MeV.) α-particles.

A 28-mc. α-particle source of polonium-210 (obtained from Atomic Energy of Canada, Ltd.) was employed. The active surface was 7 mm. in diameter, electroplated upon a platinum disk, and was supplied covered with a thin mica film to prevent contamination of the laboratory by recoil nuclei. The luminosity, which was just visible to the dark-adapted eye, occurred as expected[2,3] in the immediate vicinity of the source. The extreme feebleness of such luminosities is a major difficulty in recording their spectra. A fast (f/1·1) dense flint prism spectrograph which was specially constructed for low light-level spectroscopy, and which will be described in detail elsewhere, was used in this experiment. It incorporated a 35-mm. camera with a 9-element f/1·1 lens of 5 cm. diam. This instrument recorded the wave-length range of 3800–8000 A. on about 8 mm. of film.

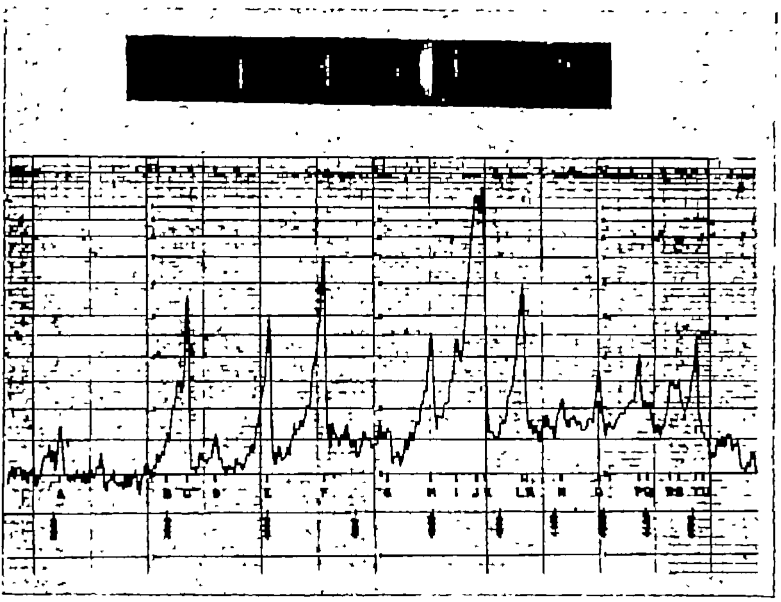

Fig. 1. Spectrum and microphotometer tracing of luminosity produced by α-particles in air

The polonium source was mounted directly in front of the slit and almost perpendicular to its plane so that the luminosity at the surface of the disk was viewed at a very acute angle to the surface by the spectrograph. A front-surfaced mirror was placed on the side of the source remote from the spectrograph to increase the amount of light gathered by it. Alignment of source and mirror was attained by autocollimation. The whole experiment was performed in a darkened room the temperature of which was maintained at 72° F. to minimize thermal exposure of the infra-red sensitive emulsion employed. Kodak *HIR* 402 (identical emulsion to 1-*N*) 35 mm. film was used in the camera, and an exposure of ten days was adequate.

A typical spectrum, together with microphotometer trace, is shown in Fig. 1. All observed features lie between 3800 A. and 4800 A. The detailed identifications are made in Table 1 and the wavelengths are certainly reliable to ± 2 A. The spectral features are entirely bands of the N_2 second positive and N_2^+ first negative systems. The N_2^+ bands appear to have approximately the same relative intensities as when excited in gas discharges through He–N_2 mixtures[4], while the intensity distribution of the N_2 bands indicate enhancement of the 0 and 1 levels of the $C^3\Pi$ state over the conditions of simple discharge through N_2. No atomic lines of NI, NII, OI, OII, HeI or HeII, nor molecular bands of O_2 or O_2^+, were observed over the wavelength range 3800–4800 A. NI and OI lines, if present, would have been registered by the most sensitive range of the emulsion (~ 7000 A.).

These results are entirely consistent with those of Sir William and Lady Huggins[5], who used α-particles from radium to excite air, and made observations over the wave-length range 2600–4300 A. The identifications of Ortner and Salim[6] are, however, not confirmed. They used a 4-mc. source of polonium

U	4723	(3,9) N_2	weak

for exciting air under conditions very comparable to those in our experiment, and made identifications (to ± 10 A.) of OI, OII, NI, NII lines together with some 'continua', in the region 3730–6000 A. A comparison of their wave-lengths (including tolerances) with those in Table 1 indicates that some of their lines and continua may in fact have been N_2 second positive and N_2^+ first negative bands.

Ionization with excitation (1), and charge transfer with excitation (2) (3), are the most probable mechanisms responsible for the excitation of the N_2^+ bands.

That is:

$$\mathrm{He}^{++} + N_2 \rightarrow \mathrm{He}^{++} + N_2^{+*} + e \quad (1)$$

$$\mathrm{He}^{++} + N_2 \rightarrow \mathrm{He}^{+} + N_2^{+*} \quad (2)$$

$$\mathrm{He}^{+} + N_2 \rightarrow \mathrm{He} + N_2^{+*} \quad (3)$$

Followed by

$$N_2^{+*} \rightarrow N_2^{+} + h\nu \text{ (bands)} \quad (4)$$

It would be unlikely, however, that the N_2 bands could have been excited by α-particles in view of the multiplicity change ($X^1\Sigma \rightarrow C^3\Pi$) required which is more readily caused by electron exchange. This could possibly be brought about by the fast helium ions or even by the fast helium atoms formed in equations (2) and (3). However, in view of the intensity of the bands, it is more likely that they were excited by the energetic electrons (δ-rays) formed along the α-particle tracks. The absence of lines of NI and OI is an indication that the primary collisions between α-particles and air molecules occur too rapidly to cause dissociation[1]. The complete absence of lines of He I and He II indicates that they are probably formed in their ground states (2), (3) at the ends of their tracks, prior to which (1) they are not formed at all.

Study of the Magnetic Leakage Field in Cobalt by means of a Divergent Electron Beam

The leakage field due to the magnetic domains in an unmagnetized single crystal of hexagonal cobalt has been shown to produce various effects on an electron beam[1]. A new method for the study of this leakage field using a divergent electron beam has been developed recently. The electron beam of a conventional electron diffraction apparatus is limited as before by a small movable aperture of 6–25μ, close to the crystal. The crystal face is adjusted to an angle of glancing incidence between a fraction of a degree and a few degrees. Immediately below the aperture are fixed on to the same holder two parallel metal plates, to which an alternating potential difference is applied. A beam is thus provided which diverges from a point close to the aperture in a direction parallel to the crystal edge. This beam scans at the level of the specimen a region which is extended in a direction parallel to the crystal edge, but which is only of the width of the aperture in a direction normal to it. The electrons of this beam are deflected by the magnetic leakage field existing in this region.

Figs. 1,*a–e* show the curves obtained by this method with a beam of 46-keV. electrons passing at distances of 10, 30, 60, 90 and 160μ from the prism face. The beam forming the centre part of the trace is approximately parallel to the hexagonal axis. The undistorted trace, obtained by removing the crystal from the beam, has been taken on the same plate for each position of the aperture. Similar curves were obtained from the hexagonal face of a cobalt crystal.

The trochoid-like nature of these curves can be interpreted in terms of the deflexion of the electrons by a periodic magnetic field[1]. Depending on the ratio between the magnitude of the field and the domain spacing, three types of trochoids can be distinguished (Figs. 1,*a–b*, Fig. 1,*c* and Figs. 1,*d–e*, respectively).

The method described has been applied to the study of the variation of the magnetic leakage field

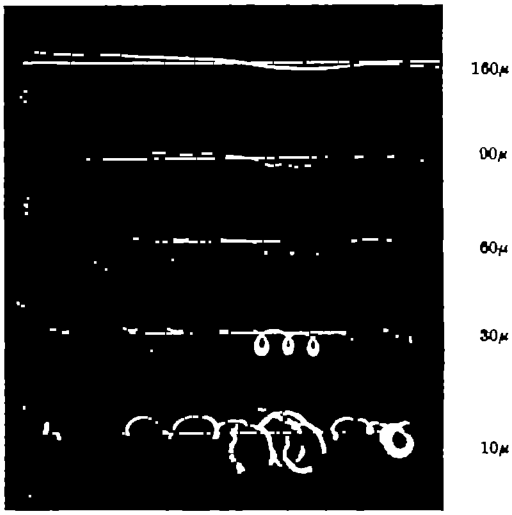

Fig. 1. Curves obtained with the divergent beam, limited by a 6μ aperture, passing at various distances from the prism face. The length of the trace corresponds to scanning a distance of 1·7 mm. along the crystal edge

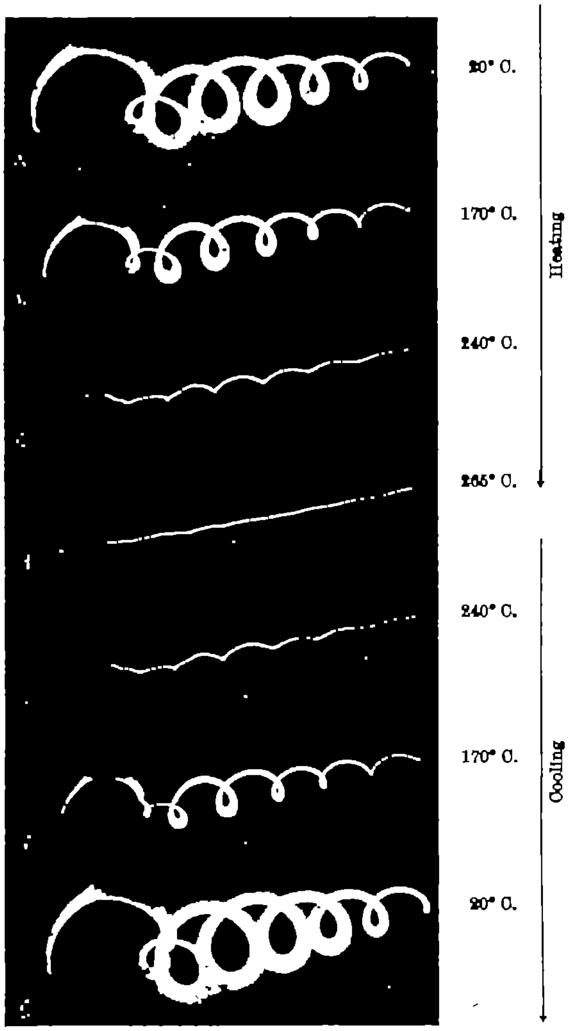

Fig. 2. Curves obtained with the divergent beam, limited by a 9μ aperture, at various temperatures. The scan is set at an angle to the edge, the left end of the beam grazing the prism face. The length of the trace corresponds to scanning a distance of 1 0 mm. along the crystal edge

with temperature. Fig. 2 shows the deflexion curves obtained at various temperatures with the divergent beam of 46-keV. electrons passing close to the prism face. The primary beam has been adjusted as before almost parallel to the hexagonal axis ; the scan has, however, been arranged so that the region traversed forms a small angle with the crystal edge at the level of the specimen and grazes the edge at one end of the scan. This procedure allows a higher accuracy to be obtained in the setting. The steady decrease of the magnitude of the leakage field with temperature is apparent. It becomes very small at about 250° C. and remains so until 380° C. (the highest temperature investigated). The variation of the leakage field with temperature has been deduced. It was also observed (Fig. 2) that the domain spacings did not change with increasing temperature up to 240° C. They returned identically from 240° C. downwards after the crystal had been heated to 300° C. and cooled again. Using the hexagonal face, the decrease of the magnitude of the leakage field with temperature was similar. However, in this case changes of the domain spacings with increasing temperature were observed. Furthermore, these were not identical after the crystal had been heated to 300° C. and cooled again.

The steady decrease of the magnitude of the leakage field is in agreement with the conclusions derived from measurements of the anisotropy constants[2]. These show that at room temperature the hexagonal axis is the direction of easy magnetization and that this anisotropy decreases with increasing temperature, the crystal becoming isotropic at about 250° C. Above this temperature the hexagonal axis is the direction of most difficult magnetization. Therefore the energy required to form 'domains of closure' at right angles to the hexagonal axis, which can give rise to a continuous flux circuit inside the crystal, is expected to decrease with increasing temperature, becoming zero at about 250° C.

A detailed account of this work will be published elsewhere. One of us (E. G.) is indebted to the British Council for a scholarship and grant and to the University of Chile for leave of absence.

Changes in the Structure of Carbon during Oxidation

IT has previously been shown that, in the so-called amorphous carbons, a part of the carbon is organized in small graphite-like layers, and a part is in a form so disordered that it gives only a gas-like scattering of X-rays. Furthermore, of the graphite-like layers, some are stacked in small parallel groups with a characteristic interlayer spacing, while others are effectively single[1]. Since cokes and other commercial carbons used in processes involving combustion have structures of this type, it is clearly of interest to determine which features of the structure of the carbon most influence its combustion properties. This communication summarizes the preliminary results of such an investigation.

The influence, on structure, of various forms of controlled partial combustion was studied; the structure of the carbons was analysed, by X-ray diffraction methods previously described[1], before oxidation, and then after subsequent removal of oxygen by heating *in vacuo* at 1,000° C.

Samples of carbon containing 2–20 per cent weight of oxygen were prepared either by heating in oxygen at 300–450° C. for several days or by reacting with ozone at room-temperature and removing the oxidation products of low molecular weight by heating to 300° C. On heating the solid product under vacuum, the oxygen adsorbed was evolved as carbon monoxide and dioxide in ratios and amounts which depended only on the temperature of the desorption : at 1,000° C. very little oxygen remained.

X-ray powder-photographs of the initial carbon, the oxidized carbon, and the final degassed product were obtained, using a bent-quartz focusing monochromator, a continuously evacuated camera, and copper K_a and molybdenum K_a radiations. From these photographs the proportion of carbon which was organized into graphite-like layers, the proportion of such layers stacked in parallel groups and the mean number (*M*) of such layers per group were determined[1].

As an example, Table 1 gives the results for a char prepared by the pyrolysis of polyvinylidene chloride at 1,000° C. and oxidized both in oxygen and in ozone.

Table 1. Structure of Oxidized Polyvinylidene Chloride Char

Analysis of structure	Initial carbon	Oxidized carbon		Degassed at 1,000° C.	
		Oxygen product	Ozone product	Oxygen product	Ozone product
Disordered (per cent)	35	60	59	32	35
Parallel groups (per cent)	22	40	41	36	45
Single layers (per cent)	43	0	0	32	20
*M**	2·0	4·0	3·0	2·6	2·2
Interlayer spacing (A.)	3·66	3·47	3·50	3·55	3·57

* *M* is the mean number of layers per parallel group, and is independent of the number of isolated layers.

It is evident that the structural changes which result from the two methods of oxidation are very similar; the oxidized carbon is characterized in each case by a disappearance of single layers and by a marked increase in the layer stacking. A clearer picture of the significance of these results is given by recalculating the figures for the ozonized product (gm./100 gm. initial carbon) as in Table 2.

Table 2. Structure of Ozonized Polyvinylidene Chloride Char

	Disordered (gm./100 gm.)	Parallel groups (gm./100 gm.)	Single layers (gm./100 gm.)
Initial carbon	35	22	43
Ozonized product, 300° C.	34	24	0
Ozonized product, 1,000° C.	17	22	10

It may be seen from this that the most vulnerable part of the structure is that which exists as single graphitic layers: the disordered part is less vulnerable but is still more reactive than the parallel groups, the amount of which remains unchanged throughout the treatment.

The apparent increase in parallel stacking of the graphite-layers on oxidation is of general occurrence; we have observed it with carbons prepared from sucrose and cellulose as well as with commercial charcoals and carbon blacks. To a lesser degree it is noticeable also in the oxidation of carbon by nitrous oxide at 500° C. and by steam at 900° C. In each case the increase in the value of *M* in the oxidized carbons is accompanied by a decrease in the low-angle scattering, suggesting that the spaces between the separate particles have been filled by oxygen to produce the diffraction effect of larger particles, and by a decrease in the interlayer spacing. We have also observed an analogous effect in a series of nitrogen-containing carbons prepared by the pyrolysis of melamine-formaldehyde resin. At 500° C. a product is obtained which contains 41·5 per cent of nitrogen and has an *M*-value of 5·5: by heating to 1,000° C. for 4 hr. the nitrogen content is reduced to 0·4 per cent and the *M*-value to approximately 3·5. It is hoped that further measurements on both nitrogen- and oxygen-containing carbons will enable these effects to be interpreted more fully.

It is significant that the shape of the 110 and 100 bands remains constant throughout the oxidation process, indicating that the graphite-like layers do not change in diameter. This again indicates that the combustion process does not consist, as is sometimes suggested, of a gradual consumption of the layers, starting from the edges and proceeding inwards. It seems, rather, that there is a tendency for the layers either to remain intact or to be wholly consumed, isolated layers being particularly susceptible to total destruction.

Effect of Nitric Oxide on the Radiosensitivity of Bacteria

Oxygen is known to increase the effectiveness of X-rays in killing bacteria[1,2] and cells from many other organisms[3] by a factor of 2 or 3. There have been numerous reports of substances which protect against the effects of irradiation under aerobic conditions[4], but there does not appear to be any report of a substance which, in complete anoxia, raises the radiosensitivity of bacteria to the level normally associated with full aeration. Before giving the evidence which suggests that nitric oxide may be such a substance, we may consider the factors which first directed attention to this gas.

The observed effect of oxygen on radiosensitivity implies that ionizing radiation produces lesions in the bacteria, some of which are converted to lethal injuries only if oxygen is present. It has been postulated that such a lesion is a radical, probably on a carbon atom in one of the molecules which are essential to cell survival[5]. It may be supposed, therefore, that oxygen affects radiosensitivity by virtue of its affinity for carbon radicals. Molecular oxygen owes its reactivity and its affinity for free radicals to the unusual configuration of electron spins in the outer orbitals. Of the sixteen electrons in oxygen, fourteen fill the σ_g $(2p)$ and lower energy orbitals which form the almost inert structure of molecular nitrogen. The remaining two electrons in molecular oxygen are in two π_g $(2p)$ orbitals. There is spectroscopic evidence that these electrons have unpaired spins, a finding which explains the paramagnetic properties of molecular oxygen[6]. The two unpaired electrons make oxygen a biradical and give it an affinity for other radicals[7].

Another paramagnetic molecule which has an unpaired electron in the $\pi_g(2p)$ orbital is nitric oxide, the most stable molecule with an odd number of electrons. Nitric oxide is a stable gas with little

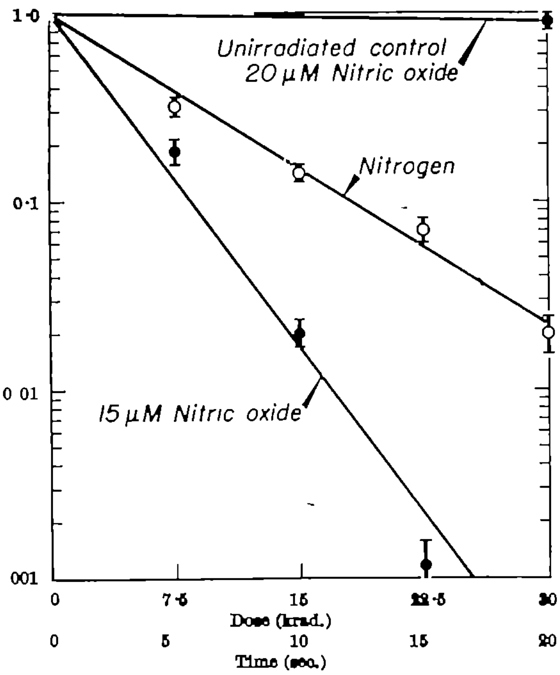

Fig. 1. Survival curves for *Shigella flexneri* irradiated with 250 kV. X-rays while the suspension was bubbled with either nitrogen or nitrogen containing 0 8 per cent nitric oxide. The upper line shows the effect of the nitric oxide mixture on the cells in the absence of any radiation

tendency to dimerize. It is more soluble than oxygen in water and it does not hydrolyse or dissociate to any great extent. Nitric oxide shows an affinity comparable to that of oxygen, for carbon radicals[7]. It combines readily with oxygen to form nitrogen peroxide, which hydrolyses in water to form nitric acid, so that nitric oxide can be used only in the absence of oxygen. Nitric oxide combines reversibly with hæmatin[8] and cytochrome oxidase[9], forming compounds similar to those of carbon monoxide. That nitric oxide is not toxic in small amounts is shown by the observation that certain bacteria form it in the course of the reduction of nitrites to nitrogen[10]. It would seem from this list of properties that nitric oxide might affect radiosensitivity in much the same way that oxygen does, while at the same time having a contrasting action on cell metabolism.

A preliminary investigation has been made into the effects of nitric oxide on the radiosensitivity of bacteria which were kept free from oxygen while in contact with the gas. The methods used follow those of a previous investigation into the effect of oxygen on radiosensitivity[2]. An overnight broth culture of *Shigella flexneri* was washed, resuspended and diluted for use in buffered saline. Samples were placed in a glass irradiation vessel with a glass filter base, through which oxygen-free nitrogen was passed. The suspension was vigorously bubbled with nitrogen for an initial period of equilibriation, as well as throughout the course of the irradiation carried out at 25° C. with 250 kV. X-rays filtered with 0·5 mm. aluminium, at a dose-rate of 1,500 rads per min. The top of the irradiation vessel was closed except for a narrow capillary outlet, through which the gas escaped. The suspension was sampled through the same capillary by tilting the vessel. The samples taken before and during the course of the irradiation were plated out on nutrient agar and incubated. The number of bacteria surviving was found from the visible colony counts. When required, nitric oxide was mixed with oxygen-free nitrogen in amount determined by a flow-meter consisting of a glass tube along which a mercury pellet was pushed by the gas. When starting an experiment, the cell suspension was bubbled with nitrogen for a period of at least 5 min. at a flow-rate of 5 ml. per sec. before admitting nitric oxide. Samples were withdrawn when required and were passed from the irradiation vessel into a vial and bubbled with nitrogen to remove the nitric oxide before there was appreciable exposure to air. In addition, control samples were bubbled with nitric oxide for a period comparable with the time of the irradiation to test the effect of the gas alone upon the survival of the bacteria.

The results are shown in Fig. 1. It was found that 0·8 per cent of nitric oxide in the gas mixture, which gave a concentration of 15 µM, was sufficient to double the sensitivity of the bacteria to radiation, while in the absence of any irradiation, exposure to nitric oxide at a concentration of 20 µM reduced the number of survivors by 10 per cent in a comparable time. The increase in sensitivity observed with nitric oxide is about the same as that observed with oxygen at a comparable concentration[3]. Further experiments will be needed to test whether oxygen and nitric oxide are comparable, molecule for molecule, in their effect upon the sensitivity of bacteria and other micro-organisms.

It is of interest that the bacteria given nitric oxide in place of oxygen should show the radiosensitivity normally associated with aerobic conditions, while all aerobic metabolism has been halted.

Delocalization in Hydrogen Bonds

It is well known[1,2] that the proton magnetic resonance 'chemical shift' of the hydroxyl peak in solutions of alcohols depends on concentration, as a result of changes in the extent of hydrogen bonding.

We have now shown that polymeric species contribute much more towards the shift to low field which occurs under conditions favouring hydrogen bonding than does the hydrogen-bonded dimer. This has been verified (*a*) by correlation of the chemical shifts with infra-red data on simple alcohols (from which taking account of the different extinction coefficient of monomer, dimer, and polymer, a

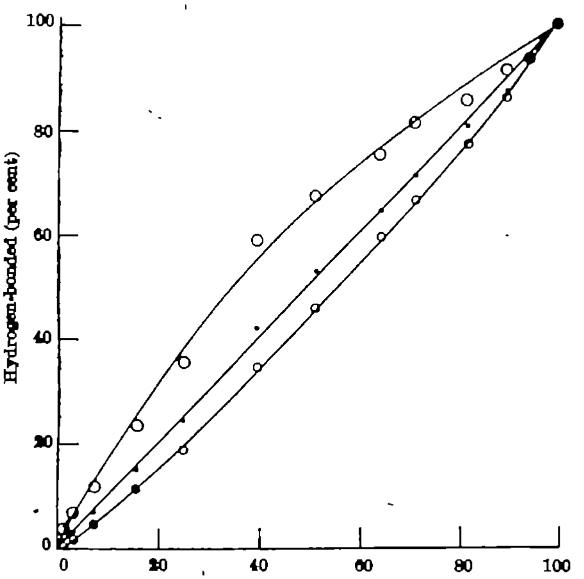

Fig. 1. Relation between degree of hydrogen bonding and chemical shift of the OH-proton in CH_3OH from its value in the un-hydrogen-bonded molecule: ○, percentage CH_3OH molecules in all forms of polymer; ∘, percentage CH_3OH molecules in polymer with $n > 2$; ●, percentage CH_3OH molecules in polymer with $n > 2$ + 32 per cent CH_3OH molecules in dimer

reasonable estimate of the relative proportions of the three forms can be made), and (*b*) in experiments with sterically hindered alcohols which can form only dimer.

Fig. 1 shows for methanol the relation between the chemical shift and the percentages of: (*a*) total hydrogen-bonded species, (*b*) polymers with $n > 2$; and (*c*) polymer + 32 per cent of the amount of dimer. The chemical shifts are expressed as percentages of the total shift observed on passing from the pure liquid to an infinitely dilute solution containing only monomer. Since the pure liquid still contains about 10 per cent of monomer, the 'per cent polymer' plotted is the percentage of the amount in the pure liquid.

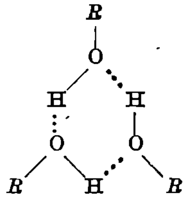
The linear relationship resulting in the last case holds reasonably well over the whole range from $< 0{\cdot}1$ molar, where only the monomer–dimer equilibrium is important, up to 2·5 molar solutions, which contain predominantly polymer. It shows that the contribution to the change in chemical shift of alcohol molecules in the dimeric form is—per molecule of CH_3OH—only about one-third of the value contributed by alcohol molecules in higher polymeric species.

We find this relation well borne out by the examination of sterically hindered alcohols such as methyl-ethyl-*t*-butyl carbinol, which, as the infra-red data show, can form only dimers. (Molecular models show that when two molecules are hydrogen-bonded, a third cannot get close enough to the hydroxyl group to interact.) In spite of the fact that the equilibrium constant for the monomer–dimer process is very close to that for methanol, the total shift, from pure substance to infinite dilution, is only 55 cycles, compared with 180 for methanol. The predicted value, using the relationship

$$\frac{\text{shift due to a molecule in dimer}}{\text{shift due to a molecule in polymer}} = 0{\cdot}32$$

is 57 cycles.

We believe that these large shifts are due to the fact that a considerable fraction of the polymer consists of cyclic species such as:



and that the effect can best be described by a 'circulating current' model where a paramagnetic shift results from the fact that the protons are largely outside the current loop. A simple calculation suggests that shifts of the observed order of magnitude may be expected if only a few per cent of a fully delocalized 6-atom orbital is mixed into the wave function representing the twelve electrons involved in the hydrogen bonding of the cyclic trimer.

In a recent review[3] Coulson estimates that the delocalization energy in a single O – H . . . O hydrogen bond is about 8 kcal. This means that the overlap energy between two oxygens at a distance of 2·7 A., making use of the H orbital to some extent, is of a similar magnitude to the exchange interaction between a pair of orbitals on the same oxygen atom (Coope, J. R., private communication). This provides a situation in which delocalization cannot be confined to a single O – H . . . O bond, but must embrace all six atoms. We thus have a system in which current circulation may occur through a system of σ bonds. This does not occur in the σ bond system of alicyclic compounds, of course, because of the great disparity between the high exchange energy in the C – C bond and that between orbitals on the same atom.

In the cyclic trimer, simple molecular orbital theory gives a set of nine orbitals, with only twelve electrons to be allocated. This allows three empty antibonding orbitals, so that the benefits of the bonding delocalized orbitals are not cancelled out by filled antibonding levels.

We believe that these proton resonance and infrared results provide an experimental demonstration of such circulating currents, and that the magnetic behaviour of other hydrogen-bonded substances in solution (for example, the cyclic acetic acid dimer, and the non-cyclic dimers formed between chloroform and acetone or triethylamine[4]) are all consistent with our explanation.

The establishment of delocalization in hydrogen bonded systems has important implications in the area of polyelectrolytes, and suggests a mechanism whereby energy migration in proteins, or deoxyribonucleic acid-type molecules, may occur over relatively long distances if excitation is brought about at some point in the molecule as a result of a chemical process, or by irradiation.

In such a system, attenuation, because of vibrational dissipation of energy during transport, can be expected to be greater than in a network of conjugated double bonds, or other tightly coupled systems (at the short-bond turning point of the OH vibration, coupling is relatively poor[3]). However, this feature also provides a possible reason why, although a number of *in vivo* and *in vitro* phenomena suggest such delocalization, it is hard to find clear evidence for it in the ultra-violet absorption spectra since, for the short time ($\simeq 10^{-15}$ sec.) required for ultra-violet absorption, the bonds are effectively localized and only delocalized when considered over times $> 10^{-14}$ sec.

Density of Water adsorbed on Wyoming Bentonite

AT the present time, two schools of thought exist concerning the density of water adsorbed on clays. Hendricks and Jefferson[1] and Macey[2] postulated structures for this adsorbed water which are less dense than free water; whereas, Williamson[3,4] and Mackenzie[5] have argued against these postulates and have suggested that the adsorbed water is denser than free water. Barshad[6] has proposed that the adsorbed water is closely packed at high states of hydration.

Attempts to measure the adsorbed-water density have been based on the pycnometer and X-ray methods. These methods have given contradictory results, probably because of the assumptions involved.

We compressed a clay–water paste between a porous filter and a column of mercury and observed, simultaneously, by means of capillaries, the change in volume of the clay paste and the volume of water forced through the filter. From these observations we were able to plot the volume of the clay paste against the weight of water in the paste. The slope of the line at any water content is the reciprocal of the water density at that water content.

By this method we obtained the densities of water adsorbed on homoionic Wyoming bentonites saturated with either lithium, sodium or potassium ions. We found that for each clay the water density decreased continuously with decreasing water content. At 25° C., and a water content of 0·6 gm. of water per gm. of clay (7·5 A. from the clay surface if the surface area is 8×10^6 sq. cm. per gm. of clay), the densities of the water on lithium, sodium and potassium clays were 0·975, 0·972 and 0·981, respectively. Thus, the adsorbed water is less dense than free water.

A detailed account of this research will be published in the *Proceedings of the Soil Science Society of America*.

Secular Changes of the Units and Constants of Physics

GERHARZ[1] has recently proposed a new method for determining the velocity of light in terms of a standard frequency and of the wave-length of an atomic radiation. He expects to reduce his experimental errors to less than 1 part in 10^9 and suggests that it should then be possible to obtain evidence about secular changes in the velocity of light. Dingle[2], on the other hand, follows Clemence in arguing that if the unit of time is defined in terms of the frequency of some atomic transition and that of length in terms of the wave-length of an atomic radiation, then the velocity of light is implicitly constant, no evidence can be obtained of its changes relative to atomic constants, and the science of physics is restricted at its foundations. The conflict between these two statements shows that the meaning of such phrases as 'secular changes in the velocity of light' needs clarification.

The measurable quantities of physics are defined in terms of a few of their own class; these latter cannot be defined verbally in terms of any other entities, but can only be indicated, that is, defined ostensively. Thus, taking length, mass and time as basic mechanical quantities, we can only indicate "*that* is length", but we can give velocity the verbal definition, "length per unit time". Since we can only define the basic quantities ostensively, we have to maintain material representations of them on which to found a system of units of these basic quantities, but once such a system is available, units of other quantities can be derived from their verbal definitions.

All physical measurements depend on comparisons of like quantities (in 'absolute' measurements the quantities compared are arranged to be fundamental quantities) and the comparisons are necessarily of the quantities at the same instant of time. If one wishes to compare A at time t_a with B at time t_b it is necessary to assume that one or other of them has not changed between t_a and t_b, and if one wishes to compare A at time t_1 with A at time t_2, it is necessary to assume that some other quantity that may be compared with A has not changed in the interval. In dealing with the material representations of the fundamental units, this assumption can be neither proved nor disproved by arguments based on other measurements, but can only be justified by arguments drawn from our general beliefs about the nature of physics. Thus, in deciding whether to derive the unit of time from the period of rotation of the Earth about its axis or that of its revolution about the Sun, the most that measurement can do is to tell us how the ratios of these periods to each other and to other observable periods have changed: the decision must be based on such theoretical considerations as the possible perturbations that may affect the motions or, bearing in mind the changes of the ratios of each to other periods, that it is more probable that one has changed than the other. A like situation arises in comparing the period of a certain transition of the caesium atom with celestial periods.

It is clear, then, that with the fundamental quantities we cannot go beyond the material representations and that it is meaningless to speak of changes in the units. Such questions as whether the unit of length has changed are without meaning within the field of experimental physics.

This is no doubt obvious, and it is equally obvious that our ideas about physics are not affected by it. But at the same time it must be realized that the question whether the velocity of light has changed is also meaningless within the field of experimental physics. For either the velocity of light is taken as a basic quantity, when the question is meaningless according to the argument above, or else it is measured in terms of other basic quantities such as length and time, in which case we can determine experimentally changes in the velocity of light as measured in certain units. But then we have no experimental means of deciding whether any observed change is in the velocity of light or in the material representations of the basic units.

It does not seem correct, therefore, to say that we restrict physics at its foundations if we represent the units of length and time by atomic quantities in such a way that the velocity of light is forced to be constant. The restriction is in the nature of the experimental method itself—in the facts that we come ultimately to the ostensive definition of certain basic quantities and that the comparison of quantities is implicitly simultaneous.

The choice of basic quantities is, therefore, essentially one of convenience—primarily of practical convenience, for the basic comparisons should be very precise and the material representations readily accessible. Subject to these overriding considerations, there is much to be said for choosing a system of units conformable to the structure of the general theoretical framework of physics and in particular for choosing a system in which the velocity of light is implicitly constant.

In one class of quantities, however, secular changes do seem to be meaningful, namely, non-dimensional quantities such as the fine structure constant, and theoretical and experimental investigations of secular changes in physical 'constants' should be formulated in terms of such numbers.

Distribution of Strontium-90 in Pond Weed and Fish

THE opportunity recently occurred to investigate a few aspects of the distribution of strontium-90 in a balanced pond, during the course of experiments on the removal of fission products from drinking water. A derelict filter bed was utilized containing $1\frac{1}{4}$ million gallons of fresh water to which was added 500 millicuries of strontium-90 in equilibrium with yttrium-90. An extensive pure growth of *Myriophyllum spicatum* was present at the beginning of the experiment and large numbers of rudd (*Scardinius erythrophthalmus*) were observed.

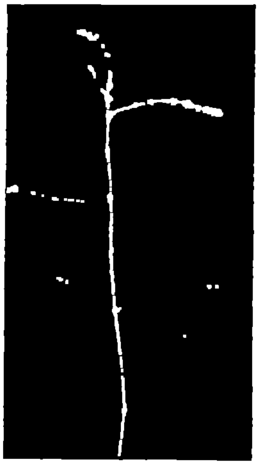

Fig. 1. Print of gross autoradiograph of *Myriophyllum spicatum*

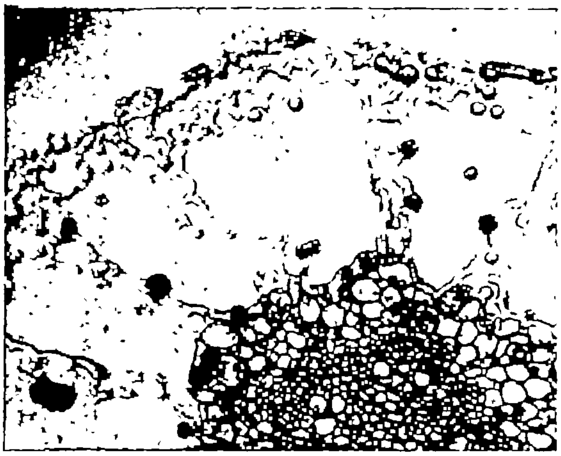

Fig. 2. Microautoradiograph of T.S stem of *Myriophyllum spicatum* at node

Samples of *M. spicatum*, rudd and water were taken at intervals and radioassayed. Results are given in Table 1.

To locate the strontium-90 more accurately autoradiographs were made. The gross autoradiographs (Fig. 1) of the dried weed indicated a larger accumulation of strontium-90 at the nodes and in the inflorescences. Transverse sections of the stem were made after paraffin embedding and microautoradiographs prepared by Pelc's technique[1].

Table 1. RADIOASSAY OF *M. spicatum*, *S. erythrophthalmus* AND WATER EXPRESSED AS MICROCURIES × 10^{-4} PER GRAM WET WEIGHT

Days from zero	Water	Muscle	Skin	Scales	Bone	Gut	Gut contents	Gills	*M. spicatum*

272	0·19	0·37	1·6	53·2	11·0	0·50	1·6	6·7	45·4
Average	0·26	0·61	1·6	53·2	17·8	2·6	19·1	24·7	68·9
Accumulation factor*	1	2·4	6·2	208·6	69·8	10·2	74·9	96·9	270·2

$$^{*}\text{Accumulation factor} = \frac{\text{microcuries per gm. wet weight of tissue}}{\text{microcuries per ml. water}}$$

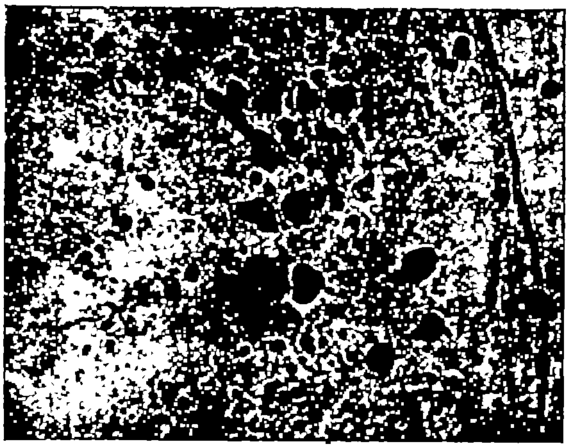

Fig. 3. Microautoradiograph of T.S. gut of *Scardinius erythrophthalmus*

The nodal sections (Fig. 2) showed that accumulation of strontium-90 was limited to crystals (probably calcium oxalate) in the cortex, the vascular tissue and the leaf traces. Martin[2] found an accumulation of strontium-90 in vascular tissues in beet and, notably, in the tertiary vascular tissue. Sections at internodes showed strontium-90 in crystals but less in the stelar region. This was in agreement with the gross autoradiographs of the *M. spicatum*.

Microautoradiographs of various fish tissues were made, including gill filaments, skin, flesh, bone and gut, and are included in the full report[3]. A photograph of the microautoradiograph of the transverse section of the ligatured gut is shown in Fig. 3. Blackening indicates the presence of strontium-90 on food particles; its absence from the gut wall is in agreement with the radioassay.

Fractionation of Phosphorus Compounds in Ossifying Cartilage

The phosphorus compounds of ossifying cartilage from the long bones of various young animals have been fractionated into two components: (*a*) 20 per cent tri-chloracetic acid-soluble fraction; (*b*) acid-insoluble fraction.

The animals were injected intraperitoneally with phosphorus-32 as orthophosphate. The acid-insoluble fraction, representing 20–40 per cent of the phosphorus content, had a very low specific activity, only 2 per cent of the total phosphorus-32 radioactivity of the cartilage was isolated in this fraction. It is assumed that the acid-insoluble fraction is protein bound, and since it is no longer present in formed bone it would appear that it is involved in the process of cartilage formation. The absence of any appreciable radioactivity in this fraction, however, would indicate that it plays no significant part in the calcifying mechanism.

The acid-soluble fraction, which contained 98 per cent of the phosphorus-32 activity in cartilage, has been further fractionated by the use of paper chromatography.

Lutwak-Mann[1] was unable by conventional means to demonstrate the presence of organic ester-phosphate in the acid-soluble extract due to the large excess of orthophosphate. Albaum[2], however, found adenosine triphosphate in preosseous tissue, enzymatically using a specific deaminase/spectrophotometric method. The main difficulty in the separation of phosphorus compounds by chromatography is the inhibitory effect of divalent ions. The effect is not so apparent in acid solvents; but it made two-dimensional chromatography, using an alkaline solvent in the second run, impossible. Numerous solvents were tried, but the best appeared to be *tert.*-butanol (80 c.c.) – water (20 c.c.) – tri-chloracetic acid (4 gm.).

The animals are injected with an amount of phosphorus-32 (0·33 mc./kilogram) in the form of orthophosphate. After 2 hr. the animal is killed, the cartilage quickly removed, and cleaned of all bone and muscle. The cartilage is placed in liquid nitrogen and crushed. The resultant powder is extracted with 1·5–4·0 ml. of 5 per cent trichloracetic acid for 30 min. with constant stirring. The mixture is centrifuged and the supernatant removed. 0·15–0·3 ml. of this extract is applied to the Whatman No. 4 paper, and the chromatogram run in the solvent for 40–60 hr. at 13–15° C. using the descending chromatographic technique. This allows for the separation of adenosine triphosphate, adenosine diphosphate and adenosine monophosphate. The R_{op} values, that is, the distance travelled with respect to orthophosphate, are approximately 0·2, 0·4 and 0·8 respectively.

The cartilage extract gives two definite spots. They are detected by means of the Hanes and Isherwood[3] spray for phosphate esters, and the purine compounds by the ultra-violet photographic method of Markham and Smith[4].

The largest spot is the orthophosphate from the calcified matrix. The other main spot has been identified as adenosine triphosphate by the following tests: (*a*) It runs the same distance as adenosine triphosphate in varying temperature conditions and is opaque to ultra-violet light when photographed. (*b*) On eluting out the spot an absorption peak at 260 mμ is obtained. The eluate also gives a positive test for pentose sugar (probably ribose). (*c*) It is chemically a phosphate compound. In addition, two further compounds are detected in trace amounts by the ultra-violet method. They correspond to adenosine diphosphate and adenosine monophosphate. No other phosphate compounds could be detected.

The adenosine triphosphate and orthophosphate were estimated quantitatively by ashing the corresponding area of the chromatogram and dissolving the ash in the amount of sulphuric acid required for the Berenblum and Chain[5] method which was used in the phosphorus estimations. The radioactivity measurements were made in a liquid counter using

TABLE 1. SPECIFIC ACTIVITY OF PHOSPHORUS-32 INCORPORATED IN ADENOSINE TRIPHOSPHATE (ATP) AND ORTHOPHOSPHATE OF CARTILAGE
(The specific activities are calculated according to Weidmann (ref. 6))

Age in days	Cat litter-mates												Dog litter	
	1		2		3		4		5		6			
	ATP	Ortho-phosphate	ATP	Ortho-phosphate	ATP	Ortho-phosphate	ATP	Ortho-phosphate	ATP	Ortho-phosphate	ATP	Ortho-phosphate	ATP	Ortho-phosphate
0			15,000	30,000	33,000	52,000	16,000	42,000			16,000	31,000	44,000	75,000
6					29,000	50,000	15,000	43,000			25,000	54,000	42,000	66,000
9			19,000	45,000										
15	29,000	61,000	18,000	45,000			15,000	40,000						
21	23,000	41,000	20,000	46,000					21,000	35,000	21,000	50,000		
28					19,000	37,000							30,000	60,000

the above solution before chemical estimations were carried out.

Using litter-mate puppies and kittens, a serial analysis with age gave the following results, which are expressed graphically in Fig. 1.

There appears to be a gradual diminution of the concentration of adenosine triphosphate with increased development of the cartilage. During this period an increase in the calcium/phosphorus ratio from 1·1–1·8 was also measured. There was no corresponding increase in the adenosine diphosphate or adenosine monophosphate content of the cartilage. The amount of adenosine triphosphate corresponding to the above phosphorus values is in newly born animals 36–38 mgm. per 100 gm. wet wt. of cartilage falling to 20 mgm. per cent in 4-week old kittens. This compares favourably with 35 mgm. per cent obtained by Albaum[2] for rat cartilage.

This chromatographic method is an improvement on that of Albaum[2] in that actual separation of adenosine triphosphate is achieved, and hence radioactivity associated with it can be measured.

These figures show a high specific activity in the adenosine triphosphate, but assume the activity to be equal in all three phosphate groups. This is certainly not true for other tissues, and the value of the terminal group may be considerably higher and be comparable to that of the orthophosphate and consequently be a possible precursor.

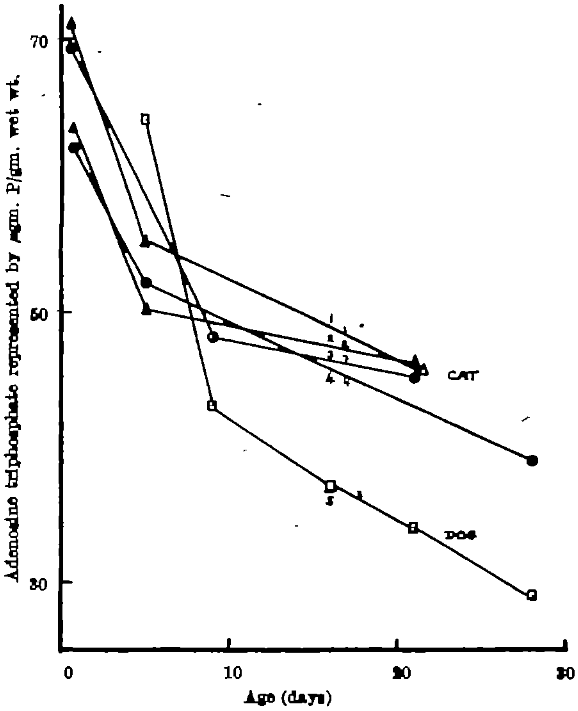

Fig. 1. Variation of adenosine triphosphate. Concentration in cartilage with age. Cat litters, 1, 2, 3, 4; dog litter, 5

The adenosine triphosphate concentration in cartilage is about one-tenth that of muscle, but is about the same value as liver and kidney, and represents quite a rich source of ester-phosphate. Cartier and Picard[7] have shown, using *in vitro* techniques, that adenosine triphosphate gives rise to much more rapid calcification than other esters. In addition, the *p*H maximum of adenosine triphosphate utilization is much nearer the physiological *p*H than with the other esters. Reis[8] has shown the presence in cartilage of 5-nucleotidase. This enzyme has a much higher activity at the physiological *p*H than alkaline phosphatase. Perkins[9] has demonstrated a high activity of adenosine triphosphatase in bone.

This idea that adenosine triphosphate may be an important intermediate in calcifying mechanism is strengthened by our findings that adenosine triphosphate is the only acid-soluble phosphate ester which accumulates due to the glycogenolysis in ossifying cartilage. The high specific activity of the incorporated phosphorus-32 in adenosine triphosphate is consistent with this idea and is supported by the fall in adenosine triphosphate concentration as calcification proceeds.

Fuller details of this work will be published elsewhere. This work has been supported by a grant from the Medical Research Council.

Effect of Analogues on the Uptake of Vitamin B_{12} by the Intact Rat

THE normal mechanism of absorption of vitamin B_{12} from the small intestine is a specialized one. In order to determine the part played by molecular configuration we have administered vitamin B_{12} analogues and studied their effect upon the absorption of the vitamin by the intact rat. Under these conditions, inhibition is probably due to competition for absorption or possibly to blockage of some part of the absorption mechanism. If no inhibition occurs then we can deduce that the difference in molecular structure has rendered the substance incapable of participation in the absorption system.

The analogues available to us were pseudovitamin B_{12}, a mixture of the monoethylamides, desdimethyl B_{12} and vitamin B_{12} lactone (Fig. 1). Pseudovitamin B_{12} contains adenine in place of the 5 : 6 dimethylbenziminazole of the vitamin molecule. The mixture of ethylamides consists of each of the three isomeric monoethylamide derivatives of a single propionamide side-chain. Desdimethyl vitamin B_{12} lacks the methyl groups of the benziminazole moiety. The lactone is formed on ring *B* (Fig. 1).

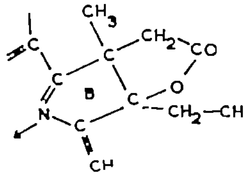

Fig. 1. Vitamin B_{12} lactone. Only ring *B* is shown, the remainder of the molecule is identical with cyanocobalamin

Young adult rats which received neither food nor drink for 16 hr. were given 1·5 ml. of a solution containing either 15 mμgm. of radioactive vitamin B_{12} alone or together with 1,500 mμgm. of an analogue. 5 hr. later each animal was killed by a blow on the head. The stomach, the intestine and its contents, and the liver were removed. The liver was weighed, and the three organs were separately dissolved in sulphuric acid[1]. The final volume of each solution was made up to 200 ml. with water, and the radioactivity determined in a scintillation counter containing a sodium iodide crystal of 2-in. diameter and 1 in. long, a re-entrant container and lead shielding at least 3½ in. thick[2]. By comparison with the radioactivity of a standard radioactive vitamin B_{12} solution the counts were converted to absolute amounts.

The results are shown in Table 1. The total uptake of the vitamin was determined by subtracting the amount in the stomach and intestine from the dose administered. The stomach content was always low. The liver uptake is expressed as μμgm./gm. wet weight of liver.

The radioactivity of the liver was a measure of uptake of the vitamin, and in all cases this measurement has correlated very well with the intestinal measurements.

Table 1

Substance administered	Total B_{12} uptake (mμgm.)	Mean total uptake (mμgm.)	Liver uptake (μμgm./gm.)	Mean liver uptake (μμgm./gm.)
B_{12} alone	7·7 6·8 4·5 2·8 7·7 6·2 2·9 5·9	5·5	— — 41·8 49·0 69·5 77·0 39·7 62·2	56·5
B_{12} + pseudo-vitamin B_{12}	6·2 6·8 2·7	5·2	— — 42·5	42·5
B_{12} + desdimethyl B_{12}	0·6 0·5	0·55	5·5 14·5	10·0
B_{12} + mono-ethylamides	2·95 0·6	1·8	12·0 9·8	10·9
B_{12} + B_{12} lactone	5·9 8·3	7·1	74·7 44·3	59·5

Pseudovitamin B_{12} did not inhibit the uptake of the vitamin. Evidently the benziminazole moiety is a necessary part of the molecule for the absorption process. Desdimethyl B_{12} did compete with the vitamin, and it must therefore be the benziminazole ring itself which is necessary.

If the acetamide side-chain of ring *B* is altered as in the lactone then the substance does not inhibit vitamin uptake. The mixture of monoethylamides interfered with uptake; in this case the acetamide side-chain on ring *B* is undisturbed.

From this evidence we can conclude that for absorption by the vitamin B_{12} system in the small intestine the benziminazole moiety of the 'nucleotide' portion of the molecule must be intact, although not necessarily methylated. A major alteration in the acetamide side-chain of ring *B* results in a loss of competitive activity.

Although we were using a hundred times the concentration of analogue to vitamin, in those instances in which the uptake was inhibited the absorption of the vitamin was diminished to approximately one-tenth. It seems reasonable to conclude that even where the analogue can take part in the absorption system the latter is still more specific for vitamin B_{12} than for the analogue.

We wish to thank Dr. J. J. Pfiffner for the pseudovitamin B_{12} and Dr. E. Lester Smith for the other analogues as well as the radioactive vitamin.

A Plain-muscle Stimulant in the Menstruum

DURING menstruation, the myometrium actively expels the disintegrating endometrium, sometimes forcibly enough to cause dysmenorrhoea[1]; the gastro-intestinal motility is increased[2]; if the subject is lactating, her breast-fed baby may suffer from mild diarrhoea[3]; and attacks of asthma are said to be commoner during the menstrual than during other phases[4].

These facts accord with the idea that the menstrual endometrium releases into the circulating blood some substance which generally increases the activity of plain muscle. With this in mind, Sieburg and Patzschke[5] examined sweat secreted at different phases of the cycle, and they concluded that the increase in the tone of the rabbit intestine caused especially by menstrual sweat was due to choline or to some similar substance. Whereas the experiments to be described do not rule out the possibility that the menstrual endometrium may produce choline, they suggest that it forms another active substance which is likely to be a lipoid-soluble acid.

If the theory outlined is correct, it should be possible to recover the active substance from the menstruum, and this has been done as follows. The subjects were several healthy medical students who, under the direction of a woman colleague were provided with vessels containing a 50 per cent acetone–

water mixture into which they put the usual perineal or vaginal dressings immediately they were discarded. The 50 per cent acetone extract was evaporated to dryness and then taken up in pure acetone or chloroform; this was added to Ringer's solution, the organic solvent evaporated off, and the pH, which was usually about 5, adjusted to 7·4 with sodium hydroxide. Control extracts of unused dressings were also made, and were found to have no effect.

The menstrual extracts showed two kinds of effect on plain muscle. One was a direct stimulation, shown by a slow increase in tone and in the amplitude of any spontaneous contractions. This was repeatedly demonstrated on the guinea pig ileum, the rabbit small intestine and uterus and the rat colon. Contrary to the findings of Sieburg and Patzschke[5], this effect was not abolished by atropine (10^{-6} or 10^{-5} gm./ml.), although with this treatment the preparations became generally less sensitive to the menstrual extracts as well as to histamine and hydroxytryptamine. Mepyramine and lysergic acid (10^{-6} gm./ml.) also failed to abolish the response.

The other effect of the menstrual extracts was to potentiate the action of certain other plain-muscle stimulants. Amounts of the extracts too small to cause more than a very slight contraction of the guinea pig ileum nevertheless, after being in the organ bath for 1–3 min., greatly increased the response to either acetylcholine or to histamine. The potentiation rapidly disappeared when the extract was washed out. The contractile response of the rat vas deferens to adrenaline was similarly potentiated; so also was that of the guinea pig seminal vesicle. In neither of these latter cases did the extracts alone cause any contraction. Macht and Davis[6] described a similar effect of 'mentoxin' on the rat vas deferens, and von Euler[7] a somewhat similar effect of prostaglandin on the guinea pig seminal vesicle.

The pharmacological and solubility properties of the active substance, so far as they have been studied, indicate that it is a lipoid-soluble acid of the general type reviewed by Vogt[8]. Its physiological significance is a matter for conjecture, but it provides a possible explanation of the facts described in the opening paragraph.

These findings were communicated orally to the Physiological Society at Oxford on July 19–20.

Deoxyribonucleic Acid Content of the Nucleus of Liver Cells after Partial Hepatectomy

MODIFICATIONS in the deoxyribonucleic acid content of the nucleus of liver cells after partial hepatectomy were recently described in the rat[1] and the guinea pig[2]. We tried to observe this phenomenon in the mouse. Hepatectomy was performed in fifteen specimens. Nearly one-fifth of the gland was removed by cautery. Three groups of 5 animals each were killed respectively 3, 4 and 9 days after intervention. Traces of neither infection nor haemorrhage were present. Fragments of the operated livers and of 4 control livers were fixed in a mixture of 80 parts of alcohol 96 per cent, 15 parts of formalin, 5 parts of acetic acid, dehydrated and embedded under strictly standardized conditions. Sections of the different livers were placed on the same slide, to assure an identical Feulgen-reaction. In each of the 10μ-thick sections, the deoxyribonucleic acid content of 200 nuclei was determined *in situ* by means of L. Lison's histophotometrical method[3].

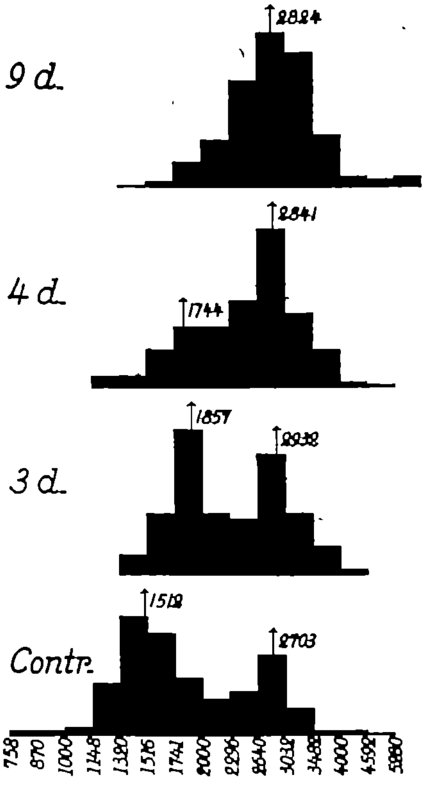

Fig. 1. Histograms of the deoxyribonucleic acid content of the nuclei of liver cells in a control and 3, 4 and 9 days after partial hepatectomy. The mean deoxyribonucleic acid contents of the different nuclear classes are indicated by the arrows and given in arbitrary units

In Fig. 1 are represented the histograms of the results obtained for one typical liver of each group (in the other liver comparable results were found). In the control the well-known nuclear-classes of mouse-liver were found—a diploid and a tetraploid class and some sporadic octoploid nuclei. In the treated livers the relative number of the nuclei of the diploid class decreases in favour of the tetraploid class, while the mean value of deoxyribonucleic acid content of the remaining diploid nuclei increases progressively. The mean value of the tetraploid elements remains unchanged; 9 days after intervention there is a complete fusion of the two classes around the tetraploid mean value. The small number of octoploid nuclei does not vary.

After partial hepatectomy in mice, a precocious and progressive increase of the deoxyribonucleic acid content of the diploid liver cell nuclei occurs. Those nuclei form finally with the originally tetraploid elements a homogeneous population as to their deoxyribonucleic acid content.

3,4-Dihydroxyphenylalanine and 5-Hydroxytryptophan as Reserpine Antagonists

The depletion by reserpine of storage in the body of 5-hydroxytryptamine ('Serotonin') and of the catechol amines is now well established[1-3]. In reserpinized animals the peripheral part of the adrenergic system does not function owing to lack of the transmitter[3]. This is presumably true also of the central part of the adrenergic system. However, it remains to be proved to what extent the central action of reserpine may be attributed to changes in brain catechol amines and/or 5-hydroxytryptamine.

If lack of amines were responsible for the central action of reserpine, administration of the amines in question should counteract these effects, provided that the amines were capable of entering the brain. However, 5-hydroxytryptamine has been shown not to penetrate the blood-brain barrier readily[4], and this may be true also of the catechol amines. This difficulty may be overcome by administering the amino-acid precursors of the amines. Thus injection of 5-hydroxytryptophan is followed by an increase in the level of 5-hydroxytryptamine in brain as well as by central excitation[4]. Preliminary experiments in this laboratory have shown that in this respect 3,4-dihydroxyphenylalanine, which is the precursor of the catechol amines (dopamine, noradrenaline, and adrenaline), behaves similarly.

Experiments were performed on mice (males weighing about 10 gm.), which received an intraperitoneal injection of reserpine (20–40 mgm. per kgm.). After about 16 hr., when the animals were markedly tranquillized and showed complete ptosis of the eyelid, 5-hydroxytryptophan, 3,4-dihydroxyphenylalanine, or a mixture of both amino-acids (in the DL-form throughout) were injected intraperitoneally. In doses up to 1,000 mgm. per kgm. 5-hydroxytryptophan was unable to antagonize the tranquillizing action of reserpine: ptosis persisted. On the other hand, the response to 3,4-dihydroxyphenylalanine was dramatic. Within 15–30 min. after a dose of 500–1,000 mgm. per kgm. the animals resumed almost normal behaviour or even showed signs of overactivity, and ptosis disappeared. The effect did not last much longer than an hour, after which the animals gradually returned to the same condition as before the injection of 3,4-dihydroxyphenylalanine. Although 5-hydroxytryptophan given alone had no effect, a mixture of equal amounts of 5-hydroxytryptophan and 3,4-dihydroxyphenylalanine 250–500 mgm. per kgm.) produced a more complete and longer-lasting counteraction of the reserpine effect than did the same dose of 3,4-dihydroxyphenylalanine alone.

A dramatic effect of 3,4-dihydroxyphenylalanine (200 mgm. per kgm. intravenously) was observed also in rabbits which had received reserpine in a dose of 5 mgm. per kgm. intravenously 4 hr. earlier. Within 10–15 min. after the injection of 3,4-dihydroxyphenylalanine the tranquillization as well as ptosis and meiosis caused by reserpine had disappeared completely. If the animal had received iproniazid (100 mgm. per kgm. intravenously) about 2 hr. before the 3,4-dihydroxyphenylalanine, the dose of the latter required to antagonize the effect of reserpine was markedly reduced. This supports the assumption that the effect of 3,4-dihydroxyphenylalanine was due to an amine formed from it. (The iproniazid, when administered about two hours after the reserpine as in these experiments, did not *per se* counteract the tranquillizing effect of reserpine.) In normal rabbits 3,4-dihydroxyphenylalanine caused central stimulation, which was likewise markedly potentiated by iproniazid pretreatment.

A full account of these experiments will be published elsewhere.

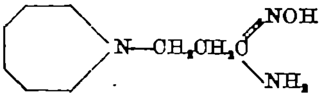
Antihypertensive Activity of Hexahydro-1-Azepinepropionamidoxime

Hexahydro-1-azepinepropionamidoxime dihydrochloride (I), designated as *SU*-4029, has been studied for its effect on the cardiovascular system of the dog.



(I)

A single intravenous dose of 30 mgm./kgm. of this compound lowered the arterial pressure of neurogenic and renal hypertensive dogs while not notably affecting the blood pressure of normotensive dogs. However, in normotensive animals 30 mgm./kgm. of *SU*-4029 given intravenously eliminated the severe hypertension elicited by high doses of amphetamine and ephedrine and also markedly antagonized carotid occlusion reflex pressor responses. These antihypertensive effects were slow in onset and lasted for approximately two to six weeks following single injection. *SU*-4029 was orally active and had a cumulative action when given in small daily doses.

To prepare the compound, hexahydroazepine was cyanoethylated and gave hexahydro-1-azepinepropionitrile[1], b.p. 121–123°/14 mm.; n_D^{30} 1·4710 (found: C, 70·82; H, 10·52; N, 18·53 per cent. $C_9H_{16}N_2$ requires: C, 71·11; H, 10·61; N, 18·43 per cent). Treatment of this nitrile with hydroxylamine in ethanol yielded the desired amidoxime which could be converted to the dihydrochloride salt with ethanolic hydrogen chloride; recrystallization from ethanol gave material that melted with decomposition at 183–185° (found: C, 42·01; H, 8·43; N, 16·22; Cl, 27·28 per cent. $C_9H_{19}N_3O$. 2HCl requires: C, 41·90; H, 8·20; N, 16·29; Cl, 27·49 per cent).

Numerous structurally related compounds have been prepared and their pharmacological activity investigated. Alteration of the side-chain and ring-size usually resulted in diminution of the aforementioned antihypertensive properties.

SU-4029 is at present being tested clinically, and the results as well as chemical and pharmacological studies will be published *in extenso* at a later date.

Oligosaccharides of Human Milk

THE presence of fucose as a constituent sugar in oligosaccharides obtained from human milk was reported by Kuhn[1] in 1952. Since that time Kuhn and his associates have characterized four oligosaccharides from this source, in all of which fucose is found: a trisaccharide, fucosido-lactose; two pentasaccharides referred to as lacto-N-fucopentaoses I and II, and a hexasaccharide, lacto-N-difucohexaose; the last three are derivatives of a common, fucose-free parent compound—lacto-N-tetraose[2]. Montreuil, in a series of communications, has reported the occurrence of compounds probably identical with those analysed by Kuhn, and in addition, a further range of fucose-containing substances of still greater complexity[3]. He has isolated thirteen sugar compounds, other than lactose, from human milk, all of which contain galactose and glucose and most of them fucose and acetylglucosamine as well.

There seems little doubt that these compounds isolated by Montreuil are in many cases identical with the series of compounds which we have ourselves obtained from human milk samples by rather different fractionation procedures. However, our agreement with this author does not always extend to his estimates of the molecular proportions of the various hexose units in his original compounds, and we give in Table 1 a summary of our own results, based on a study of the relationships existing between these oligosaccharides such as can be shown by their hydrolysis under very mild conditions. By correlating these results with analyses given by a modification of the method of Dische and Shettles for fucose[4], designed to give a simultaneous estimation and characterization of the non-fucose 'core' of the molecule in addition to a simple fucose analysis, we are able to suggest the probable identity of this range of compounds.

The substances analysed here account almost quantitatively for the total fucose in the original unfractionated milk samples, and it would therefore appear that all the fucose oligosaccharides of human milk, with the exception of fucosido-lactose and possibly the compound, or compounds, in fraction *A* (see Table 1), may be regarded as derivatives of lacto-N-tetraose or of a di- or tri- polymer of this compound. We may add that so far we have identified only one mono-fuco-lacto-N-tetraose (cf. ref. 2) and only one fucosido-lactose (cf. ref. 3), and also that tri-lacto-N-tetraose, which might be expected to occur as a member of our series, has not yet been observed except, on chromatograms, as the probable primary product of the mild hydrolysis of compound *C*.

Table 1

Fraction	*Rr**	Primary products on mild hydrolysis	Type of compound

Use of Goose Cells in Hæmagglutination Tests with Arthropod-borne Viruses

HÆMAGGLUTINATION studies with arthropod-borne viruses are normally carried out using red blood cells from one-day-old chicks, although cells from mature pigeons have been used in the case of Murray Valley encephalitis virus[1]. An observation made in the West African Council for Medical Research Laboratories in Lagos that cells from mature ducks were agglutinated by a yellow fever antigen led to a study of readily available domestic birds. Cells from Muscovy ducks (*Cairina moschata*), from a local (Badagri) variety of the domestic duck (*Anas boscas*) and from Chinese geese (*Cygnopsis cygnoides*) were compared with cells from one-day-old chicks against yellow fever, Uganda *S*, Zika and West Nile antigens. Goose cells gave titres which were at least as high as those obtained with chick cells, and usually higher, and the settling patterns were consistently sharp and easy

* For details of these viruses, see Casals (ref. 2)

to read. Duck cells, although agglutinated, gave lower titres and showed a tendency to spontaneous agglutination in controls. Goose cells were thereafter used as a routine in the Lagos laboratory, and experience over more than a year has shown them to be highly satisfactory in hæmagglutination and hæmagglutination-inhibition tests with the antigens already mentioned, and in addition with antigens prepared against Semliki forest, Ilheus and the Trinidad 1751 strain of dengue virus. Details of this work will be published elsewhere.

While on a visit to the Rockefeller Foundation Virus Laboratories in New York, it became possible to confirm and extend these observations. Antigens of known activity against one-day-old chick cells were tested against cells obtained from mature Toulouse geese (*Anser cinereus*, the common white domestic goose). Where comparative tests were carried out, titres with goose cells were as a rule one dilution higher than with chick cells (see Table 1). The *p*H range over which agglutination occurred was frequently broader with goose cells, and the tests were generally sharper and easier to read. Hæmolysis, a common finding with group *A* antigens, was less marked with goose cells, which appeared to be generally more stable than one-day-old chick cells.

So far, no antigen which is active against chick cells has been found to be inactive against goose cells. The increased sensitivity of goose cells may be valuable when antigens of low titre are being examined. The practical convenience of bleeding mature geese from a wing vein as compared with the bleeding of one-day-old chicks need scarcely be stressed. The only disadvantage so far encountered has been the finding that naturally occurring agglutinins for goose cells in human and animal sera are somewhat more common than are agglutinins for chick cells in the same sera. However, a simple absorption with normal goose cells readily removes this difficulty, and has been adopted as a routine in the preparation of sera for inhibition tests.

I thank Dr. F. N. Macnamara, director of the West African Council for Medical Research Laboratories, Lagos, and Dr. M. Theiler, director of the Rockefeller Foundation Virus Laboratories, New York, for their interest and encouragement; also Dr. J. Casals and Dr. D. H. Clarke, who generously provided many of the antigens used in New York.

Coagulant Action of Proteolytic Enzymes

Eagle and Harris[1] demonstrated that the coagulant actions of papain and trypsin differ. Trypsin acts by converting prothrombin to thrombin: papain clots fibrinogen directly. The thrombin-like action of papain on fibrinogen has been ascribed to its proteolytic property[2,3]. Light-scattering studies on the papain–fibrinogen reaction[4] have shown that the extent of polymerization of fibrinogen is roughly of the same order as in the thrombin–fibrinogen reaction.

Although Sherry *et al.*[3] include ficin in a list of substances producing coagulation of fibrinogen, careful search of the literature fails to reveal any other reference to the coagulant action of this enzyme.

Two specimens of crude ficin powder were tested against human plasma and purified human and bovine fibrinogen. Typical results with human fibrinogen may be seen in Table 1. Both ficin preparations proved to be approximately equally potent. At a concentration of 1 mgm./ml. they were actively fibrinogenolytic; at lower concentrations they caused coagulation of the fibrinogen. Similar results were obtained with plasma and bovine fibrinogen.

Table 1. COAGULATION OF HUMAN FIBRINOGEN BY FICIN

Ficin concentration (mgm./ml. of mixture)	Clotting time (sec.)	
	Preparation 1	Preparation 2
1·0	no clot*	no clot*
0·5	20	20½
0·25	26	22
$0{\cdot}12_5$	96	85
$0{\cdot}06_2$	180	165
$0{\cdot}03_1$	600	600

Clotting mixture: 0·2 ml. 0·4 per cent human fibrinogen, 0·1 ml. 0·6 per cent sodium chloride and 0·1 ml. ficin.

* After 5 min., 0·1 ml. thrombin added: no clot after another 5 min (thrombin control: 10 sec.).

The human fibrinogen was prepared by the ether precipitation method (ref. 12).

One specimen of ficin was obtained from Merck and Co., Rahway, New Jersey, and the other from Light and Co., Poyle, Bucks.

These findings confirm the assertion of Sherry *et al.* that ficin possesses a thrombin-like action. Using mixtures containing purified prothrombin, purified Factor V, calcium, and ficin at various concentrations, careful search was made for any evidence of activation of prothrombin. At certain concentrations of enzyme, prothrombin was rapidly destroyed, but no evidence of thrombin formation was obtained. Exactly similar results were obtained with papain, confirming the work of Eagle and Harris.

Eagle[5] also noted that certain proteolytic snake venoms which coagulated fibrinogen directly (*Bothrops*, *Crotalus* species) were not inhibited by the powerfully antithrombic plasma of an anaphylactically shocked dog. This was also true of papain. In view of the subsequent discovery that the anti-

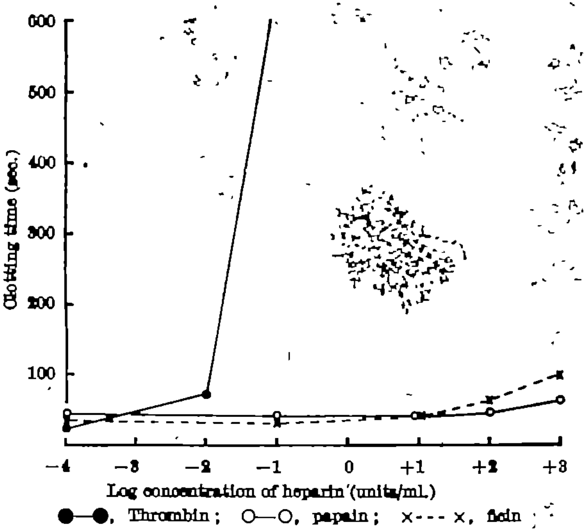

Fig. 1. Effect of heparin on coagulation of plasma by thrombin, papain and ficin. Clotting mixture: 0·2 ml. human citrated plasma, 0·1 ml. heparin at various concentrations, and 0·1 ml. thrombin, papain or ficin. The concentrations of thrombin, papain and ficin were adjusted to give a similar initial clotting time

thrombic material appearing in anaphylactic shock was heparin[6], direct determination of the effect of heparin on the coagulant ability of these proteolytic enzymes seemed important.

The action of heparin on thrombin, papain and ficin is shown in Fig. 1. At a heparin level of 0·1 unit/ml., plasma was incoagulable by thrombin. On the other hand, both papain and ficin were not inhibited by heparin. The slight prolongation of clotting time at very high heparin levels was probably due to the acid nature of heparin.

Eagle and Harris[1] noted that the clot produced by papain was softer than a normal clot. However, it has been stated that a papain-produced clot is similar to a normal clot when viewed by dark-field microscopy[7] or electron microscopy[8].

Present findings indicate that clots produced by papain and ficin are quite distinct from clots produced by the normal thrombic mechanism. If plasma or fibrinogen is clotted by papain or ficin without manipulating the tube, a bulky clot grossly similar to a normal one forms. However, the tensile strength of this coagulum is considerably lower than the normal. If the tube containing the clotting mixture is continuously tilted during coagulation, a small flocculent coagulum is produced; this contrasts markedly with a normal clot produced by thrombin in similar circumstances. When both types of coagulum were viewed by dark-field microscopy, it was found that the enzyme-produced clots were relatively deficient in fibrin strands. Those that did appear were small and late in development. The highly organized network characteristic of a normal coagulum was absent in the enzyme-produced clots.

The differences in clot morphology and in behaviour towards heparin between normal and enzyme-produced clots suggest that, though similar in general form, the coagulant action of proteolytic enzymes does not exactly correspond to that of thrombin. Papain and ficin have much broader specificities for synthetic substrates and native proteins than thrombin[2,8–10]; perhaps they attack the fibrinogen molecule at different sites than thrombin and produce a somewhat different fibrin.

Reasoning from differences in solubility between normal and venom-induced clots, Janszky[11] has also concluded that coagulation produced by proteolytic venoms was not identical with that produced by thrombin.

Structure of a New Pyridine Nucleotide isolated from *Penicillium chrysogenum*

IN the course of a study of the acid-soluble nucleotides occurring in the mycelium of *Penicillium chrysogenum*[1] we isolated a compound having a typical adenosine ultra-violet spectrum, and showing the appearance of a peak at 315 mμ on addition of potassium cyanide. This compound could be distinguished from diphosphopyridine nucleotide and triphosphopyridine nucleotide not only by its inability to act as a coenzyme for alcohol dehydrogenase and for glucose-6-phosphate dehydrogenase but also by the fact that it was eluted by formic acid from a 'Dowex-1' (formate) column behind diphosphopyridine nucleotide and before triphosphopyridine nucleotide.

Chemical and enzymic degradations of the above nucleotide have yielded results which provide strong evidence to indicate that it is the nicotinic acid analogue of diphosphopyridine nucleotide. Treatment of the compound with 0·1 *M* hydrochloric acid (2·5 hr. at 100° C.) resulted in the liberation of nicotinic acid, adenine and ribose-5-phosphate, whereas in the same experimental conditions not a trace of nicotinic acid was formed from diphosphopyridine nucleotide. On incubation with beef-spleen diphosphopyridine nucleotidase[2], nicotinic acid and adenosine diphosphate–ribose were produced, as compared with diphosphopyridine nucleotide which liberated nicotinamide and adenosine diphosphate–ribose. Using the molar extinction coefficient reported for diphosphopyridine nucleotide[3] the following molar ratios of adenine, nicotinic acid, pentose and phosphate were found: 1·00 : 0·85 : 1·92 : 2·09, which are in good agreement with the calculated figures of 1·00 : 1·00 : 2·00 : 2·00.

Conclusive proof for the structure of the pyridine nucleotide isolated from *P. chrysogenum* was provided by its identity with the nicotinic acid analogue of diphosphopyridine nucleotide prepared unambiguously from diphosphopyridine nucleotide and nicotinic acid by an exchange reaction catalysed by beef-spleen diphosphopyridine nucleotidase. This type of enzymic reaction has been utilized for the synthesis of several diphosphopyridine nucleotide analogues substituted in the pyridine moiety by pyridine

‖ Figures for the cyanide complex of the analogue are calculated from the ultra-violet spectrum determined in 30 per cent (v/v) ethanol.

derivatives other than nicotinamide[2,4]. Anion exchange chromatography ('Dowex-1' formate, gradient elution with formic acid[5]) of the products obtained after incubation of diphosphopyridine nucleotide and nicotinic acid with the beef-spleen enzyme showed four peaks. These corresponded to the following compounds, listed in the order they emerge from the column: nicotinamide, nicotinic acid and diphosphopyridine nucleotide, the new analogue of diphosphopyridine nucleotide, and adenosine diphosphate-ribose. The analogue was eluted from the resin in the same position as the product isolated from the mould: furthermore the two compounds were indistinguishable by paper chromatography (two different solvents) and by paper electrophoresis at *p*H 5, and had identical spectral properties. The chromatographic, electrophoretic and spectral properties of the new pyridine nucleotide and of diphosphopyridine nucleotide are reported in Table 1.

The presence of a carboxyl group in the molecule of the new pyridine nucleotide increases the negative charge of the molecule, as reflected in the electrophoretic mobility of the compound, which is 1·5 times that of diphosphopyridine nucleotide, and in the previously mentioned behaviour in anion-exchange chromatography. The carboxyl group is probably responsible also for the decreased reactivity of the new compound with cyanide: in fact the rate of the reaction with cyanide was quite slow in aqueous solution, whereas in 30 per cent ethanol the peak at 316 mμ appeared very rapidly. In this respect it is interesting to note that N′-methyl-nicotinic acid (trigonellin) does not react with aqueous cyanide[6] but will react in alcoholic solution[7], in contrast to N′-methyl-nicotinamide, which reacts with aqueous cyanide[6]. These two model substances are structurally interrelated in the same way as diphosphopyridine nucleotide and its nicotinic acid analogue.

At present no data are available on the biological significance of the new pyridine nucleotide. We are now investigating its possible role as an intermediate in synthesis of diphosphopyridine nucleotide from nicotinic acid by human erythrocytes. Recently, Preiss and Handler[8] have suggested that in this process "amidation may occur after nicotinic acid is converted to some unknown nucleotide derivative".

We thank Prof. E. B. Chain for his interest in this investigation.

Note added in proof. We have now isolated from human erythrocytes incubated with nicotinic acid a compound identical with the new pyridine nucleotide from *P. chrysogenum*[10]. This shows that one of the intermediates ('compound II') found by Preiss and Handler in the synthesis of diphosphopyridine nucleotide from nicotinic acid in human erythrocytes[11] is, in fact, the nicotinic acid analogue of diphosphopyridine nucleotide, that is, desamido-diphosphopyridine nucleotide, as they suggested.

Fungistatic Activity of some Hydroxamic Acids

IT was found by two of us[1] that salicylhydroxamic acid completely inhibits growth of some pathogenic fungi (*Trichophyton schoenleinii*, *T. gypseum*, *T. rubrum*, *T. violaceum*) *in vitro* at a concentration of 0·025–0·1 per cent (0·25–1·0 mgm. per 1 ml.). A similar effect was produced by benzohydroxamic acid and 2-hydroxy-3-naphthydroxamic acid[2]. It was interesting to find that 5-bromosalicylhydroxamic acid ('T 40')[3] (which has now found clinical application in Poland as an auxiliary remedy in treating tuberculosis in addition to 'INH'[4]) possesses a very low fungistatic activity.

Salicylhydroxamic acid, which formerly was found to be of low toxicity[5], was clinically examined at the Municipal Hospital No. 1 in Poznan. From the beginning of 1956 to the middle of 1957 twenty-one cases of trichophytiasis and one case of epidermophytiasis were examined. Salicylhydroxamic acid was given *per os* during 10 days in doses 1 gm. and 0·5 gm. daily to adults and children, respectively. Quick healing followed, which in many cases was very spectacular. Simultaneously, systematic investigation of blood and urine of patients did not show any unfavourable effect due to the treatment. Salicylhydroxamic acid might therefore be a possible remedy against diseases produced by pathogenic fungi. Detailed description of clinical experiments will be published by one of us (J. A.) elsewhere.

Another line of research consisted in preparing a number of derivatives of phenoxyacethydroxamic acid and determining their fungistatic activity against *Fusarium culmorum*, *Alternaria solani* and *Rhizoctonia solani*[4]. Chlor-derivatives of phenoxyacethydroxamic acid proved to exert a particularly strong fungistatic activity *in vitro*.

Thus 4-chloro-2-methylphenoxyacethydroxamic acid was effective against *F. culmorum* at a concentration 0·005 per cent in solid agar culture medium. 2,4-Dichlorophenoxyacethydroxamic acid was effective against all three fungi examined at concentration 0·025 per cent. Similar activity was shown by 3,4-, 2,5-di- and 2,4,6-trichloro-derivatives.

The same group of compounds was examined against pathogenic fungi. 3,4-Dichlorophenoxyacethydroxamic acid was found to be particularly effective not only against *Trichophyton* but also against various pathogenic yeasts. It completely inhibited growth of *Candida albicans*, *C. krusei*, *C. tropicalis*, *Cryptococcus neoformans*, *Geotrichum 1* and *Geotrichum malatensis 53* when used in concentration 0·003–0·025 per cent in liquid Sabouraud medium.

Ethyl-3-Indoleacetate: an Artefact in Extracts of Immature Corn Kernels

The isolation and identification of 3-indoleacetic acid in corn kernels has been well established[1]. While characterization of ethyl-3-indoleacetate in ethanol extracts of corn kernels, *Zea mays*, variety Golden Cross, has been reported from this laboratory[2], it has been suggested that ethanol extraction may have resulted in the formation of an artefact[3].

To avoid esterification, peroxide-free ethyl ether was used as the extractant in the present study. Freshly harvested, immature (early milk stage) corn kernels, variety Golden Cross, were covered with ethyl ether and extracted for two hours at 2° C. ('free auxin' or first fraction). Additional cold ethyl ether washings of the kernels were added to the original extract. The kernels were again covered with ethyl ether and extracted for 48 hr. at 25° C. ('bound auxin' or second fraction). The first and second ethyl ether fractions were further separated into acidic and non-acidic ('neutral') portions by extraction with 5 per cent aqueous sodium bicarbonate. The bicarbonate solution containing the acidic substances was adjusted to pH 2·8 with hydrochloric acid and extracted with ethyl ether. The aqueous layer was discarded, and the acidic substances in the ether layer were retained. Acidic and non-acidic ethereal solutions were separately concentrated under reduced pressure with the bath temperature kept below 25° C. The constituents of the concentrated extracts were partitioned by paper chromatographic techniques (Whatman No. 1 filter paper, solvent mixture 2-PrOH : NH_3 : H_2O (8 : 1 : 1 v/v)[4]) and their biological activities assayed[5].

3-Indoleacetic acid was detected in the chromatographically separated acid fractions through biological assays, by development of characteristic colours with Salkowski and Ehrlich spray reagents, and ultra-violet absorption spectra. In addition, growth-promoting zones with R_F 0·25–0·33 and growth-inhibiting zones with R_F 0·60–0·70 were noted in both acid fractions. A similar observation of growth-stimulating and -inhibiting zones has been reported for absolute ethanol extracts of corn kernels (ref. 1, Kefford).

Growth-stimulating zones of R_F 0·80–0·90 were observed in histograms of neutral fractions. The R_F values were similar to those reported for ethyl-3-indoleacetate and 3-indoleacetonitrile; however, the presence of an indole moiety could not be established by ultra-violet absorption spectra or by the reactions to Salkowski and Ehrlich colour reagents. Absence of ethyl-3-indole-acetate in the ethyl ether extracts of corn kernels, *Zea mays*, variety Golden Cross, indicated that it was previously isolated as an artefact[3]. The characterization of this neutral growth substance is now in progress, and a more detailed report will be published elsewhere.

We are indebted to Dr. F. G. Teubner for his interest and suggestions throughout this investigation. This work was supported in part by the National Science Foundation, Washington, D.C.

Actinomycete Disintegration of Raw Wool

During the course of investigations on bacterial disintegration of raw wool, the presence of Actinomycetes in rotted wool was often noted. These organisms, however, rarely appeared in culture, perhaps because of the prevalence of *Pseudomonas aeruginosa* the antagonistic effects of which are well known. Eventually Actinomycetes were isolated from nutrient agar cultures of at least one month's growth when these had been left to dry out at room temperature. Under these conditions aerial hyphæ appeared, from which pure cultures of the organisms were obtained.

A number of Actinomycetes have been isolated from the living fleece and from fleece wool, all of which are capable of bringing about a rapid disintegration of raw wool fibres, both under laboratory conditions and when inoculated into the living fleece. These organisms readily attack autoclaved wool as well as wool which has not been sterilized, when this is maintained at high humidity. The inoculated wool fibres become chalky-white and tend to clump together at the areas of inoculation. When examined microscopically these areas show extensive fibre disintegration, such as severed fibres with 'brush ends', free cuticular scales and individual fusiform cortical cells.

Actinomycetes have been mentioned previously by other workers as active agents in the disintegration of processed wool[1]; but the present observation of their degrading effects on raw wool and their mode of attack are of interest. It has been observed repeatedly that Actinomycete threads ramify freely within the wool fibre between the cuticular scales and the cortical layer below them. Entry by the Actinomycete is frequently by penetration between cuticular scales, and observations suggest that it may also be through the actual scale surface. Fibres from inoculated wool were observed with quite extensive internal Actinomycete growth before damage to the fibre was apparent. Severe disintegration under laboratory conditions may be brought about in 3–4 days by holding inoculated wool at 37° C. in high humidity. It has been demonstrated[2] that the hyphæ of the ringworm fungus *Microsporum gypseum* are able to penetrate the wool fibres of degraded cloth and grow parallel to the fibre axis, bringing about a disintegration similar to that effected by the Actinomycetes here described.

The fleece has been shown to contain fibre types[3] differing in plasticity and amorphous/crystalline ratio[4]. In order to determine whether these fibre types were attacked differentially, a sample of Romney lamb's wool was sorted according to type of fibre into six groups, and these, together with a sample of human hair, were placed in cavity slides to which a few drops of a nutrient broth culture of one of the most active of these Actinomycetes was added. These were maintained aseptically under humid conditions at 37° C. After two days, damage to fibres and to the human hair was evident on microscopic examination, and after seven days all six types of wool fibres became characteristically opaque and showed severe to very severe disintegration. Human hair was extensively degraded, showing brush ends, fractures and free cortical cells, but the damage was not as severe as that brought about in the wool fibres.

The effect of Actinomycetes isolated from soil from a sheep paddock was investigated by inoculating these on to wool samples maintained in a humidity chamber at 30° C. These soil isolates brought about varying degrees of fibre degradation. After six days, three of the seven isolates brought about well-advanced disintegration, two had penetrated the wool fibres without causing visible damage, and two had neither damaged nor penetrated the wool fibre.

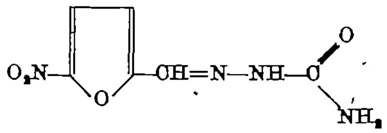
Site of Reduction of Nitrofurazone by Bacteria

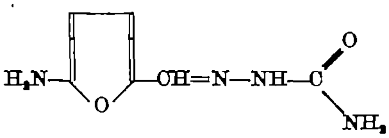
ANTIBACTERIAL nitrofurans are reduced to the corresponding amino-compounds by *Aerobacter aerogenes*[1]. The site of the reaction (in a different organism) is now shown to be the cytoplasmic membrane rather than the cell wall or cytoplasm. Lack of an enzyme system capable of effecting this reaction in the bacterial cell walls was not unexpected[2].

Attempts to obtain isolated protoplasts from *A. aerogenes* were unsuccessful. However, *Bacillus megaterium*, strain *KM*, reduced nitrofurazone (5-nitro-2-furaldehyde semicarbazone, I) in 0·04 *M* phosphate buffer (pH 7·0) in presence and absence of 0·2 *M* sucrose;



(I)

the ultra-violet absorption pattern observed after drug-bacteria contact was identical with that previously obtained using *A. aerogenes*, indicating reduction to 5-amino-2-furaldehyde semicarbazone (II)[1].



(II)

Protoplasts, obtained by lysozyme digestion of *B. megaterium* in the above buffer with sucrose as stabilizer[3], also reduced nitrofurazone but at a slower rate than that observed for the whole cells. Centrifuging the protoplasts, to allow removal of the digestion medium, and careful re-suspension in the phosphate–sucrose solution further decreased the rate of reduction of nitrofurazone. The difference in rates probably indicates damage to the fragile protoplasts.

Lysis of the protoplasts by osmotic shock (resuspension of centrifuged protoplasts in buffer only) or lysozyme digestion of whole cells in absence of a stabilizer both yielded preparations incapable of reducing nitrofurazone. McQuillen[4] previously reported some synthetic ability in suspensions of protoplasts which had been lysed by shaking in a stabilizing medium. A similar preparation from *B. megaterium* showed slight ability to reduce nitrofurazone, but 'Anoptral' contrast microscopy revealed the presence of a small proportion of unbroken protoplasts which may well account for the observed reduction. Isolated

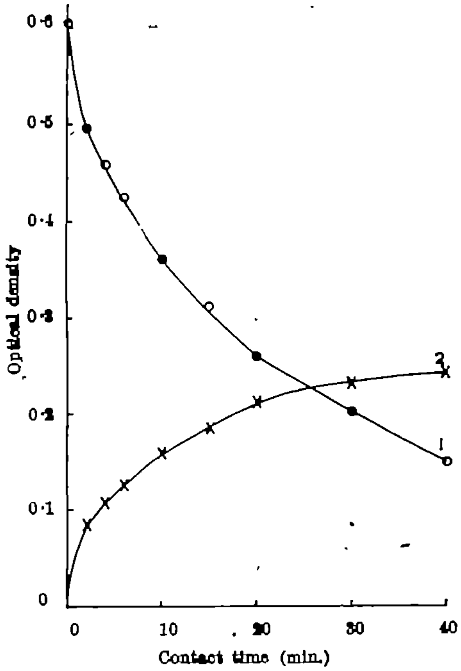


Fig. 1. Changes in the ultra-violet absorption of solutions of nitrofurazone (initially 10 μgm. per ml.) after varying times of contact with *B. megaterium* (optical density of suspension *c.* 0·4 at 500 mμ in a 1-cm. cuvette) in presence of buffer and sucrose. Curve 1, loss of nitrofurazone (λmax. 375 mμ), as indicated by the optical density at 400 mμ; curve 2, optical density (corrected for absorption due to unchanged nitrofurazone) at 333 mμ, the absorption maximum of 5-amino-2-furaldehyde semicarbazone

cell walls, prepared by the method of Salton and Horne[5], failed to reduce nitrofurazone.

The rate of reduction of nitrofurazone by whole bacteria was rapid and proceeded with no detectable lag (Fig. 1); loss of the 375 mμ absorption peak of the drug was accompanied by an increase in absorption and subsequent development of a peak at 333 mμ due to 5-amino-2-furaldehyde semicarbazone. The speed of this reaction indicated that it occurred at the surface of the bacterial cell. The concept of the cell wall as a rigid but open structure freely permeable to ions and molecules of low molecular weight is currently accepted. Such a cell wall, apparently devoid of enzyme systems, would allow free passage of both nitrofurazone and its corresponding amino-derivative. No loss of nitrofurazone due to adsorption by whole cells or cellular fragments occurred.

The results indicate that the enzyme system responsible for the reduction of nitrofurazone is probably located on the surface of the intact protoplasts. In the absence of added co-factors, all ability of the protoplasts of *B. megaterium* to reduce nitrofurazone is lost upon disorganization of the cytoplasmic membrane; presumably reduction is dependent upon correct orientation of drug, enzyme(s) and co-factor(s) in sufficient concentrations upon the membrane. Disorganization of the latter results in denaturation of the enzyme, or separation, or incorrect alignment of the various components.

Annis[6] has shown, however, that cell-free extracts of *Escherichia coli* are capable of reducing nitrofurazone upon addition of diphosphopyridine nucleotide and an oxidizable substrate. His results indicate the possibility that the nitrofurazone reducing enzyme(s) are located in the contents of the cell. However, cell disorganization may have liberated the enzymes from association with the cytoplasmic membrane, and the added materials may be present in relation to the enzyme systems in concentrations completely different from those obtaining in the intact organism. These results do not therefore invalidate the above arguments.

A detailed account of this and related work will be published elsewhere.

We thank Dr. M. R. J. Salton for a culture of *B. megaterium* and Smith, Kline and French Laboratories, Ltd., for a gift of nitrofurazone.

Reversal of Boric Acid Inhibition of Growth in Certain Soil Micro-organisms

An investigation has been made concerning the degree to which various concentrations of boric acid inhibit the growth of three soil micro-organisms and the extent to which this inhibition may be reversed.

Boric acid has been reported to inhibit the growth of *Micrococcus pyogenes* var. *albus*, *Streptococcus* sp. *beta-haemolyticus*, and *Diplococcus pneumoniae* at concentrations of 0·5, 2·0, and 1·0 per cent respectively[1]. Boric acid at a concentration of 0·25 per cent reduced the growth of *Escherichia coli*, and a concentration of 0·5 per cent produced marked bactericidal action[2]. Tyner[3] found no bacterial growth in soil samples grown on plates containing boric acid when the concentration of the acid was 0·18 per cent or higher.

The current study was concerned with determining the lowest concentration of boric acid required to reduce the growth of the organisms under study, the differentiation of boron effect from a *p*H effect, and the feasibility of reversing the effects of boric acid.

Azotobacter chroococcum (A.T.C.C. 4412) and *Rhizobium meliloti* (A.T.C.C. 10312) were grown in media containing extracts of African violet soil plus 2 and 1 per cent mannitol respectively. *Streptomyces* sp. (A.T.C.C. 11238) was grown in Czapek's medium. The addition of increasing amounts of boric acid to the media yielded increasingly acid solutions. In the cases of *A. chroococcum* and *R. meliloti*, a *p*H lower than that of an equivalent solution of pure boric acid was obtained due to the interaction of the boric acid with mannitol.

Reduction in the growth of *R. meliloti* occurred at a boric acid concentration of 0·06 per cent; the medium had a *p*H of 5·2. *A. chroococcum* evidenced reduced growth at a boric acid concentration of 0·12 per cent; the *p*H of this medium was 5·6. In both cases the organisms showed reduced growth in media the acidity of which was such that the reduced growth would have been expected even in the absence of a specific boron effect.

Table 1. GROWTH AT VARIOUS BORON-LEVELS

Boric acid (per cent)	*Rhizobium meliloti* A.T.C.C. 10,312	*Azotobacter chroococcum* A.T.C.C. 4,412	*Streptomyces* sp. A.T.C.C. 11,238

0·04	+++	++	++
0·06	+++	++	+
0·08	+++	++	+
0·12	+++	++	±
0·16	+	++	–
0·32	±	±	–
0·40	±	±	–

Table 2. EFFECT OF MANNITOL ON THE GROWTH OF BORATE-INHIBITED *R. meliloti*

Boric acid (per cent)	Mannitol (per cent)					
	1	2	3	4	6	8
0	+++	+++	+++	+++	+++	+++
0·12	+++	+++	+++			
0·16	+	++	++	++	++	++
0·32	±			++	++	++
0·40	±			++	++	++

In order to delineate the toxic effect of boron from the *p*H effect, the organisms were grown in media adjusted to *p*H 7·0–7·8 after the addition of the requisite amounts of boric acid. Under these conditions considerably larger amounts of boric acid were needed to inhibit the growth of the organisms (Table 1). The growth of *Streptomyces* sp. is reduced at 0·06 per cent, that of *R. meliloti* at 0·16 per cent, and of *A. chroococcum* at 0·32 per cent boric acid.

In an attempt to reverse the boric acid effect on *R. meliloti*, the media was supplemented with increasing amounts of mannitol. The results shown in Table 2 were obtained. Good growth of this organism could be obtained at levels of boric acid which had previously been shown completely to inhibit its growth. However, the experiments do not show whether the observed reversal of inhibition is accomplished through an extracellular sequestering of borate by mannitol or through intracellular competition for the boron.

Roush and Norris found that borate inhibited the action of the enzyme xanthine oxidase[4]. This inhibition is presumably brought about by the complexing of borate with the *cis*-hydroxyl groups on the ribose moiety of the riboflavin coenzyme. The inhibition produced by 0·032 *M* borate was completely reversed by the addition of a slight excess of sorbitol (0·04 *M*). Four times as much glucose on a molar basis, 0·128 *M*, was required to reduce the borate inhibition from approximately 50 to 15 per cent.

In the current studies with *R. meliloti* the inhibition of growth resulting from the addition of 0·026 *M* boric acid could be reversed by 0·11 *M* mannitol, whereas poor growth resulted in the medium containing 0·055 *M* mannitol. Additionally, the inhibition observed when 0·052 *M* boric acid was added was not at all alleviated by the addition of 0·22 *M* glucose.

Recombinations in *Streptomyces rimosus*

UP to the present time, recombinations among Actinomycetes have been obtained only in *Streptomyces coelicolor*[1] and *S. fradiae*[2]. This communication presents some data concerning recombinations in another species of Actinomycetes, namely, *Streptomyces rimosus*, which produces terramycin.

To obtain recombinations, biochemical mutants of two strains of *S. rimosus* (2*a* and 8229) were used. When two biochemical mutants were grown together on a complete medium there appeared tufts of exuberant growth in the zones of contact between colonies of the two types (Fig. 1). These tufts resembled those described by Sermonti and Spada-Sermonti in *S. coelicolor*[1]. When spores from a mixed seven-day culture grown on a complete medium were transferred to the minimal medium, prototrophic colonies arose in some combinations. The appearance of prototrophic colonies was observed in five out of fifteen combinations tested. From other combinations of biochemical mutants no stable prototrophic colonies were obtained[3]. The following three combinations of biochemical mutants were studied more thoroughly: (1) between strain 2*a*–870 requiring histidine and strain 8229–310 requiring valine and isoleucine; (2) between strain 2*a*–870 and strain 8229–1361 requiring threonine; (3) between strain 8229–310 and strain 8229–1361. The frequency of prototrophic colonies from these combinations is presented in Table 1.

Table 1. FREQUENCY OF PROTOTROPHIC COLONIES DERIVED FROM MIXED AND SEPARATE GROWTH OF BIOCHEMICAL MUTANTS

Spores derived from	No. of spores plated on minimal medium	No. of prototrophic colonies	Frequency of prototrophs
2a–870	$3\cdot9 \times 10^7$	0	0
8229–310	$5\cdot2 \times 10^7$	0	0
8229–1361	$3\cdot7 \times 10^7$	0	0
2a–870 + 8229–310	$4\cdot0 \times 10^7$	122	3×10^{-6}
2a–870 + 8229–1361	$6\cdot4 \times 10^6$	391	6×10^{-5}
8229–310 + 8229–1361	$7\cdot2 \times 10^7$	31	4×10^{-7}

In all three combinations of the biochemical mutants there appeared several types of prototrophic colonies differing from each other by their morphological characters and antibacterial activity. Fig. 2 shows the colonies of the parental types and of the three types of prototrophs from the combination 2*a*–870 + 8229–310. As it is evident from the photographs, two types of prototrophs produced well-sporulating colonies in contrast to the both parental types.

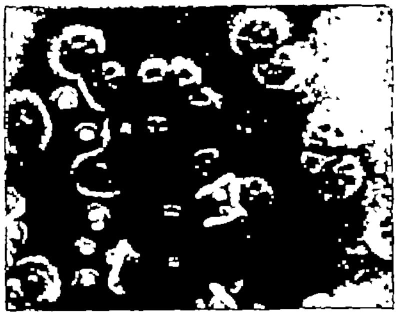

Fig. 1. Tufts between colonies of two biochemical mutants

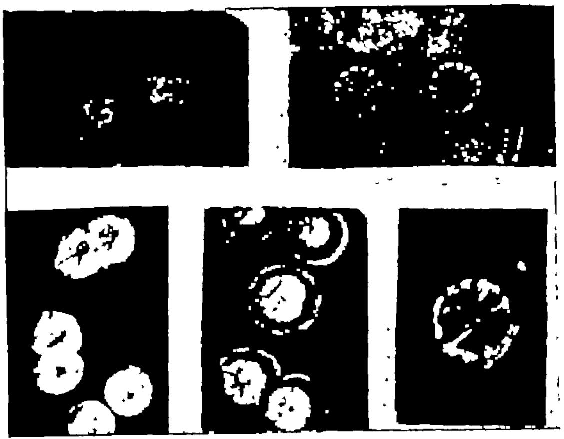

Fig. 2. Parental types (above) and three types of prototrophs (below) from the combination 2a-870 + 8229-310

The comparative antibacterial activity of the biochemical mutants and prototrophs developed from them is presented in Table 2. This table also shows the activity of the original strains 2a and 8229.

Table 2 shows that the activity of almost all prototrophs was much higher than that of their parents. The activity of some types of prototrophs reached, and even exceeded, that of the original strains.

Special experiments were carried out to study the stability of the prototrophic colonies on successive transfers. It was observed that two types of the prototrophs from the combination 8229-310 + 8229-1361 regularly produced auxotrophic segregants in several generations. The frequency of their appearance was 3-4 per cent. Just like one of their ancestors (8229-1361), all auxotrophic segregants required threonine. Auxotrophs similar to the other ancestor (8229-310), that is, auxotrophs requiring valine and isoleucine, were not detected. It should be noted that auxotrophs requiring threonine differed morphologically from the corresponding biochemical mutant. The auxotrophs arising from one type of prototrophs morphologically differed from the auxotrophs arising from the other type.

The results presented indicate a great similarity between the recombination processes in *Streptomyces coelicolor* and *S. rimosus*. In both species the development of prototrophic colonies was not observed in every combination of biochemical mutants. Likewise the development of auxotrophic segregants from the spores of prototrophs was not regular in both species[1,4]. However, there are some differences between these two species. For example, in *Streptomyces coelicolor* all combinations of biochemical mutants tested produced only one type of prototrophic colonies, whereas in *S. rimosus* several types of prototrophic colonies appeared.

Table 2. COMPARATIVE ANTIBACTERIAL ACTIVITY OF THE ORIGINAL STRAINS, THEIR BIOCHEMICAL MUTANTS AND PROTOTROPHS

Strains	Antibacterial activity (units/ml.)

A Haploid Plant of the Potato Variety Katahdin

A PLANT with a somatic chromosome number of 24 was found among an F_1 population of a cross between the tetraploid *Solanum tuberosum* variety Katahdin and the cultivated South American diploid species *Solanum rybinii*. This plant resembles the female parent Katahdin and lacks any of the distinctive characters of the male parent *S. rybinii*. It is therefore presumed to be a haploid plant of Katahdin which arose through parthenogenesis.

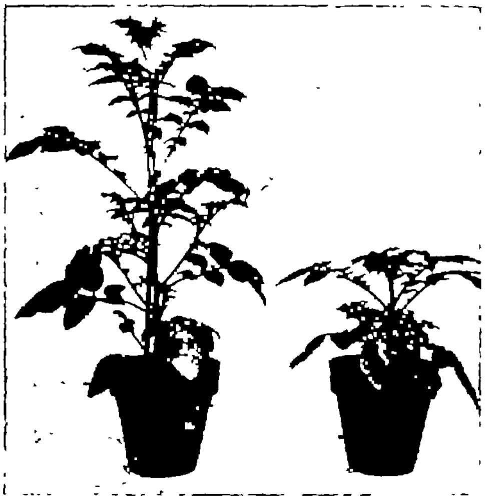

Fig. 1. Plants of haploid (right) and triploid F_1 hybrid

The haploid of Katahdin is a thrifty plant, but its rate of growth is considerably slower than the triploid F_1 *S. tuberosum* × *S. rybinii* hybrids. Much of the marked difference in height between the F_1 hybrid and the haploid is due to the short internodes of the latter (Fig. 1). Mature leaves of the haploid are smaller than comparable leaves of the F_1 plants and of the variety Katahdin (Fig. 2, Table 1). The

Table 1

Plant	Chromosome number (2n)	Mean terminal leaflet width–length (mm.)	Mean stomatal length (μ)
Haploid	24	53-81	31
F_1 hybrid	36	71-99	38
S. tuberosum var. Katahdin	48	84-110	43

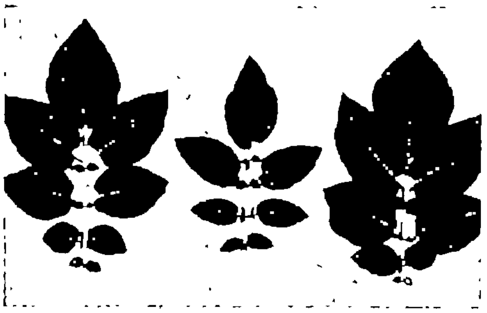

FIG. 2. Mature leaves (left to right) of triploid F_1 hybrid, haploid and Katahdin

stomata of the haploid are smaller than those of Katahdin and of the F_1 hybrids (Table 1).

Haploid plants of the tuber-bearing *Solanum* species have been described previously. Several haploid plants ($2n = 36$) of the late blight-resistant Mexican hexaploid, *S. demissum* ($2n = 72$) have been reported (Bains and Howard[1], Dodds[2] and Hougas unpublished). Ivanovskaja[3] reported a haploid plant ($2n = 24$) of *S. tuberosum* variety Aurora from pollination of the cultivated potato Aurora with pollen of *S. rybinii*. One of the twin seedlings in the progeny of a tetraploid F_1 interspecific hybrid (*S. chaucha* × *S. tuberosum*) was found by Lamm[4] to be a haploid ($2n = 24$). A single germinable seed resulting from the pollination of the Mexican tetraploid *S. polytrichon* with the Mexican tetraploid *S. stoloniferum* produced a haploid plant ($2n = 24$) of *S. polytrichon*[5].

The significance of haploids as tools for experimental research in cytogenetics and genetics as well as for breeding has been recognized in other crops such as corn and cotton[6]. Similar researches with the *Solanum* species would appear equally promising.

The haploid of Katahdin has not flowered yet. Studies of meiosis, pollen fertility and seed set will be reported later.

Leptospira Antibody Production by Bovine Fœtuses

IT is commonly stated that calves are born without γ-globulin and that the bovine fœtus is unable to produce antibodies. The first part of the statement is invalidated by the detection of measurable amounts of γ-globulin in pre-colostral serum of new-born calves[1-3]. The question whether this globulin has been developed by the calf or passively acquired *in utero* was left open by Pierce[3]. Little and Orcutt[4] found *Brucella* agglutinins in pre-colostral serum of a premature *Brucella*-infected calf and in serum of aborted fœtuses from *Brucella*-infected cattle, but expressed no opinion about the origin of these antibodies.

The ability of the bovine fœtus to develop immunologically active γ-globulin is indicated by the following observation.

5 ml. of a cotton-filtered guinea pig liver suspension, containing approximately 2×10^3 guinea pig infective doses of *Leptospira saxkoebing* per ml., were injected into a placentome in each of two laparotomized cows on the 214th day (cow 39) and the 223rd day (cow 41) of pregnancy. In order to prevent maternal leptospirosis, the dams had been passively immunized against the infecting strain by the intravenous injection of bovine immune serum 24 hr. before the inoculation.

The dams were only slightly affected by the operation. Cow 39 gave birth to a calf on the 261st day of pregnancy (that is, 47 days after the inoculation) and cow 41 to twin calves on the 264th day of pregnancy (that is, 41 days after the inoculation). The membranes were expelled in both cases within 8 hr. after birth; the cotyledons appeared normal except for three uniformly necrotic cotyledons in the membranes of calf 39.

The three calves were smaller and less vigorous than normal calves, but developed normally until killed when nine (calf 39) and seven (calves 41 *A* and *B*) days old. Necropsy of the calves showed no gross lesions, but histological examination revealed small interstitial cell infiltrations in the renal cortex and in the periportal tissue of all three calves. The infiltrating cells were predominantly histiocytes, with some eosinophilic leucocytes and cells resembling lymphocytes. These findings could be explained as results of a fœtal leptospirosis. However, leptospiræ could not be demonstrated in the kidneys by impregnation *ad modum* Levaditi or by cultivation in Korthof's medium.

The results of agglutinin–lysin titrations against *L. saxkoebing* are given in Table 1. As the titres of pre-colostral sera from the calves greatly exceeded those of the dams at any time during the experimental period, it is highly improbable that the antibodies found in the unfed calves were transferred from the dams. Moreover, the steadily rising titres of the calves suggest that already at birth the calves were in a state of antibody production.

Electrophoresis on paper (kindly performed by A. Birch-Andersen, Statens Seruminstitut, Copenhagen) disclosed the presence of small amounts of γ-globulin in all three pre-colostral calf sera. Agglutinin–lysin titration of eluates of the various protein fractions

Table 1 AGGLUTININ–LYSIN TITRES AGAINST *L. saxkoebing* OF SERA FROM THE EXPERIMENTAL COWS AND THEIR CALVES AND OF COLOSTRAL WHEY

Fractionation of Human Erythrocytes on the Basis of their Age

Human erythrocytes have a life-span in the circulation of approximately 120 days[1]. They are incapable of cell division and consequently leave no progeny. These characteristics make them attractive subjects for the study of biochemical changes incident to normal maturation and senescence, assuming it were possible to separate them into groups of old, middle-aged, and young cells without the use of artificial hæmatopoietic stimuli[2]. This communication presents a method of red cell fractionation which complies with these criteria.

$^{59}FeSO_4$ was administered intravenously to four normal human subjects. At intervals during the succeeding 140 days, venous blood, drawn into heparin, was subjected to so-called serial osmotic hæmolysis as follows. A 2·5-ml. aliquot of fresh erythrocytes was washed three times in 0·85 per cent sodium chloride and then exposed to 5 ml. of unbuffered saline, varying in concentration from 0·41–0·38 per cent, which was previously determined to produce about 2 per cent hæmolysis. After centrifugation the supernatant hæmolysate was removed and the residual cells treated with saline of lower concentration. This process was repeated 8–12 times, until hæmolysis of the initial aliquot of blood was complete. After the hæmolysates were cleared by centrifugation, hæmoglobin concentrations were determined by the cyan–methæmoglobin method[3], and the radioactivity assays were performed. From such data and the known volume of each hæmolysate the percentage of cells represented by individual fractions and the corresponding specific radioactivity were calculated.

This procedure differs from the conventional method of osmotic hæmolysis[4] in that all fractions are derived from a single aliquot of blood, and cumulative effects resulting from superimposition of one fraction on another are eliminated.

Fig. 1*A* represents specific radioactivity versus fragility data obtained in a typical subject 3 days after intravenous administration of iron-59, at a time when only young cells are tagged[5]. Ostensibly there are two varieties of young cells, and they are found at extreme and opposite ends of the fragility scale. In subsequent investigations we assumed that the initial small peak represented an artefact, and attempted to demonstrate this. It was felt that *in vitro* exposure of the cells during the interval between venepuncture and recovery of the first fraction or the unique proximity of white cells to the younger red cells residing at the top of the centrifuged column of blood[6] might traumatize some of the young erythrocytes. However, neither preincubation at room temperature or at 37° C. for 1–4 hr., nor removal of at least 80 per cent of the leucocytes altered the pattern depicted in Fig. 1*A*. In addition, leakage of non-hæmoglobin iron as a possible source of radioactivity in the first fraction was eliminated by the observation that washing with either isotonic or hypotonic saline did not result in any loss of activity from the cells. It should be noted that these fractionations were carried out at room temperature (21–23° C.). Fractionations performed at 37° C. produced essentially similar results, whereas no consistent pattern could be obtained at 4° C.

In the light of the failure to ascribe this double-peaked pattern to a methodological artefact, our present interpretation is that normal blood may contain two populations of young red cells which are separable on the basis of the parameter here studied, namely, serial osmotic fragility. A short-lived population of red cells in normal individuals has been postulated[7,8]. However, we have no information relating to the life-spans of the two populations described above.

It has been estimated that 80–98 per cent of the cells three days old or younger are represented in the terminal peak. It has also been calculated, on the basis of ten experiments, that more than 50 per cent of all the cells represented in a terminal 5 per cent fraction are derived from such young cells. Similarly, it has been estimated that 1·5–10 per cent of the cells three days old or younger are represented in the initial peak and that only about 2·5 per cent of all the cells in an initial 2 per cent fraction are derived from such young cells. These values are only approximations since they are based on the assumption that the distribution of counts per tagged cell is similar in both peaks.

This pattern gradually gives rise to the pattern depicted in Fig. 1*B*, which is representative of specific radioactivity versus fragility data obtained about two months after the administration of the radioactive isotope. It will be noted that the terminal fraction has a specific radioactivity only about half as great as the large middle fraction. This is consistent with the earlier calculation that about 50 per cent of the cells in a terminal 5 per cent fraction are derived from cells ranging in age from 1 to 3 days, the tracer content of these cells now being very low. In addition, Fig. 1*B* demonstrates that the initial fractions are also impoverished with respect to middle-aged cells. In so far as it has been shown that only a very few per cent of the erythrocytes herein represented are derived from young cells, it follows that this fraction is enriched with respect to cells older than two months.

By the end of the third month the specific activities of the initial fractions increase while those of the terminal fractions remain low.

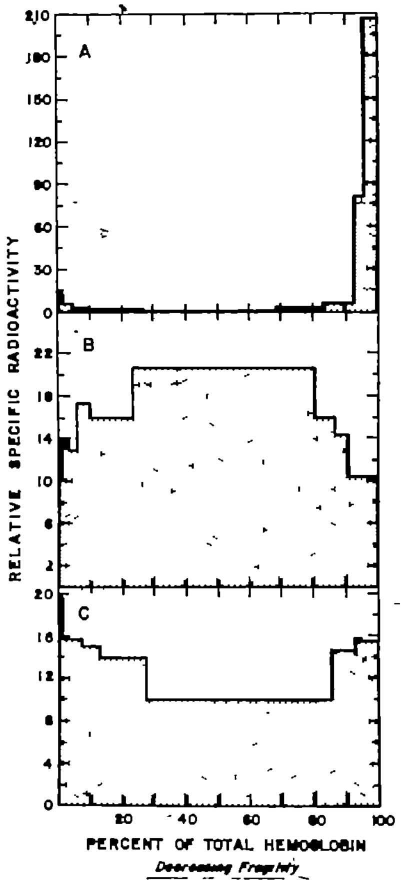

Fig. 1. Serial osmotic hæmolysis at room temperature (21–23° C.) *A*, 3 days; *B*, 57 days; *C*, 115 days after the intravenous administration of iron-59. Relative specific activity is defined as counts per min. per unit amount of hæmoglobin compared with a number assigned to represent the specific radioactivity of the least-active fraction

A new pattern evolves toward the end of the fourth month as illustrated by a typical curve obtained 115 days after the administration of iron-59 (Fig. 1*C*). It is of interest to contrast this pattern with the one depicted in Fig. 1*A*. Thus, whereas within the first few days following labelling the terminal peak was twenty times greater, on the average, than the initial peak, now, in this late stage of the experiment the initial peak is as great as or greater than the terminal one. These results indicate that cells older than 100 days of age tend to be concentrated in the most fragile fraction. The terminal peak is presumably a result of the re-utilization of iron-59. Confirmation of this interpretation was obtained by fractionating red cells obtained from a subject who, 99 days earlier, had received a transfusion of normal chromium-51 labelled blood. Since chromium-51 is not re-utilized by erythrocytes[9], all cells containing tracer at the time of fractionation were older than 99 days. Data obtained revealed a sharp specific radioactivity peak in the most fragile fraction with rapid decrease in specific radioactivity thereafter. Recently, results have been reported relating to the centrifugal separation of human erythrocytes as a function of cell age[10]. The authors' conclusion, that the bottom layer contains the cells of oldest mean cell age, does not appear entirely compatible with the chronological appearance of maximal specific radioactivity in this layer.

The present results demonstrate that by the use of serial osmotic hæmolysis human erythrocytes can be resolved, to a significant extent, into fractions enriched with respect to old, middle-aged, or young cells. In addition, evidence has been adduced which suggests that normal blood may contain two populations of young red cells.

Chromsoome Number in the Sugar-Beet Nematode *Heterodera schachtii* Schmidt

Mulvey[1] made a preliminary study of oogenesis in a species of *Heterodera* (probably *H. schachtii* var. *trifolii* Goffart, 1932) from the roots of hairy vetch (*Vicia villosa* Roth), this being the first record of oogenesis in a cyst-forming nematode. This is a report on the chromosome number and arrangement during meiosis of the sugar-beet nematode, *H. schachtii* Schmidt, 1871.

As the males are numerous, this nematode is evidently bisexual and has normal oogenesis, that is, two polar bodies are produced and the diploid number of chromosomes is reduced during maturation. Living white gravid females (both monocyst and mass cultures) taken from the roots of rutabaga, cabbage and red beet plants were prepared for study by the squash technique[2]. The material was fixed in an iron–mordant fixative[3] to which a few drops of propionic–orcein stain was added. Squash preparations were then prepared in the normal manner. By

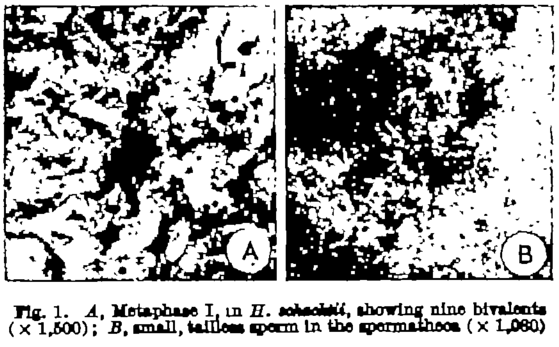

Fig. 1. *A*, Metaphase I, in *H. schachtii*, showing nine bivalents (× 1,500); *B*, small, tailless sperm in the spermatheca (× 1,060)

this method the chromosomes were stained intensely and were easily photographed.

Nine bivalents are regularly formed at meiosis (Fig. 1*A*). The chromosomes are very small, and at metaphase I of meiosis the largest bivalent is about 1 micron long. Mitotic divisions in the anterior part of the ovary show discrete chromosomes which are extremely small and difficult to count.

The well-developed spermathecae are usually amply supplied with small, tailless sperm (Fig. 1*B*).

The many oocytes examined showed few did not contain sperm, but only one sperm was observed in each oocyte.

Chromosome Number in the Ferret (*Putorius furo*)

The testes of two male ferrets were teased in distilled water, where they remained for about 10 min., and then the pieces were put into aceto-orcein and temporary slides were made by the usual squash method.

The testicular materials under observation provided numerous spermatogonial cells undergoing division. Chromosome counts were made from those cells only that seemed to be intact and had the chromosomes well spread. From the mitotic metaphase plates it was clearly seen that the diploid chromosome number was 40 (Fig. 1 (1)).

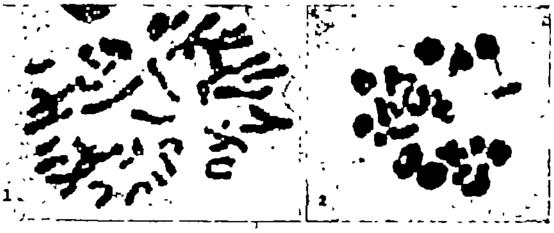

Fig. 1. Chromosomes of the ferret (× 1,350): (1) mitotic metaphase with 40 chromosomes; (2) first meiotic metaphase with 20 bivalents

The primary spermatocyte divisions contained 20 bivalent chromosomes (Fig. 1 (2)). Thus the first meiotic metaphase showed 19 ordinary bivalents and one element with a heteromorphic structure which was thought to be the *XY*-complex.

That the haploid chromosome number was 20, was also confirmed from counts of second meiotic metaphase chromosomes.

The results obtained in this investigation indicate that the diploid chromosome number in the male ferret (*Putorius furo*) is 40 and not 34 as previously reported by Koller[1], who made his cytological observations on sectioned testes material.

Paravortex scrobiculariae (Graff) in Great Britain

The genus *Paravortex* was established by Wahl[1] for a vorticoid Rhabdocoele living in the intestine of the lamellibranch *Scrobicularia plana*. Three species are now recognized with some certainty, all associated with bivalve molluscs. *Paravortex* (= *Graffilla*) *gemellipara* (Linton) lives as a commensal in the mantle cavity of the American ribbed mussel, *Modiolus demissus*[2,3]; *P. cardii* Hallez in the stomach of the common cockle *Cardium edule*[4] and *P. scrobiculariae* (Graff) in the intestine, and occasionally also in the stomach, of *Scrobicularia plana*. All three species are viviparous, the eggs developing in thin-walled capsules embedded in the mesenchyme of the mother. The embryos escape by passing across the maternal tissues, and, after a short free-living period, reinfect another, or perhaps the same, host.

The two European species were distinguished morphologically by Hallez[5]. *P. cardii* is yellow-white in colour, attains a maximum length of 1 mm., the genital pore is situated one-quarter of the body-length from the anterior end, the ovaries are corniculate, and the embryos on hatching have a length of 0·088 mm. The adult lives in the stomach of *Cardium*, and only young stages are found in the intestine, attaining a length of 0·35–0·40 mm. before being discharged through the exhalant siphon. *P. scrobiculariae* has a reddish tint, can reach a length of 1·2 mm., the genital pore is at the end of the second fifth of the body, the ovaries are disposed longitudinally, and the embryos on hatching measure 0·08 mm. The adult lives in the intestine, as well as in the stomach, of the host.

P. cardii has frequently been described from cockles in Great Britain (for review, see Atkins[6]), but the species from *Scrobicularia* has not hitherto been recorded here. Examination of *Scrobicularia* from Whitstable in Kent recently revealed an occurrence of this parasitic Rhabdocoele. Altogether some forty animals were examined and eight parasites recovered from three of them. All the specimens were found in the intestine. They were red in colour, body-length 0·53–1·15 mm., with longitudinally placed ovaries. The genital pore was situated between 0·35 and 0·39 of the total body-length from the anterior end. All the specimens included capsules, none of which contained more than two eggs, and one specimen contained at least 54 embryos with well-developed eyes, many of them already free in the mesenchyme of the mother (Fig. 1). The largest of these embryos was 0·077 mm. long. These characters clearly identify the parasite as *Paravortex scrobiculariae* (Graff).

The presence in the intestine of a specimen in full production of advanced embryos illustrates a difference between the life-cycles of the two European

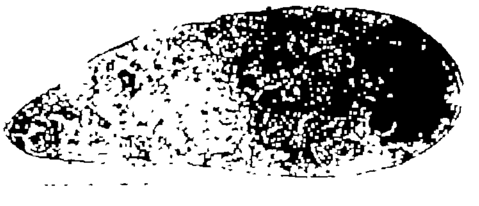

Fig. 1. *Paravortex scrobiculariae*. Adult containing embryos. (× 55)

species. Comparable adult stages of *P. cardii* only occur in the stomach of *Cardium*, and, although development of capsules may commence in the young forms as they pass along the intestine, these intestinal forms are essentially the dispersive and infective stages in the life-history. As Hallez observes[4], "une fois installés dans l'estomac de leur hôte, les parasites y achèvent leur vie sans émigrer de nouveau". The adult shown in Fig. 1 was recovered from the posterior end of the intestine where it traverses the pericardium. The parasite was wedged between two of the compacted, cylindrical, fæcal pellets of the host, and it is difficult to imagine how it would be able to maintain its position in the intestine, particularly in view of the extensive and vigorous ciliation of this part of the gut. In view of the large number of advanced embryos present in this individual, these considerations lend some support to the view put forward by Wahl, but disputed by Hallez, that simultaneous liberation of the embryos involves degeneration and death of the mother in this species, as has been established for *P. gemellipara*.

The number of *Scrobicularia* found to be harbouring the parasite at Whitstable was not great when compared with the 72 per cent infection at Naples and 55 per cent at Trieste found by Wahl, and the 55 per cent found by Hallez at Étaples. The American species was found to be rare in mussels from certain localities, with some evidence of a seasonal periodicity in numbers[7], and investigation of other populations of *Scrobicularia* in Britain may well reveal further and more intensive occurrences of this interesting parasite.

European Foul Brood: a Disease of the Larval Honeybee (*Apis mellifera* L.) caused by a Combination of *Streptococcus pluton* (*Bacillus pluton* White) and *Bacterium eurydice* White

RESULTS of preliminary experiments[1] have shown that European foul brood disease of the larval honeybee can be caused in bee colonies by spraying their brood with suspensions of *Streptococcus pluton* (*Bacillus pluton* White) and *Bacterium eurydice* White if the two organisms are grown together in mixed anaerobic culture; fifth subcultures of a mixed culture were usually virulent, although virulence diminished rapidly after further sub-cultivation. It was not possible to cause the disease by simultaneous inoculation with separate cultures of the two organisms. As there is a tendency for colonies of *S. pluton* and *B. eurydice* to grow within, or upon, each other on agar in anaerobic cultures, the separate cultures of each organism were subcultured five times to try to ensure the exclusion of the other. The results of these experiments showed that virulence was maintained by one or both organisms in mixed culture, but the possibility remained that only one of the organisms was pathogenic; its virulence may have been maintained by the growth of the other which may, *in vivo*, be a secondary invader of the diseased larva.

It was found later[2] that anaerobic growth of *B. eurydice* was considerably improved by the addition of fructose + glucose (or honey) to the culture medium; either sugar alone supported only feeble anaerobic growth. *B. eurydice* produced much acid when grown with the two sugars; this prevented the growth of *S. pluton* when a mixed culture of *S. pluton* and *B. eurydice* was subcultivated into a medium containing honey. Thus, the use of a honey-medium made it easier to ensure the separation of the two organisms in early subculture, and an experiment was made to test the pathogenicity of such cultures.

On May 5, 1957, a loop-full of the mid-gut contents of a larva with European foul brood disease was streaked on a plate of agar of the following constitution: 10 gm. glucose; 10 gm. yeast extract ('Difco'); 13·6 gm. potassium dihydrogen phosphate; 20 gm. agar; 1,000 ml. water; the *p*H was adjusted to 6·6 with potash and the medium was autoclaved for 20 min. at 10 lb./in.^{2} (116° C.). The plate was incubated at 35° in a McIntosh and Fildes jar which contained hydrogen 95 per cent (v/v) + 5 per cent (v/v) carbon dioxide. Colonies of *B. eurydice* were visible after 24 hr. and colonies of *S. pluton* after 2½ days. Single, well-isolated colonies of each organism were subcultured, each on a plate of the medium described above + 1·0 per cent (v/v) honey. *B. eurydice* grew vigorously after 24 hr., and a well-isolated colony was subcultivated into 150 ml. of broth of the honey-medium which became very turbid after 24 hr. Colonies of *S. pluton* were visible on the other plate after 2½ days; there were no visible colonies of *B. eurydice*, and a well-isolated colony of *S. pluton* was subcultivated into 150 ml. of broth of honey-medium. This broth was slightly turbid after 2 days; growth was heavy after 3 days. The bacteria were centrifuged from the broths and each deposit was suspended in 10 ml. of 30 per cent (w/v) sucrose syrup. A third suspension was made of a mixture of one-third of each of the two suspensions.

On May 17, 1957, each suspension was sprayed over the combs of one of three small bee colonies. The bee colonies were taken from an apiary, the colonies in which had never had European foul brood and showed no sign of disease during or after these experiments. The inoculated colonies were equal in size and were placed on separate sites, well out of range of drifting bees from each other or from any other bee colonies.

After 11 days, a few larvæ, dead or dying with European foul brood disease, were seen in the colony which had been sprayed with the mixed suspension containing *S. pluton* + *B. eurydice*; 6 days later, the disease was general. *S. pluton* and *B. eurydice* were re-isolated from the diseased larvæ. There was never any sign of the disease in the two colonies which had been inoculated with the separate suspensions of bacteria. These two bee colonies were again similarly inoculated with new isolates of the respective organisms, but no sign of disease appeared.

It seems certain that European foul brood of honeybees is caused by simultaneous infection with the two bacteria *S. pluton* and *B. eurydice*. When pure cultures of *S. pluton* have been sprayed into healthy bee colonies, the organism has appeared to grow in coccal form in the mid-guts of the larvæ for a day or two afterwards; then, for a further day or so, diminishing numbers of thick rod-like bacteria only were found. These forms appeared similar to the aerobic form of *S. pluton* which can be cultivated *in vitro*[1]. The lumen of the mid-gut of the larval honeybee may not, therefore, be anaerobic. In a normal infection, *B. eurydice* may reduce oxygen tension enough to allow *S. pluton* to develop in coccal form as when a mixed culture of the organisms is grown with air in a closed bottle[2].

Occurrence of the Muskrat in Hu Ma District, North-eastern China

The muskrat, *Ondatra zibethica* L., has been introduced into many parts of Europe since 1905 and into the U.S.S.R. in 1927.

Its occurrence in the Amur region or Hehlung Kiang, on the northern part of Manchuria or north-eastern China, was first reported by Shaw and Chu[1], based on two living specimens and three dead ones collected by Mr. Tsong of the Animal Products Co. in early summer of 1954. Later, in the spring of 1955, Mr. C. Chang made a special trip to Hu Ma district, where he collected twenty-one specimens. Still later, Mr. T. H. Lo obtained a few more specimens and made some observations in the same region in the summer of 1956 [2].

Hu Ma District lies on the southern bank of the Amur River. Its climate as a whole is rather cold. Winter is long, and air temperature may fall to − 46° or even − 49° C. Summer seems to be rather short and not very hot; the warmest weather in June, July and August being 35° C.

According to local information, individual muskrats have been observed in Hu Ma District for more than ten years. Due to the severe and long winter in this region, the shortness of growing season, and the lack of proper protection, the population of the animal increases rather slowly.

The coloration of the muskrat shows some variation. The head, neck and back of Hu Ma specimens are darker than the original stock. The size of both sexes, however, is smaller, largest specimens weighing only 2,200 gm.

The animal is chiefly nocturnal, but is also active in daytime, and can be seen in bright sunlight. Nest and tunnels are excavated underground and rather complex in nature. There is only one entrance to the nest. The largest colony so far observed contained fourteen individuals in a single burrow.

Like those which inhabit other parts of the world, the males are larger than the females. It is difficult to determine the sex, for it is necessary to examine the nipples (three or four pairs) or external genitalia. The animal breeds twice a year. The first litter appears from the end of May to the beginning of June and the second litter between July and August. The animal does not hibernate in winter, and is chiefly herbivorous. Aquatic plants are very rare during the coldest months, so the animal then lives mainly on fishes or other animals.

Elephant Seals on the Antarctic Continent

The elephant seal (*Mirounga leonina* (L.)) has not previously been recorded in any numbers away from its known breeding grounds. These are antarctic and subantarctic islands from the South Shetlands to Macquarie and the Campbell Islands, extending north to Tierra del Fuego and the Falklands. The southernmost known breeding ground is King George Island in the South Shetlands, in about 62° S. South of this, stragglers are fairly common off north Graham Land in 64°–65° S.[1,2], and single individuals have been recorded in summer from Terre Adélie (66° 45′ S.)[3], Cape Denison (67° 0′ S.)[4], Scott Island (67° 24′ S.)[5], Cape Hallett (72° 25′ S.)[6] and McMurdo Sound (77° 40′ S.)[7]. A young male was seen on March 24, 1954, at Mawson (67° 36′ S.). There are also a few records of sightings in the pack-ice.

In February, 1957, a regular summer hauling-out ground for several hundred elephant seals was discovered in the Vestfold Hills, Australian Antarctic Territory, 68° 35′ S., 77° 58′ E.

This area contains about 300 square miles of exposed rock, ice-free in summer, with beaches suitable for these seals. During the establishment of the Australian National Antarctic Research Expeditions' Station 'Davis', a number of moulting elephant seals were found in the neighbourhood. Seven were seen on February 1, 37 on February 8 and 77 on February 19. Later, Robert Dingle, commander of the station, reported counts of more than 400 on March 6, more than 250 on April 2 and 17 on April 28. These counts were made on four beaches with a total length of about 1,800 ft. One female was seen in February but all the rest were males. Bachelor bulls were in the majority, but there were a number that could be classed as mature harem bulls; adolescents 2–4 yr. old made up 5 per cent of the total on March 6 and 25 per cent on April 2. Skulls, teeth and carcasses on the beach showed that it must have been visited regularly for a number of years. By the end of April the last seals to leave had to cross 5 miles of fast ice to reach open water.

There is no difference in date of moulting between these seals and more northerly populations. Although nothing is yet known of the behaviour of the sea-ice at the Vestfold Hills in spring, it is extremely unlikely that the beaches are ice-free in time for the breeding season (September–November). Even if the shores were ice-free, it is unlikely that the elephant seals would penetrate the wide belt of pack-ice farther north. It is much more probable that a small part of the large population breeding at Kerguelen and Heard Island goes south in summer. Since branded elephant seals from Heard Island have twice been reported at Marion Island, a distance of 1,614 statute miles, the 1,082 miles from Heard to the Vestfold Hills is well within their powers. The situation may best be compared with that at the South Orkneys[5], where the breeding population is very small but the summer population is about 10,000, and reflects a wide dispersal of elephant seals over suitable feeding grounds.

The Freshwater Eel *Anguilla obscura* Gunther, 1871, in Southern Africa

On August 8 fifteen eels were collected in the Mgqakwebe River (27° 22′ E., 32° 50′ S.), a tributary of the Buffalo River, Cape Province. One specimen, a short-fin species 35·5 cm. in length and very dark in colour, differed in appearance from any of this group previously found. A subsequent detailed examination has shown this to be without doubt *Anguilla obscura* Gunther, 1871, a Pacific species not previously reported west of New Guinea and a notable discovery on the African continent.

In his revision of the genus *Anguilla* Shaw, Ege[1] examined Gunther's type of *obscura*, and detailed specifications are available for identification of this species. The characteristics of this specimen from the Buffalo River system have been found to fall within the range of those given for *Anguilla obscura* in every detail. The following critical evaluations were observed in the specimen now described: (*a*) length of intermaxillary-vomerine band of teeth, 73 per cent of the distance from the front margin of that band to the posterior end of the right maxillary band; (*b*) the distance between verticals through the anus and the origin of the dorsal fin, 2·4 per cent of the total length; (*c*) total number of vertebræ = 103. The gonads were not developed, and the sex could not be determined.

Whether this specimen of *Anguilla obscura* in the Buffalo River system is a stray or not can only be shown by future investigations. That in its larval life and metamorphosis it may have endured a most extensive migration is of far-reaching significance.

It has been shown that Indo-Pacific freshwater eels have several, presumably well-separated spawning areas[2], all of which are close to land, though only a few have been positively located. Larvæ of *Anguilla bicolor bicolor* McClelland and of *Anguilla mossambica* Peters, have definitely been found between the northern tip of Madagascar and the African mainland[2]. Elvers of the former, 5·0–6·0 cm. in length, have been collected near Dar-es-Salaam[3], and elvers of the latter, as well as those of *Anguilla marmorata* Quoy and Gaimard, from the rivers of Madagascar[1]. In consequence, for these African eels an area east of Madagascar has been suggested as a spawning ground. In the case of *Anguilla marmorata*, which is dominantly western Pacific in distribution, we can expect to find other spawning areas nearer its major distribution area.

In this connexion it is probably significant that young eels of all species migrating up the Buffalo River are variable in size, ranging from 10 to 22 cm. in length[4], an unusual feature if they belong to a single age-group. No specimens of migrating young eels of this type from the Buffalo River that I have examined are fully pigmented; on Strubberg's specification[5] they are elvers in the last stages of metamorphosis, which means that they can have been in fresh water only a very short time. The range in size can therefore not be explained by sojourn in fresh water, but more likely indicates an unusually long period, anything from 2 to 5 years, at sea—much longer than would be required for those elvers to travel from the vicinity of Madagascar to southern Africa. It may well be that a number of the elvers found migrating up the Buffalo River do not come from the same spawning ground as those reaching Madagascar, but from one possibly much more distant, which they may well share with other species such as *marmorata* and *obscura*.

Maintenance *in vitro* of *Haplometra cylindracea*

During the past two years, attempts have been made in this laboratory to keep alive *in vitro* sterile trematodes of the species *Haplometra cylindracea* (Zeder, 1800) obtained by aseptic dissection from the lungs of frogs (*Rana temporaria*). Of the 338 frogs dissected to date, 194 were uninfected with this trematode and the remaining 144 frogs provided a total of 576 living flukes. One remarkable frog had 23 flukes in the left lung and 17 in the right lung; but the majority of infected frogs had either two or three flukes in each lung.

In previous work of this kind with *Fasciola hepatica* it was shown[1,2] that Hédon–Fleig is a valuable saline to use. In the present work it was used once more; but sodium dihydrogen phosphate was substituted for di-sodium hydrogen phosphate, with consequent alteration of the *p*H range from 8·4–8·8 to 8·2–8·4. In addition, a frog Ringer's solution with the following composition and *p*H range was used: sodium chloride 6·5 gm., potassium chloride 0·25 gm., calcium chloride 0·3 gm., sodium bicarbonate 1·2 gm. and distilled water 1,000 c.c.; *p*H 8·1–8·3. Both solutions were filtered as in previous work and both were used either with or without additions of D-glucose (0·5 per cent). *Haplometra cylindracea* continued to live in a fairly active condition in these solutions when kept at 20° C. for the periods specified as follows:

	Duration of culture period (days)	
	Ranges	Means
Hédon–Fleig − glucose	48–105	69
Hédon–Fleig + glucose	60–82	71
Ringer − glucose	50–88	68
Ringer + glucose	54–84	64

Thus, *H. cylindracea* remains alive under these simple conditions of culture for much longer periods than does *F. hepatica*, partly no doubt because of the lower temperature of incubation but also because of its smaller size. There seems to be no significant difference in periods of survival in Hédon–Fleig and Ringer's solutions with or without additions of glucose, whereas *Fasciola* will not continue to live for more than about 48 hr. in the absence of glucose, while in the presence of glucose it has been found to live under these conditions for as long as 34 days. In a sterile medium somewhat enriched with nutrients ('Bacto' beef extract 0·3 per cent, sodium chloride 0·5 per cent, 'Bacto' tryptose 1·0 per cent and D-glucose 0·5 per cent) and having a *p*H range of 7·2–7·4, twelve separately treated *Haplometra* continued to live for 57–110 days, with a mean period of 88 days. In all these experiments, as in those with *Fasciola*, histological examination of the fluke revealed abnormalities of spermatogenesis, but in *Haplometra* these first appeared much later and only after about five days of culture.

After dissecting out the compact testes of *Haplometra* it was easy to make permanent fixed and stained smears showing stages of spermatogenesis, and examination of these revealed some variability in the rate of meiotic division in the primary spermatocyte stage. The mean rate is fairly constant *in vivo* at about 24 divisions per 1,000 spermatocytes examined at random, and this falls only slightly to about 14 per 1,000 after 24 hr. of culture in dextrose broth, but it falls to zero in the Ringer's solution without glucose and to 4 per 1,000 in this saline with added glucose. An initial fall to 14 per 1,000 is seen after 4 hr. of culture in all the solutions employed, so that in dextrose broth the meiotic division-rate does not fall appreciably after 4 hr. for a further 20 hr., and there is some foundation for the statement that it does not fall below this figure for periods up to five days.

Both flukes freshly removed from their hosts and flukes which had been maintained in the Ringer's solutions with or without glucose and in dextrose broth were examined for glycogen deposits after freeze-drying. In fresh flukes glycogen is stored in the muscles and in the cells of the parenchyma. Flukes cultured in Ringer's solution plus glucose and in dextrose broth showed heavy deposits of glycogen in the muscles and only slightly reduced deposits in the parenchyma, but flukes cultured in the Ringer's solution without glucose showed practically no glycogen in the parenchyma, though deposits were still present in the muscles. Quantitative studies based on the photometric estimation of glucose by Nelson's method[3] showed clearly that glucose is abstracted from the medium by the flukes and that in Ringer's solution plus glucose and in dextrose broth the glycogen deposits are maintained at the *in vivo* level of 1·5 per cent wet weight for periods up to three weeks, but that in Ringer's solution without glucose the gross deposits of glycogen are substantially reduced to a mean of 0·8 per cent wet weight after one week. However, Warburg determinations show that the rate of respiration of flukes maintained in Ringer's solution plus glucose falls from a mean of 4·8 µl./mgm. dry weight per hr. at 25° C. to about one-half of this value after about two weeks.

It appears that *H. cylindracea* depends on aerobic respiration to a greater extent than do any other helminths so far studied[4]. It dies within 4 hr. under anaerobic conditions, but after shorter periods of anaerobiosis the oxygen debt incurred is completely repaid when the medium is placed in equilibrium with atmospheric oxygen. Experiments are now proceeding to determine the amount of increase in glucose uptake from solutions and to estimate lactic acid production by worms placed under anaerobic conditions.

Note added in proof: Recent estimates indicate that lactic acid production during a short period of anaerobiosis (2 hr.) is increased threefold.

Colonial Differentiation between *Escherichia coli* B and *Escherichia coli* B/r

A great deal of radiobiological research has been carried out on *Escherichia coli*, strain B, and its radiation resistant counterpart, *Escherichia coli*, strain B/r[1]. Aside from the fact that *E. coli* B/r demonstrates increased resistance to various physical and chemical agents[1–4] when it is compared to the more sensitive parental type, there is little else to distinguish one strain from the other.

It was recently noticed in our laboratory that *E. coli* B and *E. coli* B/r exhibited an unmistakable difference in colonial morphology when either strain was plated on the surface of A–C agar[4], a medium commonly used in our laboratory and consisting of 1·0 per cent N–Z–Case (Sheffield), 1·0 per cent yeast extract ('Difco'), 0·2 per cent potassium hydrogen phosphate, 0·1 per cent glucose and 1·5 per cent agar. On the surface of this medium the colonies of the B/r strain appear with a smooth (S) outer edge, while the B strain takes on the classically rough (R) appearance with a highly serrated outer edge.

The experimental protocol in its entirety entails growing cultures of *E. coli* B and B/r for 19 hr. at 37° C. in test tubes containing 10 ml. of liquid medium that is identical in nutrient composition to the solid medium employed in the plating procedure. The cells are centrifuged, washed twice in 10 ml. aliquots of physiological saline and finally resuspended in 10 ml. of saline. An appropriate dilution of this cell suspension is made through a series of saline dilution blanks and the cells are plated on the surface of the solid media. (These agar plates are poured and dried at 37° C., 48 hr. prior to use.) After an incubation period of 24 hr. at 37° C., an examination of the colonies on the plate reveals the characteristic S–R differentiation.

Attempts were made to observe this difference among colonies of the two strains that had been cultured on media normally associated with these organisms; this phenomenon could not be demonstrated with nutrient agar ('Difco') or the M-9 medium of Anderson[6].

Since capsular formation is very often related to colonial morphology, the significance of these data would seem to imply that the radiation resistance of *E. coli* B/r may very well be related to a capsular property of this organism.

Sexual Dimorphism in Labiatae

In a recent communication, Baker[1] directed attention to the difference in size of pistillate and hermaphrodite flowers in gynodioecious and gynomonoecious plants and suggested that the hormonal control of sex-expression might be connected with the level of auxin activity in the developing flower bud. In the course of genetical studies of gynodioecy in members of the Labiatae, I have made some observations on the origin of this size difference in the case of *Glechoma hederacea* L.

Some individuals of this species produce female flowers only; others are gynomonoecious, the proportion of female flowers to hermaphrodite varying with the stock and also with the season. The female flowers on predominantly hermaphrodite plants are smaller than the hermaphrodite flowers and are equal in size to those on purely female individuals. Occasional flowers are found which have one, two or three aborted anthers and these are intermediate in size between the female and the complete hermaphrodite flowers.

Table 1. EFFECT OF REMOVAL OF ANTHERS FROM HERMAPHRODITE FLOWER BUDS ON THE LENGTHS OF THE MATURE COROLLAS

No. of anthers removed	0	1	2	3	4	Natural female
No. of flowers measured	10	10	25	9	8	3
Mean length of mature corollas in mm.	16·5	15·6	14·3	13·2	11·8	11·3

Artificial emasculation of hermaphrodite flowers in bud reduces the size of the corollas, in proportion to the number of anthers removed. When all four anthers are removed, the corolla does not grow beyond the size of the naturally occurring female flowers (Table 1). An associated effect is that in emasculated, as in natural female, flowers the stigma opens immediately after the opening of the corolla, whereas in complete hermaphrodite flowers it remains closed until after anthesis.

It seems reasonable to suppose that the growth of the corolla is influenced by a hormone produced in the anthers, but I have not yet succeeded in replacing the anthers effectively to prove this. The application to emasculated hermaphrodite flower buds of β-indolylacetic acid in lanolin at a range of concentrations 1,000–10 p.p.m. did not stimulate the growth of the corolla. Strong inhibition of corolla growth occurred when 1,000 p.p.m. of β-indolylacetic acid were used and some inhibition was apparent with 500 p.p.m. of β-indolylacetic acid. It is hoped to extend this work during the next flowering season.

Such a hormone must be released post-meiotically. The data given in Table 1 were obtained from buds emasculated when about 5 mm. long, the critical stage for effective treatment being a length of about 7 mm., whereas meiosis is completed when the buds are only about 1 mm. long. This seems to correspond with the observations of Wittwer[2], who investigated the production of growth hormone in the staminate flowers of corn. He found that this occurred only after the onset of meiosis, the greatest concentration being attained ten days to two weeks after the beginning of synapsis. In *Glechoma*, female flower-buds 5 mm. long do not contain anthers, so that the determination of the mature corolla-length must occur at a stage later than that of the determination of the sex of the flower.

Baker stated that in at least some gynodioecious members of the Labiatae, the abortion of the anthers is associated with a dwarfing of the plant in all its aerial parts. This does not appear to be a general manifestation. For example, in *Thymus vulgaris* L., female and hermaphrodite plants in the progeny of a cross female × hermaphrodite are equal in size, whereas selfing hermaphrodite plants produces much smaller hermaphrodite offspring (apparently a heterotic effect) (Table 2). I have not noticed any dwarfing of the females in the other species which I have studied (*Thymus serpyllum* L., *T. drucei* Ronn., *T. pulegioides* L., *Salvia verticillata* L. and *S. pratensis*

Table 2. COMPARISON OF THE SIZE OF FEMALE AND HERMAPHRODITE PLANTS OF *Thymus vulgaris* L.

Parents	♀ × ☿		☿ – S
Sex	♀	☿	☿
No. of plants measured	14	12	35
Mean lengths of main axis in cm.	27·0	28·2	17·7

L.).[2] The effect on corolla size of the hypothetical anther hormone of *Glechoma* is evidently quite localized since small female and large hermaphrodite flowers occur close together in the same inflorescence. However, it was not found possible to destroy the symmetry of the corolla by removing two anthers asymmetrically.

In conclusion, it seems to me that the reduction in size of the pistillate flowers is a secondary sexual characteristic, resulting directly from the loss of the anthers, and not necessarily connected in any more immediate way with the factors which determine the sex of the flowers.

I am much indebted to Prof. D. Lewis for helpful discussion.

Germinating Spores in the Rhynie Chert

A SMALL loose block of Rhynie Chert (Scottish Middle Old Red Sandstone) has been found to contain a number of isolated spores which appear to have been germinating at the time when the onset of conditions favouring their preservation occurred. In some cases it is clear that development had only just commenced, the spores having split open and produced small sac-like outgrowths in which no evidence of structure can be distinguished (Fig. 1*a*). A few specimens have been obtained, however, which probably represent slightly later stages, and in some of these, the outgrowths seem to be composed of thin-walled cells, although the possibility cannot be entirely excluded that they may be merely artefacts resulting from shrinkage or re-arrangement. The largest and best-preserved specimen found so far has an overall length of about 0·5 mm., the distal end of the rather narrow outgrowth showing a clearly defined multicellular pattern although this can be recognized discontinuously to the basal portion where it emerges from the spore. Owing to its obliquity in the matrix, it has not proved possible to obtain a satisfactory photograph, but its form is generally similar to that of the specimen shown in Fig. 1*b*. While the outgrowth in this case is slightly smaller and rather badly decayed, the tripartite splitting of the spore is clearly visible. Another specimen showing this feature together with evidence of possible cellular structure appears as Fig. 1*c*, part of the (? incomplete) outgrowth being shown at a higher magnification in Fig. 1*d*.

While there can be no certainty regarding the identities of any of the spores, size measurements, taken in conjunction with the recorded flora of the deposit[1], make it not unlikely that some of them, at least, may have been the products of one of the known vascular plants. A few spores, the maximum diameter of which prior to splitting has been estimated at about 67μ, compare fairly closely both in size and appearance with those of *Rhynia major* (65μ for unshed spores, Kidston and Lang[1]). Most of the spores showing evidence of development, however, although generally similar in form to those of *Rhynia*, are appreciably larger, being about 81μ in diameter. While there is evidence to suggest that these were formed in tetrads, the plant which produced them is as yet unknown.

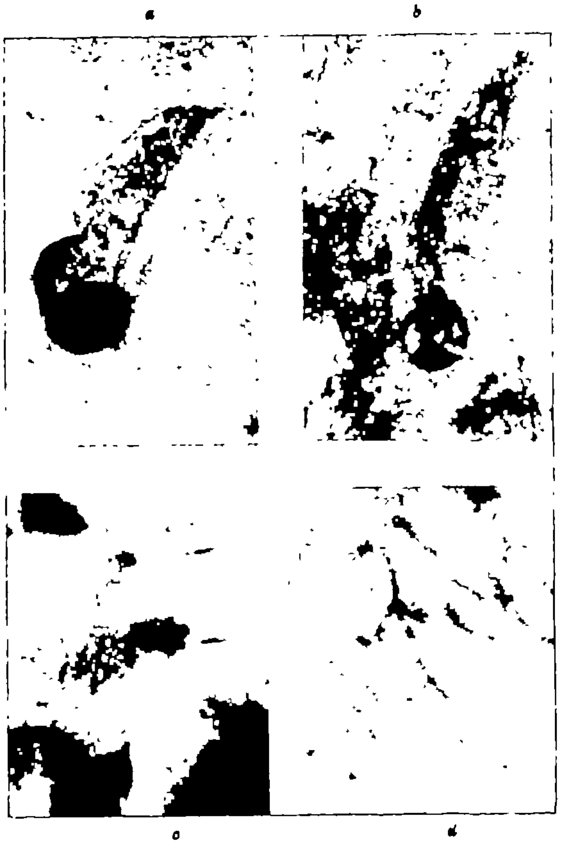

Fig. 1 *a*, Germinating spore (? of *Rhynia major*) (× *c*. 190); *b*, spore of similar size with more extensive outgrowth (× *c*. 98); *c*, spore estimated to be about 81μ in diameter with outgrowth (× *c*. 95), *d*, part of the above outgrowth showing evidence of possible cellular structure (× *c*. 375). All figures are reproduced from untouched photographs

Associated with the spores in the block are abundant fragmentary remains of *Algites* (*Palaeonitella*) *cranii* the occurrence of which, at certain levels in the deposit, has been interpreted by Kidston and Lang as suggesting the existence of highly aquatic and probably submerged conditions. There are no certain means of knowing, however, whether it was under such conditions that germination took place or whether the spores, having germinated elsewhere, were carried into the positions which they finally occupied during a period of inundation at a late stage prior to petrifaction.

It seems reasonable to suppose that the outgrowths represent early stages in the development of the gametophyte generation of certain Middle Devonian plants, some, if not all, of which may well have been Psilophytes. While those found up to the present have been, at the best, imperfectly preserved and of uncertain identity, their presence in the chert increases the hope that something may yet be known of the adult prothallia of the early land plants of the Rhynie deposit.

A fuller account may be published elsewhere, when the examination of the remaining material has been completed.

"The Origins of Life"

N. W. Pirie's characteristic and entertaining account of the symposium in Moscow on the origin of life mainly consists of an exposition of his views on the subject and a metaphysical criticism of a minor part of my own contribution to the discussion.

The scientific value of the symposium lay, it seemed to me, in the fact that so many distinguished and active scientists in fields ranging from astrophysics to genetics, with a strong central weighting in biochemistry, had come together to discuss a subject of such wide scope and importance as the origin of life on the Earth. It is true that most of the prepared contributions had only an incidental bearing on the subject, but taken together they began to build up a picture which can be the basis for further directed research. They also brought out by their weaknesses the nature of the major gaps in the story that still need to be filled.

On the whole, the original Oparin–Haldane hypothesis of evolution of life on this Earth in a primary reducing atmosphere was supported by the later contributions.

Urey, who could not be present himself, summed up in favour of a primitive atmosphere containing mainly nitrogen and hydrocarbons with ammonia mostly dissolved in sea water. Miller reported further work on the synthesis of amino- and vegetable-acids from such simple molecules, which has been largely confirmed and extended by Terenin, Pavlovskaya and Passynsky, who also used ultra-violet light. Asymmetric syntheses on quartz catalysts were also reported by Klabunowski.

On the next and critical stage of polymer formation, there was an interesting paper by Akabori on the polymerization of amino-acetonitrite on clay to form polyglycine and the subsequent introduction of other amino-acid side-chains. This was about as far as the synthetic approach from simple molecules had progressed, though the work of Oparin and his school on reactions in coacervate drops is suggestive of the conditions of the next stage of Pirie's 'eobionts'.

The rest of the discussions turned on the reverse approach, by analysis of existing biochemical processes in a variety of organisms. Despite Pirie's criticisms of the limitation this implies to the more successful mechanisms, it is unfortunately the only way open to us until we get to other planets. We had, on the most general question of the evolution of metabolism, an important paper by Prigogine on the thermodynamics of cyclic biochemical systems and of their evolution from simpler forms. Other ideas on the open character of organic metabolism were furnished by Broda and Mitchell.

I put forward a suggestion of how the apparent improbability of the enormous complexity of biological structures could be understood in terms of the formation of a sequence of structural units, such as macro-molecules, fibres and membranes, determined by the nature of their progressively weaker ultimate binding forces, each including all the smaller and more tightly bound lower structures. The functions of such structures in cell metabolism was well brought out in the paper by Sissakian.

In the field of biochemical evolution, Calvin brought forward a general hypothesis for the production of catalytic activity from progressively more complicated substances up to the present-day protein enzymes. Nicolaev provided some experimental evidence for this from the catalase-like activity of certain copper complexes.

On the evolution of proteins and enzymes, we had interesting papers from Šorm and Hoffmann-Osterhof showing the persistence of common features pointing to an earlier peptide stage. Straub provided further evidence in experiments that seemed to show that the synthesis of proteins in liver cells proceeds in two stages, first that of a common basic protein and then the addition of a specific terminal grouping conferring on it specific—enzymic or antibody—character.

The two other major biochemical activities, those of energy transfer and control of reproduction, seem to be carried out by the same groups—the nucleotides as coenzymes, and the polynucleotides or nucleic acids as basic genetic material. There was naturally much discussion of the nucleic acids, and their role in stabilizing biochemical reaction patterns, at the symposium, particularly in the contributions of Chargaff on the relations of proteins and nucleic acids, and in those of Fraenkel-Conrat and Schramm on specific protein synthesis by viruses, which I did not find as irrelevant to the subject as did Pirie. At the moment we have to consider the triad of mutual synthesis:

$$\begin{tikzcd} \text{RNA} \arrow[d, shift left] & \text{DNA} \arrow[l] \\ \text{Protein} \arrow[u, shift left] \arrow[ur] & \end{tikzcd}$$

but this cannot have been the original state, and it is one of the major problems of biopoesis to find what were its antecedents.

On biochemical evolution there was general agreement that the Pasteur effect implied, as Oparin had first suggested, the priority of fermentative over oxidative cycles in the evolution of life, a point well brought out in Aubel's paper. It was also dealt with in an impressive paper by Braunstein on the evolution of nitrogen metabolism.

Closely connected with this is the question of photosynthesis, which was the means of liberating the molecular oxygen necessary for oxidative cycles. Here a series of interesting papers, especially those of Reid, Oda, Krasnovski, Sorokin and Sabozhnikow, indicated that before the chlorophyll-operated oxygen-liberating photosynthesis, there was one operating photocatalytically through simpler porphyrins and producing mainly molecular sulphur or sulphur compounds as some bacteria do to-day. Here Pirie is not quite fair in his claim that really primitive types were not studied, though it is now clear that there is much more to be learned in this field.

Nearly all the papers presented belonged or fitted in with the now almost orthodox scheme of biopoesis, including those as far removed as Pauling's on the relation of blood-group mutations by minor protein molecule changes. However, one interesting heresy appeared in the paper by Fox on the hydrothermal production of many enzymic reactions, suggesting that life had originated not in a cold but a nearly boiling ocean, to-day represented only by hot springs.

I hope these remarks may do something to enlarge Pirie's view of the symposium, but they still are far from doing justice to the wealth of information presented and the interesting discussions that ensued. However, in some months time scientists will have the opportunity to judge for themselves by the publication in several languages of the Proceedings of the Symposium.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, December 2

Institution of Post Office Electrical Engineers (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2), at 5 p.m.—Mr. R. V. Leedham: "Junction Transistors and their Application to Switching Circuits".

British Society for the History of Science, Philosophy of Science Group (in the Joint Staff Common Room, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. H. J. Eysenck: "The Confirmation of Hypotheses in Psychology".

Royal Institute of Chemistry, London Section (joint meeting with the London Section of the Society of Chemical Industry, at the Society of Chemical Industry, 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Prof. D. M. Newitt, F.R.S.: "High Pressure Reactions".

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 8.30 p.m.—Dr. D. C. Martin: "International Geophysical Year".

Tuesday, December 3

Society of Chemical Industry, Agriculture Group (at 14 Belgrave Square, London, S.W.1), at 10.30 a.m.—Water Meeting.

Institution of Chemical Engineers (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. M. J. Gattiker: "Shell Gasification Process and its Application to Industry".

Institution of Civil Engineers (at Great George Street, London, S.W.1), at 5.30 p.m.—Mr. August Knobel: "Snow Clearance Problems in Switzerland".

Institution of Electrical Engineers, Measurement and Radio Sections (at Savoy Place, London, W.C.2), at 5.30 p.m.—Scientific Papers.

University of London (at the Royal College of Science, South Kensington, London, S.W.7), at 5.30 p.m.—Prof. D. H. R. Barton: "Some Modern Trends in Organic Chemistry" (Inaugural Lecture).

Wednesday, December 4

Powder Metallurgy Joint Group of the Iron and Steel Institute and the Institute of Metals (at Church House, Great Smith Street, London, S.W.1), at 10.30 a.m.—Inaugural Meeting. Dr. Ivor Jenkins: "Recent Developments in Powder Metallurgy"; followed by a discussion on "Developments in the Production and Quality of Metal Powders".

British Computer Society (at the Northampton College of Advanced Technology, St. John Street, London, E.C.1), at 2.30 p.m.—Dr. D. J. Wheeler: "The EDSAC II Order Code—Some of the Reasons Underlying its Choice".

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 2.30 p.m.—Dr. Frank Wokes: "Some Nutritional Aspects of Vitamin B_{12}".

Institute of Fuel (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 5.30 p.m.—Mr. E. J. Lawton: "The Manufacture of Town Gas from Liquid or Gaseous Fuels".*

Institute of Petroleum (at 26 Portland Place, London, W.1), at 5.30 p.m.—Mr. D. Downs: "Recent Engine Developments in Relation to Fuels and Lubricants".

Institute of Physics, Education Group (at 47 Belgrave Square, London, S.W.1), at 6 p.m.—Mr. F. L. G. Rawlins: "Physics and Æsthetics".*

Institution of Electrical Engineers, London Graduate and Student Section (at Savoy Place, London, W.C.2), at 6.30 p.m.—Mr. W. H. Dunkley: "Man/Machine Relationships".

Society for Analytical Chemistry (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6.30 p.m.—Discussion on "Standardization" opened by Mr. R. C. Chirnside, Mr. L. S. Theobald, Dr. J. Haslam and Mr. G. Ingram.

Royal Society of Medicine, Surgery Section (at 1 Wimpole Street, London, W.1), at 8 p.m.—Trans-Atlantic Discussion—"Advances in Chemotherapy of Cancer".

Thursday, December 5

Royal Society (at Burlington House, Piccadilly, London, W.1), at 11 a.m.—Discussion on "Parity Conservation" opened by Prof. R. E. Peierls, F.R.S.

University of London (at the Institute of Obstetrics and Gynæcology, Chelsea Hospital for Women, Dovehouse Street, London, S.W.3), at 4.30 p.m.—Dr. G. I. M. Swyer: "Intersex".

Institution of Naval Architects (in the Weir Lecture Hall, 10 Upper Belgrave Street, London, S.W.1), at 4.45 p.m.—Dr. R. W. L. Gawn: "Aspects of Propellers for the Royal Navy" (to be read by Mr. R. N. Newton) (Parsons Memorial Lecture)

Royal Society of Arts, Commonwealth Section (at John Adam Street, Adelphi, London, W.C.2), at 5.15 p.m.—Prof. G. Macdonald: "The Conquest of Malaria".

Institute of Refrigeration (at the Junior Institution of Engineers, Pepys House, 14 Rochester Row, Westminster, London, S.W.1), at 5.30 p.m.—Mr. G. O. Eddie: "The Development of a Quick-Freezing Plant for Distant-Water Trawlers".

Institution of Electrical Engineers (in conjunction with the British Nuclear Energy Conference, at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. J. V. Dunworth: "Advanced Types of Power Reactors".

Sir Thomas Middleton Memorial Trust (in the Auditorium, The Wellcome Building, 183 Euston Road, London, N.W.1), at 5.30 p.m.—Dr. Alan Robertson: "Modern Trends in Animal Breeding"* (Fifth Middleton Memorial Lecture).

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. R. J. W. Rees: "Experimental Approach to the Problems of Resistance to Tuberculosis".* (Last of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

Society of Chemical Industry, Microbiology Group (at 15 Belgrave Square, London, S.W.1), at 6.15 p.m.—Meeting on "The Microbiology of Meat". Dr. M. Ingram: "The Importance of pH in Meat Microbiology"; Dr. Betty C. Hobbs: "Characteristics of Heat-Resistant *Clostridium welchii* in Carcass Meat".

Women's Engineering Society, London Branch (at the Central Electricity Authority Headquarters, Winsley Street, London, W.1), at 6.45 p.m.—Meeting on "The Radio Telescope". (Speaker from the Cavendish Laboratory, University of Cambridge.)

Royal Institute of Chemistry, London Section (joint meeting with the Battersea College of Technology Chemical Society, at the Battersea College of Technology, Battersea Park Road, London, S.W.11), at 7 p.m.—Prof. R. S. Nyholm: "The Modern Approach to Inorganic Chemistry in Schools, Colleges and Industry".

Friday, December 6

Society of Dyers and Colourists, London Section (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 6 p.m.—Mr. J. P. Gill: "Colour in Writing and Copying".

Society of Chemical Industry, Fine Chemicals Group (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Mr. K. G. A. Hammer: "Problems in Supplying Laboratory Chemicals"

Institution of Mechanical Engineers, Internal Combustion Engine Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6.45 p.m.—Discussion on "Are Crankshaft Torsional Vibration Problems Things of the Past?"

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Dr. Mary Woodall: "Gainsborough's Landscape Drawings".

Saturday, December 7

Association of Agriculture; and the British Agricultural History Society (at the Institute of Education, University of London, Malet Street, London, W.C.1), at 11 a.m.—Conference.

British Mycological Society (at the Linnean Society of London, Burlington House, Piccadilly, London, W.1), at 12 noon—Annual General Meeting. At 2.30 p.m.—Dr. C. J. Hickman: "Phytophthora—Plant Destroyer" (Presidential Address).

British Interplanetary Society (in the Tudor Room, Caxton Hall, Caxton Street, London, S.W.1), at 6 p.m.—Dr. G. Fielder: "The Physical Nature of the Surface of the Moon".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Experimental Officer (with a degree in botany with one or more of the following: chemistry, physics or mathematics, as supporting subjects) at Merlewood Research Station, Grange-over-Sands, Lancashire, for work on woodland ecology with particular reference to plant/soil relationships—The Establishment Officer, The Nature Conservancy, 19 Belgrave Square, London, S.W.1 (December 6).

Advisory Officer (with a degree in engineering or science and experience of dairy processing and manufacture) in Dairy Engineering—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow, C.2 (December 10).

Deputy Director (with high qualifications, preferably in physics, mathematics or engineering, with a breadth of experience and some distinction in research and in the direction of research, either in the academic field or in Government or industrial research) of the National Physical Laboratory, Teddington (D.S.I.R.)—The Secretary, Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S 4781/57 (December 12).

Assistant Experimental Officer (with an ordinary degree or diploma in botany or agriculture)—The Secretary, Scottish Plant Breeding Station, Pentlandfield, Roslin, Midlothian (December 14)

Lecturer in Theoretical Physics—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1 (December 14).

Lecturer (preferably with a veterinary qualification and some teaching experience) in the Department of Veterinary Physiology, Royal (Dick) School of Veterinary Studies—The Secretary, The University, Edinburgh (December 14).

Plant Physiologist (with a first- or good second-class honours degree in botany and preferably some research experience and a knowledge of physics and its application in biology) in the Botany Department, to work on water relations of plants in connection with studies of growth of field crops under irrigation—The Secretary, Rothamsted Experimental Station, Harpenden, Herts, quoting 1051/9 (December 14).

Chief Technician in the Department of Chemistry, University College of Ghana—The Assistant Registrar (London), University College of Ghana, 29 Tavistock Square, London, W.C.1 (December 16).

Soil Surveyors with the New South Wales Department of Agriculture for duties which include carrying out soil surveys in any part of New South Wales, the preparation of data and draft maps from surveys, laboratory work, etc.—The Agent General for New South Wales, 56 Strand, London, W.C.2 (December 20).

Lecturer in Education at the University of Tasmania, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, December 31).

Official Fellow or Lecturer (preferably able to teach inorganic chemistry, physical chemistry or physics), to share in the teaching of the final Honour School of Natural Science—The Principal, St. Hilda's College, Oxford (December 31).

Staff Tutor in Natural History in the Department of Extra-Mural Studies—The Secretary, The Queen's University, Belfast (January 1).

Lecturer in Microbiology at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, January 6).

Junior Research Fellow (with a good honours degree in zoology or entomology) in the Department of Zoology, University College of Rhodesia and Nyasaland, to undertake work on a problem of locust physiology under the direction of the Head of the Department—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (January 7).

Senior Research Assistants (honours graduates in engineering or physics) in the Departments of Civil and Mechanical Engineering, for work in the fields of the fatigue of metals and photoelasticity—The Registrar, The University, Nottingham (January 15).

Demonstrator in the Department of Geology—The Secretary of the Appointments Committee, Department of Geography, The University, Downing Place, Cambridge (January 31).

Lecturer in Anthropology in the Department of Geography—The Secretary, The University, 38 North Bailey, Durham (January 31).

Royal Society Research Fellow in Cytology and/or Cytochemistry, with special reference to malignant cells—The Assistant Secretary, The Royal Society, Burlington House, Piccadilly, London, W.1 (February 15).

Cox Chair of Anatomy—Joint Clerk to the University Court (University of St. Andrews), Queen's College, Dundee (February 28).

Assistant Experimental Officer (preferably with experience of chromatography, use of radioactive isotopes and a variety of techniques of chemical analysis), for biochemical research on amino-acids and proteins of plants—The Secretary, Rowett Research Institute, Bucksburn, Aberdeenshire.

Assistant Lecturer (Grade B) in Chemistry—The Registrar, Hatfield Technical College, Roe Green, Hatfield, Herts.

Assistant Lecturer (with a degree or diploma in horticulture) in Horticulture—The Registrar, Massey Agricultural College (University of New Zealand), Palmerston North, New Zealand.

Assistant Librarian—The Recorder, The College of Aeronautics, Cranfield, Bletchley, Bucks.

Biochemist, Basic Grade, to work under the direction of the Consultant Chemical Pathologist—The Chief Administrative Officer, The United Sheffield Hospitals, West Street, Sheffield 1.

Biologist (male or female, with a bias towards plant pathology, and preferably postgraduate experience) to continue investigations into the fungal diseases of turf and allied matters—The Secretary, The Sports Turf Research Institute, Bingley, Yorkshire.

Experimental Officer or Assistant Experimental Officer (woman graduate in chemistry or domestic science) in the Domestic Food Preservation Section—The Secretary, Research Station (University of Bristol), Long Ashton, Bristol.

Experimental Officer (preferably with H.N.C. or a degree in electrical engineering, or at least H.S.C. (Science) or equivalent, and previous experience in one of the following fields: instrumentation; electrical circuitry design; high speed oscillography), to work in a Section engaged in the preparation, assembly and testing of electronic and electro-mechanical weapon equipment for U.K. and overseas trials—The Senior Recruitment Officer, Atomic Weapons Research Establishment, Aldermaston, Berks, quoting Ref. No. A.1470/34.

Graduate, to take part in research work in the field of bacterial viruses—The Secretary, Guy's Hospital Medical School, London Bridge, S.E.1.

Junior Biochemist, to work on human plasma proteins in the Blood Products Laboratory—The Secretary, The Lister Institute of Preventive Medicine, Elstree, Herts.

Lecturer (with a university degree in either physics or electrical engineering and teaching and/or industrial experience) in Physics or Electrical Engineering (Light Current)—The Clerk to the Governors, South-East Essex Technical College and School of Art, Longbridge Road, Dagenham, Essex.

Lecturer (with an honours degree or equivalent, and with suitable industrial or research experience) in Chemistry at Coventry Technical College—The Director of Education, New Council Offices, Coventry.

Metallurgist or Metallurgical Chemist (graduate, preferably Ph.D.), to join in fundamental research on surface reactions—The Director, Arthur D. Little, Research Institute, Inveresk, Midlothian.

Principal Research Officer (with a good honours degree in chemistry or agricultural chemistry and considerable postgraduate research experience which must include administration and organization of a research unit) in the Department of Agriculture, Western Region of Nigeria, to take charge of the Chemistry and Soils Division which is responsible for soil survey, classification and analysis work; and soil fertility and plant nutrition investigations with particular reference to cocoa and general agricultural chemistry—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.63/420/017.

Research Assistant (with a qualification in chemistry, biochemistry or physiology, and preferably experience in analytical or physical methods) in Biochemistry, for research on serum lipoproteins—Dr. W. G. Dangerfield, Pathology Department, North Middlesex Hospital, Edmonton, London, N.18.

Research Assistant (with at least B.Sc. (special chemistry) or B.Sc. (general) with chemistry as one subject) in the Medical Unit, to work on problems of intermediary metabolism in man—The Secretary, St. Bartholomew's Hospital, Medical College, London, E.C.1.

Research Assistants (honours graduates) in Chemistry—The Clerk to the Governors, Woolwich Polytechnic, London, S.E.18.

Research Assistants (with H.N.C. or equivalent qualification), to join a team working on the efficient use of existing forms of energy and fuel in the iron and steel industry, and the introduction of new forms of energy and new techniques in this field—The Personnel Officer, British Iron and Steel Research Association, 11 Park Lane, London, W.1, quoting F.T.4.

Research Officer (female, with an honours degree in bacteriology, microbiology or zoology)—The Secretary, The Research Institute (Animal Virus Diseases), Pirbright, Surrey.

Senior Scientific Officer or Scientific Officer (with a veterinary qualification or a first- or second-class honours degree in a biological subject) in the Department of Parasitology, for research on the ecology of parasitic worms in sheep—The Secretary, Moredun Institute, Gilmerton, Edinburgh 9.

Technician (with A.I.M.L.T. or similar qualification), for biological research work—H. E. H. Jones, Courtauld Institute of Biochemistry, The Middlesex Hospital, London, W.1.

DIFCO

BACTO-CEPHALIN CHOLESTEROL ANTIGEN

For Hanger Flocculation Test

An approved and stable reagent for use in the Hanger Flocculation Tests to determine disturbance of liver function. Available in packages of six units, each unit equivalent to 150 ml. final test antigen.

Hanger: J. Clin. Invest. 18:261:1939.

BACTO-THROMBOPLASTIN

For Prothrombin Determination

A stabilized rabbit brain substance for use in determining the Prothrombin Time of Blood. Bacto-Thromboplastin is applicable to the procedures described by Quick, Link-Shapiro, Smith, et al., Kato and Poncher, and other tests requiring a potent thromboplastin. Each box of Bacto-Thromboplastin contains 6 ampoules, sufficient for 210 Quick determinations or 420 Link-Shapiro determinations.

RESEARCH AND THE RESEARCH WORKER

IN the Fourth Fawley Foundation Lecture, "The Strategy of Research", given at the University of Southampton on October 17, Sir George Thomson discussed the factors which make for success in research, both in societies and in individuals. Sir George did not attempt more than a few tentative answers to such questions as why science has taken so long to get established and why it has made false starts; whether the present high rate of discovery is likely to slow down; or what are the most favourable conditions and how far such favourable conditions can be ensured. These questions have been widely discussed in the past fifteen years in these columns and elsewhere, notably in the Barlow Report on scientific staff; but if Sir George Thomson said little that was new, he gave a fresh emphasis to certain points that frequently tend to be overlooked. Moreover, while in title his lecture recalls Sir Henry Tizard's Messel Memorial Lecture, "The Strategy of Science", given before the Society of Chemical Industry five years ago, and the two lectures have something in common, Sir George Thomson's lecture is essentially complementary to the other.

By the strategy of science, Sir Henry Tizard meant the art of so directing the application or advance of science as to make the most rapid progress of society or knowledge. The tactics of science, on the other hand, are to be understood as the procedure—the skilful devices—calculated to gain the strategy, or, in other words, 'research'. Nevertheless, although Sir Henry might appear thereby to deny the title of 'strategy' to Sir George's lecture for that of 'tactics', in fact both addresses insist on the importance of flexibility in outlook, penetrating thought as to the objectives that really matter, the avoidance of dogma and dispassionate minds in reaching conclusions.

Sir George Thomson was concerned, in the main, with the individual; and although he glances at the organization of research, it appears to be rather as the form of organization affects the productivity or creativeness of the research worker than in relation to its appropriateness or the intrinsic advantages of particular forms. Scientific research, he pointed out, demands an inquiring mind, sustained by the belief that some of the questions it asks have real and discoverable answers, and it must have both leisure and freedom. Further, it is essential not merely to ask sensible questions but also to know the kind of answer that it is reasonable to expect; and this is obviously allied to what Sir George claimed is the most important gift of all in research—that of choosing the right subjects.

This gift Sir George regards as rare, and he commented severely on the tendency to work on unpromising subjects and on the failure to break off an investigation when it no longer seems likely to be productive. This faculty is of supreme importance for a director of research, and while Sir George did not minimize the difficulties involved in expenditure of both time and money in discontinuing a project, he was emphatic that it is as important to make bold and wise decisions here as in the selection of projects originally. Neither in discussing the individual qualities needed for success in research nor in considering the merits of different forms of organization did he appear to attach much importance to the ability of a director of research to handle his men wisely, and it is implied rather than explicitly stated that the director should possess qualities similar to those of the research worker—ability above average, the capacity to understand difficult ideas and grasp their interrelation, to assimilate a considerable mass of fact without being swamped by detail. If the director himself is not called upon to handle complicated apparatus without forgetting the main purpose, there are other duties which make analogous demands, and, like the research worker, his duties must allow him reasonable time to think if not also to experiment in the laboratory.

It seems to follow that, if the director possesses the qualities Sir George Thomson considers necessary in the research worker, he will have that intimate understanding of the mind and outlook of the research worker which is stressed as so important by Sir Henry Tizard; this will help him in using his authority to provide adequate equipment and services and to maintain the conditions most fruitful for creative work. Moreover, those conditions—perhaps especially those touched upon by Sir George Thomson, in quoting a well-known passage from his father's "Recollections and Reflections"—which stimulate critical judgment and new ideas, are the conditions most helpful to the research administrator in arriving at the difficult decisions as to the selection and discontinuance of projects. It follows emphatically from what is said in this lecture that seniority has its dangers in the direction, as in the execution, of research. There may well be a limit to the fruitful life of a director of research as there usually is to that of the investigator himself, and the further study of this aspect of the organization of research, for which Sir George Thomson pleads, might yield a really important contribution to the wise use of trained man-power.

Attention to such matters in our present shortage of scientific man-power is essential if first-class men are not to be wasted on second-class objectives. Moreover, in work that particularly demands originality and imagination and leisure to think, it cannot be too often emphasized that hours and other conditions of work have no relation to those best suited for routine and repetitive work. What is most efficient and even essential in one sphere may waste valuable assets in another. Sir George Thomson frankly suggests that the five-day week is wasteful for research. The breaks are too frequent and long, and this is a factor that should perhaps be given more weight in deciding the allocation of scientific research between a university institution and an industrial establishment, and certainly in considering the development of technological institutions and their role in industrial research.

In considering the three main types of research organization in Great Britain, Sir George placed the universities first from the point of view of supplying the most fruitful conditions for creative work, and especially in their steady stream of young and able minds who are not likely to accept without question traditional ways of looking at things. Against this immense advantage, the provision of services is bad, and though he did not enlarge on this, the improvement of such services, especially the ratio of mechanics and assistants to graduates, is one way in which for small expenditure the country's research effort could be greatly improved.

Sir George Thomson thinks that the serious difficulties of Government research establishments in Britain, particularly in securing a steady stream of fresh minds and in eliminating those who have lost their enthusiasm and ability for research, outweigh their advantages. He suggests that Government science would be more fruitful if a man's stay in one establishment were limited to ten or twelve years, so that most men would serve in at least three during their working life. Like Sir Henry Tizard, he believes that since the War the Government has been taking too large a share of limited resources of men capable of scientific research, and he urged the importance of increasing the opportunities for scientific research at the universities. Of industrial establishments he said little, though recognizing that they are responsible for much first-class work; but he thought that holidays are too short and ill-arranged and that contact with other workers in the same field could be improved.

For the improvement of research generally, Sir George thought that the formation of temporary teams of men from different institutions but working in one building on a specific problem, as proposed by P. Kapitza, have real advantages in preventing stagnation. To some extent the device is already used by the Road Research Board and in the establishments of the Atomic Energy Authority; but the dispersal when a problem has been solved is important. He also stressed the need for attention to the problem of relieving the head of a large university department of administrative work so that he has sufficient time for research.

As regards the future of research, Sir George does not believe that there is any real limit to discovery or even to what is worth discovering. There is a serious difficulty inherent in the increase of knowledge; and a man may have to know so much before he reaches the frontiers of knowledge that he will have lost his originality. It is very likely that he would go by such a narrow path and be so specialized as to be unable to appreciate what other people are doing. Each divergent line of research would gradually degenerate and die out for lack of cross-fertilization with other lines, and this, if anything, probably determines the real limit to knowledge. This is a long way off, but it was in this connexion that, after stressing the value of good abstracts in helping to cope with the relentless growth of literature, Sir George urged that it is of the first importance to encourage men whose business it is to interpret scientists to one another. In addressing the Library Association recently, Dr. J. Bronowski suggested that the publication in one series of the old and new classics of science would help to make the language of science familiar to a new generation, and his plea for more classics of science looking at new discoveries in a personal way found an echo in Sir George Thomson's plea for encouraging the interpreter of science to non-scientific audiences. It is also important, he believes, to encourage the interpretation of advances in one science to workers in another, and even of one branch to those working in another branch of the same science. Sir George does not think that this could usually be done by the specialist himself. It is usually done best by a man who has got up the subject for the purpose, and such men should be given adequate recognition in scientific circles.

The real menace to the advancement of science, however, is loss of freedom, above all, freedom to think. Even here Sir George was optimistic, though his address sets in its rightful perspective the current discussions about academic freedom in the universities of the world. No less important is that he indicates the way in which theories of morality, as well as political doctrines, particularly the view that a scientist is responsible for the consequences of his discoveries even if he has not foreseen them, can threaten freedom.

Apart from this glance at the future and the review of the development of science with which it began, this Fawley Foundation Lecture might be described as an exposition of the theme that wise rather than large expenditure is what matters in research. No less clearly than Sir Henry Tizard, Sir George points to Government neglect as largely responsible for the current waste of resources of trained man-power: the significance of such projects as the National Science Centre and both the National Reference and Lending Libraries for science and technology is clearly seen in the context of his restrained but incisive remarks about the exchange of information and the meeting of minds. If, however, the Government is to be turned from its mistaken ideas as to how to economize in scientific and technical matters, scientists and their professional associations must use to the full the arguments which Sir George Thomson has outlined, both in pressing such views on the Government and in developing for themselves increasingly efficient means of securing the interchange of men and of information and establishing the conditions in which creative work is most fruitful and effective.

THE 45-FT. RADIO TELESCOPE AT THE ROYAL RADAR ESTABLISHMENT, MALVERN

By STAFF OF THE ROYAL RADAR ESTABLISHMENT

RADIO methods of observation have extended to many branches of astronomy during the past ten years, and have led to contributions of considerable importance both to radio and to astronomy. This field of research includes the study of radar reflexions as well as radio emissions from astronomical bodies, gaseous media, and associated astrophysical phenomena. The application of radar is limited to comparatively near objects in the vicinity of the Earth or within the solar system, but it has the advantage of providing an accurate measurement of range.

Although progress in radio astronomy has been rapid, it depends much on advances in radio techniques. A basic need is for improved sensitivity and angular resolving power. Both these demands can be fulfilled by increasing the aperture of the aerial used for the radio telescope. A limit to size is set by practical considerations, since very large steerable aerials tend to become vast mechanical structures which are consequently expensive and take a long time to construct. Also, the larger the aerial the more difficult it is to achieve the accuracy of surface necessary for short radio wave-lengths.

These conditions were in mind when the radio telescope here described was planned early in 1956. A parabolic reflector was specified so that the aerial could be used over a wide range of wave-lengths. It was decided to economize by adapting an old radar-turning mechanism, raised on a tower, as the mount for the reflector. This imposed a restriction on the size of the reflector; but it was consequently more practicable to achieve the desired accuracy of the surface.

There were several reasons for designing the radio telescope to work down to short wave-lengths of 10 cm. or less. The smallest angle which can be resolved is approximately equal to λ/D, the ratio of the wave-length to the diameter of the telescope aperture. Hence, although the power received is proportional to the collecting area, and thus to D^2, the angular resolution is improved if λ can be made small. If the telescope is used as a radar, then the power transmitted is contained in a beam of width approximately λ/D radians (and hence of solid angle $\sim\lambda^2/D^2$). Consequently, the shorter the wave-length the more the power is concentrated on the radar target by a factor proportional to D^2/λ^2. The relationship between diameter and wave-length for the combined transmitter-receiver aerial system is thus D^4/λ^2 in power sensitivity, which means a factor $D/\sqrt{\lambda}$ in maximum detection range. If other parameters were constant, then the detection range could be improved by increasing D or by reducing λ. Many phenomena, for example, emissions from 'radio stars' or radar reflexions from meteor trails, are, however, very much more intense at longer wave-lengths. Radio astronomy at these wave-lengths is now strongly represented by the work at Jodrell Bank (University of Manchester) and at Cambridge. In comparison there has been little work in Great Britain at centimetric wave-lengths, although research

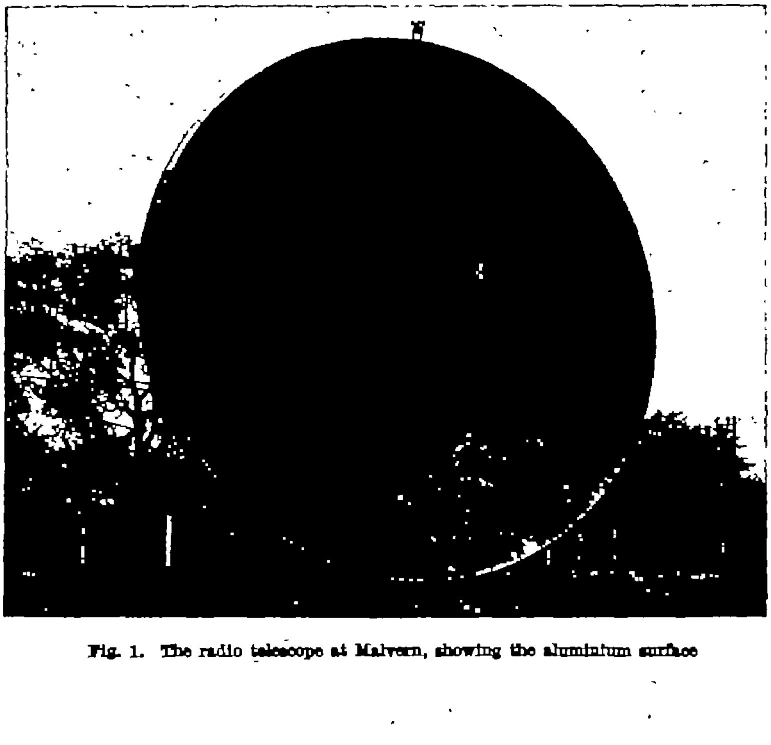

Fig. 1. The radio telescope at Malvern, showing the aluminium surface

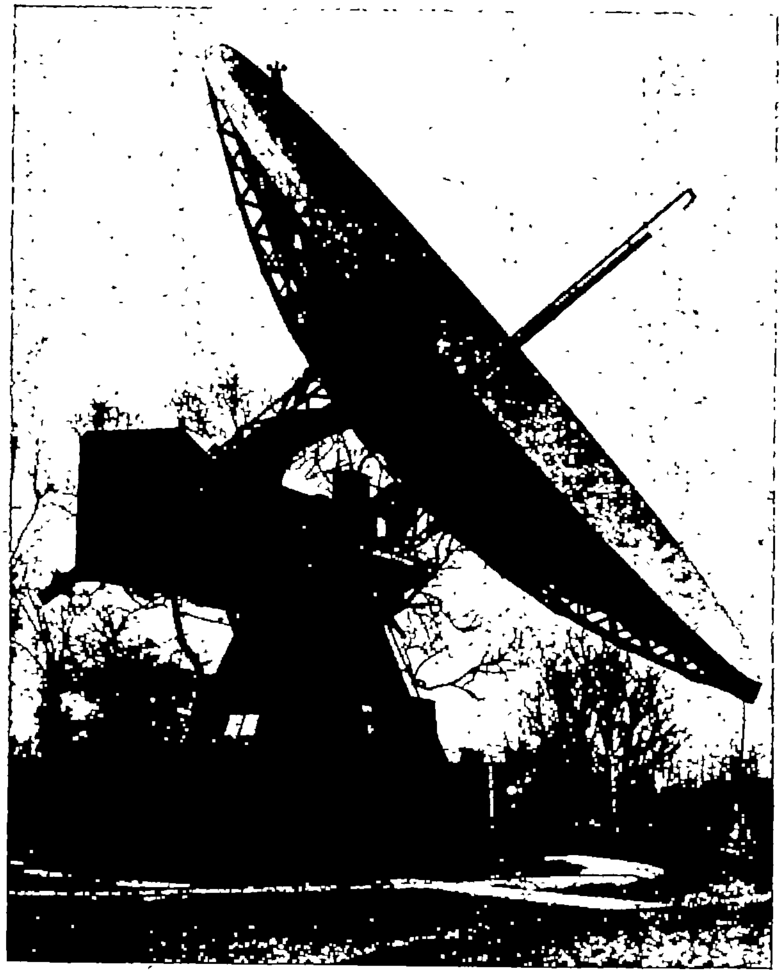

Fig. 1. The radio telescope, showing the supporting structures

elsewhere has shown that much significant information may be obtained in this band.

The specification to meet the above requirements stipulated the provision of a parabolic reflector 45 ft. in diameter, with a focal length of about 20 ft., and weight less than 4 tons. An accuracy of surface contour within $\pm \frac{1}{4}$ in. of the parabolic form had to be maintained in any operating position, which included elevations of 5°–85° at all azimuths in various conditions of temperature and in steady winds up to 30 m.p.h. When not in use, the reflector had to be capable of withstanding steady winds up to 60 m.p.h. with gusts up to 110 m.p.h., and the deposition of ice or snow, without suffering any permanent distortion.

The contract for the reflector was placed with Precision Metal Spinnings (Stratford-on-Avon), which agreed to complete construction and erection in less than a year. The design was prepared by the consultant firm of Messrs. Jenkins and Potter. The framework, consisting essentially of two rings connected by curved radial arms, and the riveted plates forming the reflector surface, were all manufactured in aluminium supplied by the British Aluminium Co. The radar tower was designed and constructed by the Ministry of Supply at the Military Engineering Experimental Establishment, Christchurch. The engineering planning of the whole scheme was co-ordinated and assisted throughout by the Engineering Department of the Royal Radar Establishment.

In the operation of a radio telescope, several types of distortion can occur. These are principally due to temperature gradients, which may be particularly pronounced in sunlight, to stresses due to gravity, which alter as the elevation is changed, and to the effects of wind. To meet the specified tolerance of $\pm \frac{1}{4}$ in. in operating conditions, it was consequently necessary to impose closer manufacturing tolerances of $\pm \frac{1}{16}$ in. at the centre of the bowl and $\pm \frac{1}{8}$ in. at the periphery. The reflector was assembled at the prepared site in Malvern during winter months and, despite adverse weather conditions, the telescope was satisfactorily completed and mounted within a year of placing the contract. Due to the incorporation of turning mechanisms from old equipment, the principal item of expenditure was the parabolic reflector, and the total cost was of the order of £10,000. As an example of the improvisation to keep the cost low, the support for the instruments at the focus of the telescope is a steel telegraph pole bought from the General Post Office for £3 0s. 3d. The completed radio telescope is shown in Fig. 1.

It was originally intended that the telescope should first be used in an attempt to detect the radio spectral line from deuterium in the galaxy at a wave-length of

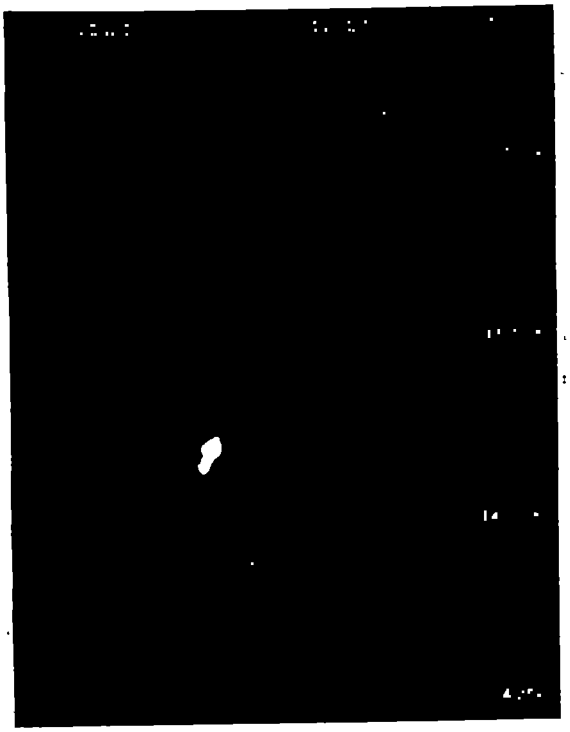

Fig. 3. Radar echo of the first Earth satellite rocket observed on October 30

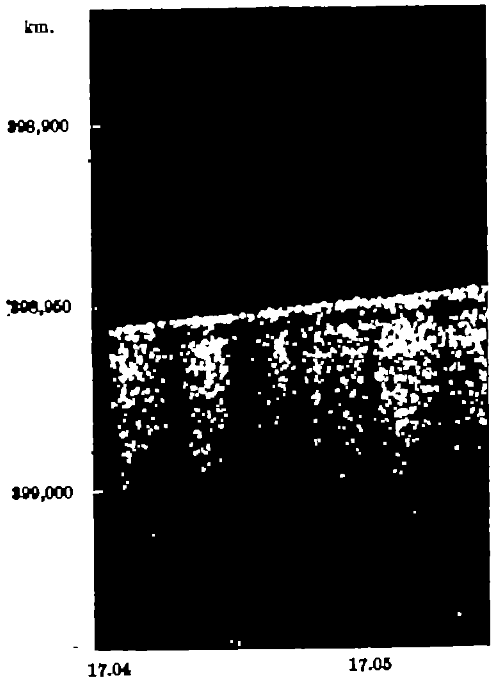

Fig. 4. Radar echo of the Moon, showing distance from radar to Moon's surface in kilometres against Universal Time

91 cm. An extremely sensitive radiometer, capable of measuring changes of aerial temperatures of less than 0·1 deg. K., was constructed. The receiving dipole and reflectors for this experiment can be seen in Fig. 1 at the focus of the telescope, and observations were about to commence when the first Russian Earth satellite was launched. It was then decided to suspend the deuterium line measurements temporarily, and instead to accelerate a later development which had been planned in the research programme, the building of a 10-cm. radar transmitter and receiver into the radio telescope, since this would make it possible to obtain radar echoes from the satellite and its rocket. Several departments within the Royal Radar Establishment co-operated in the construction of the apparatus, which by an intensive effort was completed within three weeks. Essentially this equipment consists of a high-power radar which operates at a wave-length of 10 cm., radiating a peak power of 2 megawatts with a pulse length of 5 μsec., a receiver of 500 kc./s. bandwidth, and appropriate display units. The waveguide and horn at the focus of the radio telescope can be seen in Fig. 2.

The field of view of the radio telescope at this wave-length extends over an angle of only ¼°. It had been hoped that predictions deduced from the radio-interferometer measurements of the satellite transmissions at 40 Mc./s. combined with visual observations would have been sufficiently precise to direct the radio telescope within ¼° of the paths of the satellite and rocket; but unfortunately, this has so far proved a major problem. However, on several occasions since October 30 radar echoes have been received from the rocket and these have been of strong intensity at ranges of about 1,400 km. Fig. 3 shows a photograph of a radar echo of the rocket of the first Earth satellite on a brightness-modulated display with the radar beam maintained in a fixed direction. The form of the echo indicates a scintillation of echoing area due to the varying aspect of the rocket as it passed across the beam. It is estimated that the first Earth satellite itself, assuming it is a metal sphere of radius $r \sim 30$ cm., and hence echoing area $\pi r^2 \sim 0\cdot25$ m.^{2}, would be detectable up to ranges of about 1,000 km. A radar reflexion from the second Earth satellite was first detected on November 14; but it is understood that the carrier rocket is an integral part of the satellite.

The equipment has also successfully observed radar echoes from the Moon, which are of special interest because they are obtained at centimetric wavelengths using a short pulse-length, and hence capable of giving precise measurements of range. Previously reported radar observations of the Moon have been with pulses usually several milliseconds in duration. These are long enough to encompass most of the Moon's surface in the returned echo, and measurements of range are correspondingly inaccurate. In

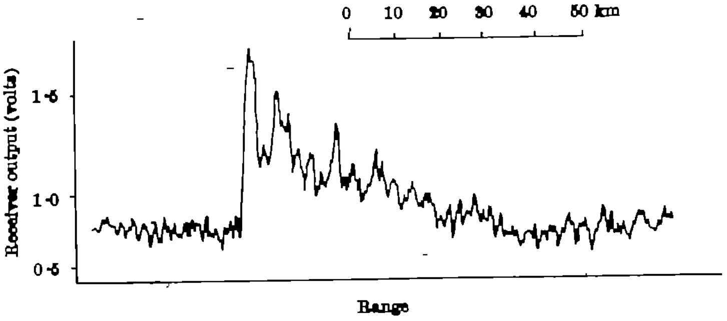

Fig. 5. Amplitude of the Moon echo

the radar here described the pulse-length was 5 μsec., equivalent to a distance of about 1 km., so that echoes from each part of the surface of the Moon corresponding to increments of the order of a kilometre in depth can be distinguished. As a short pulse-length reduces the area of the surface illuminated within a pulse-length, it becomes necessary to have an equipment with high aerial gain as well as high peak power. This has been achieved with the present equipment.

A photograph of the Moon echo on the range–time display is shown in Fig. 4. The echo begins at the nearest part of the Moon's surface and the range drifts with time due largely to the movement of the observing site with the rotation of the Earth. Because of the initial sharp rise of echo intensity, as illustrated in Fig. 5 by the photometric analysis of the photograph, the range at any instant may be found to an accuracy of the order of a kilometre, which is better than that obtained so far by optical methods.

Acknowledgment is made to the Controller, H.M. Stationery Office, for permission to publish this communication.

THE RADIOCHEMICAL CENTRE, AMERSHAM

By Dr. W. P. GROVE
General Manager

THE demand for radioisotopes continues to grow vigorously both at home and abroad, and during the past three years the combined output from the United Kingdom Atomic Energy Authority's establishments at Harwell and Amersham has more than doubled. The larger part of the work of making and distributing these versatile materials now falls upon the Radiochemical Centre, which will have sent out nearly twenty thousand consignments this year.

To keep pace with the demand a new laboratory of 12,000 sq. ft. (Fig. 1) and a block of offices have been erected at Amersham, and these were opened by Lord Salisbury on November 1 in the presence of

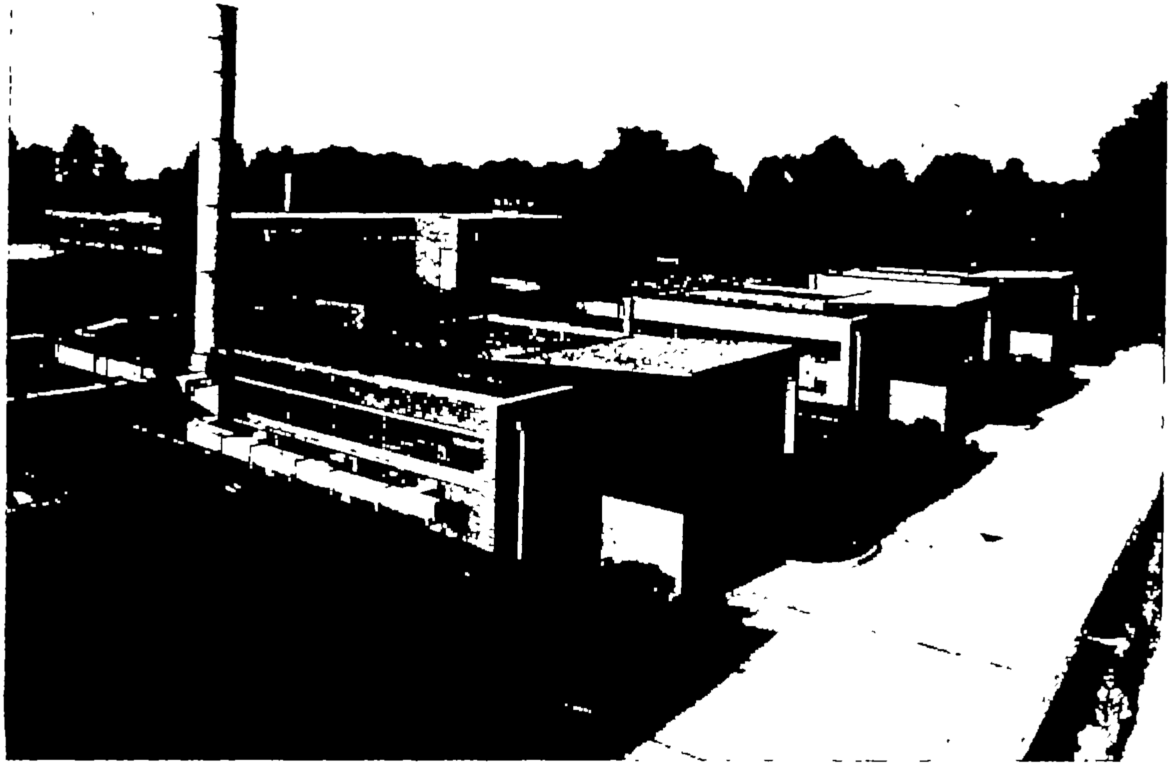

Fig. 1. A general view of the laboratories showing the new block in the background

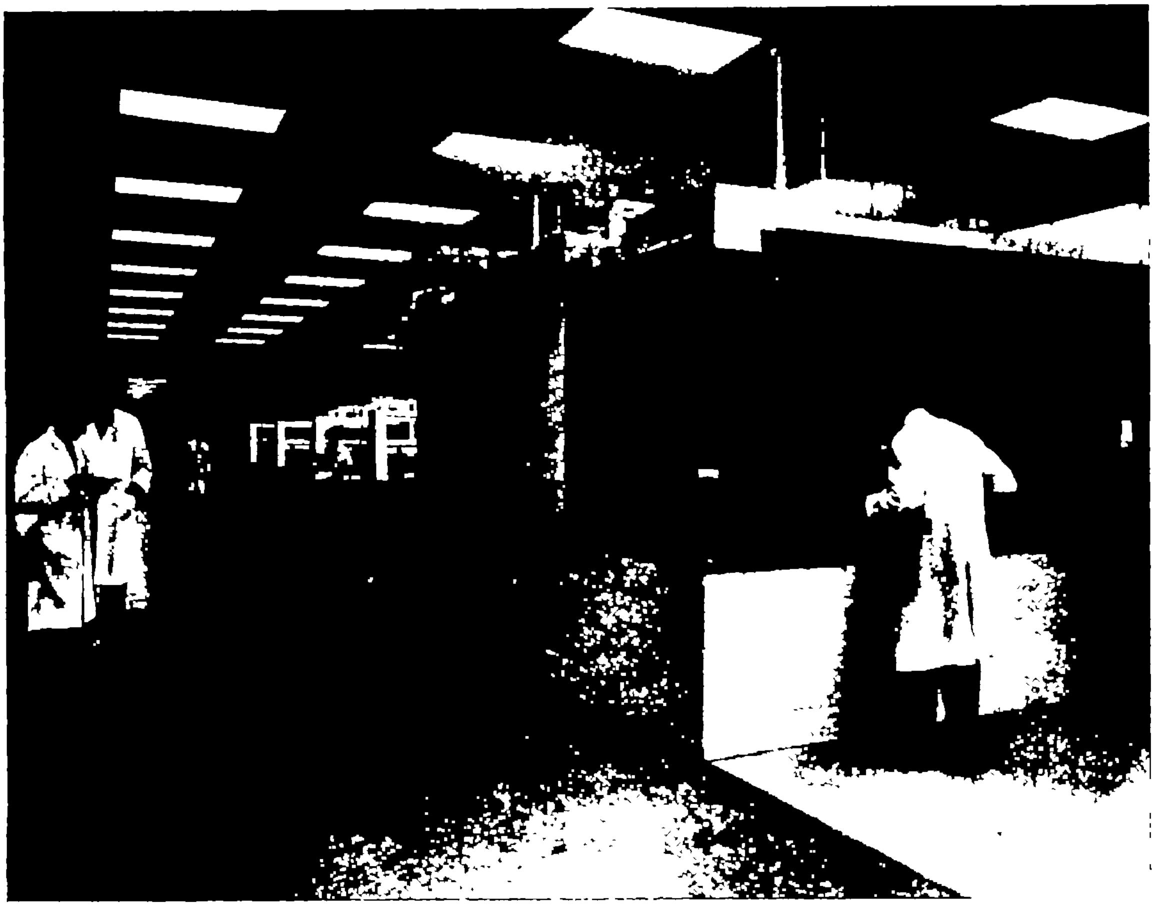

Fig. 2. A general view of the isotope laboratory in the new technical building

Sir John Cockcroft, Sir Henry Dale—who opened the first group of isotope-processing laboratories in 1954 (*Nature*, 173, 1067 ; 1954)—Sir Ernest Rock Carling and other distinguished guests.

The new laboratory is to house processes with beta- and gamma-emitting isotopes. It is needed because of the increasing radioactive scale of operations, the greater diversity of radiochemical work and the higher standards of protection that are now in vogue following the latest report of the International Commission on Radiological Protection (1955). Whereas the older plants were shielded for amounts of gamma emitters of ten to fifty curies, the present need is for equipment capable of handling a thousand curies. Also for large amounts of beta emitters, which may not require heavy shielding, it is still necessary to provide for effective containment within 'gloved' boxes and to exercise strict radiological control. A large part of the new laboratory is devoted to this type of work and a versatile system of 'gloved' and 'tonged' boxes has been installed (Fig. 2).

In particular, the facilities for processing fission products are being improved. Caesium-137 and strontium-90 have to be manufactured into the various special forms required by industry, as, for example, sources for industrial radiography and for thickness gauges. There is also a need for more of the 'minor' fission products—promethium, cerium-144, yttrium-90, zirconium and niobium-95. For these purposes a 'hot cave' facility is being constructed to accommodate activities up to one thousand curies of caesium-137. It comprises three inter-connecting compartments which are shielded by three feet of high-density concrete bricks. Vision is obtained through liquid windows of concentrated zinc bromide solution and manipulation within the cells is done with the aid of three pairs of the Argonne pattern of master-slave manipulators. As these caves are intended for chemical work with highly toxic materials, it has been necessary to provide them with enclosed metal liners, each measuring about 7 ft. × 8 ft. × 15 ft., which will be kept under slightly reduced pressure to prevent the escape of radioactive dust. Access to the caves for servicing will be made by the 'captive man suit' technique (Fig. 3).

Labelled Compounds

The demand for some of the less-common isotopes, and particularly for labelled compounds containing iodine-131, phosphorus-32 or sulphur-35, has now grown sufficiently to warrant formal chemical plants for producing them. The number of separate syntheses of labelled compounds (other than carbon-14) has risen to more than five hundred this year, incorporating some twenty different isotopes. There is an increasing appreciation of the value of tracer methods in chemical technology, particularly in the study of such specific chemicals as weed-killers, pesticides, fertilizers, rubber additives and detergents. The use of labelled drugs for determining their mode of action and metabolic fate, and of special compounds as diagnostic aids is also increasing steadily. An interesting recent example (*Nature*, 178, 799; 1956) is a study of the uptake of 'Dapsone' (diamino-diphenyl-sulphone) in the skin and tissues of leprosy patients by using the drug labelled with sulphur-35.

Fig. 3. A 'captive man suit' of plastic is viewed by (left to right) Dr. W. P. Grove, general manager of the Radiochemical Centre at Amersham, Lord Salisbury and Sir Henry Dale

For tracer studies, carbon-14 remains pre-eminent and many new compounds labelled with this isotope have been synthesized recently for use by biochemists and others: more than two hundred compounds are now available from Amersham. The synthesis of generally labelled benzene and toluene has been much improved, and so the simpler aromatic substances are now accessible with ring labelling. Other classes of compound which have recently received attention include the steroids (chloresterol, testosterone, progesterone, oestrone), the carcinogens dibenzanthracene and benzanthracene, specifically labelled sugars (glucose labelled in the 1 or 2 or 6 position, ribose, sorbitol, gluconic acid and glucuronic acid), and several of the amino-acids specifically labelled (DL-tryptophan, 5-hydroxytryptamine and 5-hydroxytryptophan, L-histidine and L-serine).

The standard of labelled compounds is constantly improving. Specific activities are now commonly five to ten millicuries per millimole, compared with one to two millicuries per millimole three years ago, and they may be much higher in exceptional cases. The best samples of carbon-14 carbonate to-day are nearly 50 per cent isotopic abundance, as compared with less than 2 per cent three years ago. The technique of gas-phase chromatography has done much to improve chemical purities, and standards are now generally much higher than has been customary with inactive chemical reagents. In some cases the limit of radiochemical purity is now set by the susceptibility of a compound to decomposition under its own radiation. Techniques for preserving labelled materials against this effect are being studied.

Biochemical methods of labelling are becoming more important. The scale of production of generally labelled sugars by photosynthesis in green leaves and of protein by growing the alga *Chlorella vulgaris* has been increased some ten times, and it is not exceptional to commit a curie of carbon-14 in a single batch. This larger scale of working has led to improved stocks, to a better quality of generally labelled amino-acids, and to useful quantities of certain minor components such as the nucleic acid fractions and lipids.

Human serum albumin iodinated with iodine-131, which has been in regular production since January 1955, is finding increasing application in diagnostic procedures such as the measurement of blood volumes and cardiac efficiencies. It may also have therapeutic possibilities. Another compound of considerable medical interest is vitamin B_{12} labelled with one or other of the cobalt isotopes—cobalt-56, -58 or -60. A process for making radioactively labelled B_{12} has been devised with the co-operation of Glaxo Laboratories and the first product labelled with cobalt-58 will be available in January.

Radiation Appliances

Notwithstanding the great variety and quantity of radioisotopes now produced artificially, the use of natural radioelements has not declined. During the past three years some eight thousand clinical radium needles and 120,000 radon seeds have been manufactured—mainly for British hospitals, but partly exported. The production lines for filling radium containers, which is an unusually delicate and exacting operation, have recently been entirely rebuilt so that all manipulations are now done by remote control and the work is totally enclosed. A new plant has also been installed for producing polonium–beryllium neutron sources which are now in demand industrially for well-logging and for reactor experimentation. Each source usually contains between five and ten curies of polonium.

For beta emitters which are to be used clinically or industrially, the preferred form is in metal foils or plaques, and these are produced with a number of different isotopes — strontium-90, thallium-204, cerium-144, ruthenium-106—according to the beta-ray spectrum required for particular applications. Some eight thousand sources of this kind have been manufactured during the past three years, mainly for thickness gauges and static eliminators. Improved manufacturing techniques make it possible to handle much larger quantities of beta emitters in this way, and a radiating unit containing ten curies of strontium-90 has recently been made for therapeutic use. In collaboration with the Royal Marsden Hospital, special applicators have been designed to fit in contact with the eye, and these are being used for improving corneal grafts and treating certain disorders of the eye.

THE ROYAL SOCIETY

ANNIVERSARY ADDRESS*

By SIR CYRIL HINSHELWOOD, F.R.S.

AWARD OF MEDALS, 1957

Copley Medal: Sir Howard Florey, F.R.S.

PROF. FLOREY has made a number of outstanding contributions to experimental pathology and medical science. He is best known for his work in connexion with the isolation and detailed study of penicillin and its development as a successful non-toxic anti-bacterial agent for use in medical treatment. It is difficult to over-emphasize both the scientific importance and the practical value of this contribution.

He described his earlier work on mucin and its functions in the Croonian Lecture of the Society of 1954. Since then, with his collaborators, he has carried these investigations considerably further, in particular by the development of auto-radiographic methods depending upon the use of sulphur-35. Florey's work on Brunner's glands, in which he determined the nature and mode of their secretion, is considered to be an outstanding contribution to this subject. In his studies of acute inflammation and the development of tuberculous foci in the living animal, he made use of the transparent-chamber technique and of cinematography to clarify the part played by the various types of cells. By using coloured vital dyes he investigated the penetration of substances into tuberculous lesions.

His investigation of the effects of cortisone on cell division in regenerative hyperplasia of the liver and his very recent work on the regeneration of aortic endothelium are also important contributions. In addition, Florey and the workers in his laboratory have continued to work steadily on the discovery, development and mode of action of new antibiotics, including cephalosporin *N*, nisin and micrococcin. In particular, these endeavours have been directed toward the improvement of the chemotherapy of tuberculosis.

All his investigations are characterized by the choice of difficult and worth-while problems and by a fine technique which has usually involved both the development of original methods and the use of methods new to the particular problem.

Royal Medal (A): Prof. W. V. D. Hodge, F.R.S.

Prof. Hodge has for many years established an international reputation as a geometer of the first rank. He is perhaps most widely known as the creator of the theory of harmonic integrals. Since his exposition of this theory, first in a series of papers in the *Proceedings of the London Mathematical Society*, and later in his book, "The Theory and Applications of Harmonic Integrals", the subject has grown rapidly in scope and importance. The book has been described as one of the great landmarks in the history of mathematics in the present century.

In the application of this theory, above all to algebraic geometry, Hodge has played an important part, and has greatly enriched our knowledge of the transcendental theory of algebraic varieties, and revealed new, and unsuspected properties, among which may be mentioned his 'signature theorem'. He has also shown how many of the results obtained from his theory can be extended to manifolds of a type more general than algebraic ones (Kähler manifolds). He has written on a wide range of geometrical topics besides harmonic integrals; among his more notable papers are recent ones dealing with the characteristic classes of algebraic varieties, and has recently made (with Atiyah) an important contribution to the theory of double (and multiple) integrals of the second kind.

Hodge has also worked on the purely algebraic aspect of the subject. His three-volume work (with Pedoe) "Methods of Algebraic Geometry" is one of the most important expository mathematical works recently published in Great Britain.

Royal Medal (B): Prof. F. G. Gregory, F.R.S.

Gregory's work in plant physiology has been dominated by an appreciation of the importance of the responses of the intact integrated organism, and has been of decisive importance for this subject. Early in his career he elaborated a technique which analyses growth in terms of three parameters, the relative growth-rate, the net assimilation-rate and the leaf-area ratio. From variations in these quantities it is possible to assess the primary effects of various environmental factors, and the general technique has been applied with conspicuous success in ecological, physiological and agronomic studies in many parts of the world.

Gregory was a pioneer in studying vegetative growth in a controlled environment. In an investigation based on this technique, he made a detailed examination of the growth of the leaf and produced the first cogent evidence for the operation of a specific chemical stimulant for leaf growth. Since then, he has been particularly concerned with nutritional effects in growth and with the nature of the mechanism that determines the induction of the reproductive phase. The nutritional studies have extended over the past thirty years and they provide the most extensive analysis available of the effects of nitrogen, phosphorus and potassium.

Gregory's studies on the induction of flowering have made him a leading authority on this important subject. He has promoted a series of notable investigations on the low-temperature effect in vernalization and on the day-length effect in photoperiodism. He has shown that short-day-induced *Kalanchoe* may be characterized by a remarkable correlation of a surprising range of phenomena which include flower production, alternative leaf morphology and a biochemical change of induced carbon-dioxide fixation in the dark accompanied by acid production followed by carbon-dioxide release in the light which is accompanied in turn by conversion of acid to carbohydrate. The demonstration of the development of these biochemical changes, and the induction of flowering and other morphological modifications when plants are subjected to the appropriate day-length, is one of the major advances in the complex field of plant morphogenesis.

---

* Delivered at the Royal Society on November 30.

Gregory has also made contributions to the study of leaf-fall, the transport of auxin, transpiration and stomatal movement.

Gregory's indirect influence has been profound, and he has stimulated the interest and activity of many research students who have carried the impetus they received from him to many parts of the world.

Davy Medal: Dame Kathleen Lonsdale, D.B.E., F.R.S.

Dame Kathleen Lonsdale is a pioneer in the field of X-ray crystallography. She joined Sir William Bragg's original team of workers in the early 1920's and made many accurate measurements on the various organic crystals which were at that time being studied in the laboratory. One of her first tasks in this field was of a more mathematical nature, that of working out the consequences of space-group theory in terms of diffraction effects, a task which was completed and published with W. T. Astbury in 1924. The mathematical development has continued to occupy her attention throughout the years, as author and editor.

It is, however, as a careful and accurate experimental investigator that she is most widely known. The great triumph came in 1928 with her complete elucidation of the structure of hexamethylbenzene. This work established the true geometry of the benzene ring for the first time, and paved the way for all future X-ray studies on the aromatic hydrocarbons.

It has been the simple rather than the chemically complex structures that have generally appealed most to Dame Kathleen, and the problems of crystal physics rather than those of crystal chemistry. Her studies of the thermal vibrations of atoms in crystals have been a continuing interest, and she has made outstanding contributions both in theoretical treatment and in very beautiful experimental work to the subject of the diffuse scattering of X-rays by crystals. Her work on the two types of diamond crystal belongs to the same category. Mention should also be made of her work by the method of divergent-beam X-ray photography on the diamond structure, which has enabled the fundamental lattice constant to be determined with extraordinary precision. The great range of Kathleen Lonsdale's interests are indicated and illustrated in her book "Crystals and X-rays".

Buchanan Medal: Sir Neil Hamilton Fairley, K.B.E., F.R.S.

Sir Neil Hamilton Fairley has carried out much research on diverse aspects of tropical medicine and has made many discoveries which have played a part in eradicating or preventing disease.

His earliest work was on immunity reactions in helminthic diseases. He showed that stable antigens could be prepared from helminths at different stages in their development, including the stages found in intermediate hosts, and that these antigens reacted with antibodies in the serum of infected vertebrates. He devised skin tests and complement-fixation tests for the diagnosis of infection with schistosomes and filaria, which have been of great value in making surveys of infection in different communities.

He has carried out researches which had a significant bearing on the etiology and treatment of sprue, and on the hæmoglobin in blackwater fever. In Egypt in 1941 he played a leading part in introducing sulphonamides in the treatment of bacillary dysentery, and showed that sulphaguanidine cured the potentially fatal type caused by Shiga's bacillus.

His most important work has been on the chemoprophylaxis and chemotherapy of malaria. In 1943 he was made director of the Land Headquarters Medical Research Unit at Cairns, Queensland. Here he built up a unit in which large-scale experiments were carried out in human volunteers on the prevention and cure of malaria. Rigid controls were imposed and new techniques were devised. He was able to prove conclusively that quinine, even in doses of ten grains daily, failed to suppress heavy infections with the sporozoites of *Plasmodium falciparum*. He showed that certain sulphonamides which at that time were being advocated as suppressants were not suitable for the type of malaria then occurring in New Guinea. On the other hand, he found that 'Atebrin' ('Mepacrine'), in doses of 0·1 gm. daily, gave complete protection.

This work led to the introduction of 'Atebrin' suppression, and the incidence of malaria was reduced from 740 per 1,000 in 1943 to 29 per 1,000 in 1945. He also assessed the value of the 4-aminoquinolines and later of 'Paludrine', both for suppression and for therapy.

Apart from these practical findings, his observations have thrown much new light on the life-cycle of the malaria parasite.

Fairley's work has been the basis of all subsequent investigations on malaria suppression and therapy, and in its application has been of incalculable value to the health of all tropical populations.

Hughes Medal: Prof. J. Proudman, C.B.E., F.R.S.

Prof. Proudman has carried out research on physical oceanography over a period of forty-five years. Outstanding among his earlier papers are a series in which the dynamical equations of the tides are used in a form which involves an infinite sequence of discrete co-ordinates. During the past ten years, his main achievements are the writing of a book, "Dynamical Oceanography", published in 1953, and his researches on the interaction between tides and storm-surges in estuaries.

In his work on storm-surges he was the first to obtain definite and applicable results on the dynamical interaction between tide and surge. He has obtained precise results for the two cases in which the combination of tide and surge in an estuary is (1) a progressive wave, and (2) a standing oscillation. Defining an 'apparent surge' as the excess of the disturbance of sea-level over that of the predicted tide, and taking a surge at the mouth of an estuary to be determined by the sequence of meteorological conditions over the sea, his chief results may be expressed in terms of the apparent surge at a place up an estuary due to a given range of tide and a given sequence of meteorological conditions over the sea. In the case of a progressive wave, the maximum apparent surge is less when it occurs at the time of tidal high water than when it occurs at the time of tidal low water, while in the case of a standing oscillation, the exact opposite holds. But both for a progressive wave and for a standing oscillation, the maximum apparent surge is greater when it occurs three hours before tidal high water than when it occurs three hours after tidal high water. These results have application to the incidence of coastal flooding.

Proudman's book is the only one on dynamical oceanography in the English language. In a review of it by a leading dynamical oceanographer there occurs the phrase "Publication of this splendid volume makes one feel that oceanography has at last come of age".

The year which is now closing has been eventful, and I can only mention a few of the many things which have made it so. The Society has had the honour of enrolling H.M. Queen Elizabeth, The Queen Mother among its Fellows. The International Geophysical Year has been successfully inaugurated, and we are grateful to H.R.H. Prince Philip, who in his capacity as a Fellow of the Society gave so auspicious a send-off to this great international scientific adventure. The spoils of the adventure itself are being accumulated, but their evaluation is for the future. It is impossible, however, to pass over in silence the successful launching by our Russian scientific friends of the first artificial Earth satellites—an event which, whatever else it betokens, marks the opening of a new era in human history.

On the personal side there are two matters to which I should like to refer. The first is the award of the Nobel Prize in Chemistry for 1957 to one of our Fellows, Sir Alexander Todd, for his magnificent work in organic chemical synthesis. The other I do with a different kind of feeling, since it is the retirement from the post of secretary on the physical side of Sir David Brunt, who for nine years has filled the office with distinction, and made upon it all the impress of his vivid and energetic character. The Society has very much to thank him for, and I should like to place upon record our most sincere gratitude.

To Dr. D. C. Martin and the staff here, few save the officers can know quite fully—though many know in very varied ways—how much we all owe. It is meet that the president should speak of this to-day, and I hope my words will be noted by those about whom they are most sincerely spoken.

But in the words once made famous by one of our Fellows whose birthday it is to-day, "each to his task". The president by tradition must offer you some scientific reflexions on his own account, however much this involves a departure from the higher themes.

SOME OBSERVATIONS ON THE MECHANISM OF CHEMICAL REACTIONS

In the complexity and elaboration of modern scientific work, the question should occasionally be asked as to the pattern which it all makes. To do this for the whole of science would be an almost superhuman task, but even within the confines of more limited fields the effort is both necessary and revealing. Perhaps I may now attempt a brief elaboration of this theme in relation to a branch of chemistry which has occupied a good deal of my own time over the years and which deals with the intimate mechanism of chemical transformations.

In some ways it is a highly specialized and even abstruse subject, yet it illustrates in its own way a general type of evolution.

Knowledge is pursued for two ends, for power and for understanding. Fortunately for those who believe with the preacher that wisdom is better than strength, the two ends are inseparable. Nobody who has witnessed the developments of the plastics industry, of internal combustion, the production of organic fine chemicals and drugs, or who has seen the many ways in which knowledge of the working of living cells is of value in practical investigations, can fail to realize how fruitful has been the analysis of chemical mechanisms. Nor can those who have studied such mechanisms fail to be impressed and perhaps disconcerted at their luxuriant diversity.

Yet what the true seeker after knowledge in his heart desires is some simple design which he feels must underlie the facts. Nearly a century has gone to the seeking of it. The search for principles which are æsthetically satisfying seems often frustrated by the complexity of Nature, and the conflict between imagination and austere regard for truth seems often to result in the passage of scientific theories through three stages. The first is that of gross over-simplification, reflecting partly the need for practical working rules, and even more a too enthusiastic aspiration after elegance of form. In the second stage the symmetry of the hypothetical systems is distorted and the neatness marred as recalcitrant facts increasingly rebel against conformity. In the third stage, if and when this is attained, a new order emerges, more intricately contrived, less obvious, and with its parts more subtly interwoven, since it is of Nature's and not of man's conception.

The problem of chemical mechanisms has certainly passed through two of these stages. Is there perhaps hope that it is entering the third ?

The major questions of chemical kinetics can be recapitulated in uncomplicated terms. Matter is largely not in equilibrium. What principles govern the inevitable passage towards it ? This is a clear-cut question. To what extent do the answers correspond ?

The very broad lines are set by the principles of energy and entropy. The molecules of a chemical system are in a trough of energy from which they need to be lifted to a transition state of higher energy before they proceed to reaction. The necessary energy is the activation energy, E, derived from the dependence upon temperature of the rate constant, $\boldsymbol{k}$, by the famous Arrhenius equation $d \ln \boldsymbol{k}/dT = E/RT^2$ or $\ln \boldsymbol{k} = A \exp(-E/RT)$.

Since the molecules must pass from an average to a transition or activated state in the reaction, the rate constant can be envisaged as the product of two terms, one dependent on an equilibrium between the transition-state structures and the average structures, the other measuring the rate of passage from the transition to the final state.

By standard thermodynamics an equilibrium constant is related to a free-energy change, and from the connexion between free energy, total energy and entropy follows a well-known formula expressing the rate constant as a product of an entropy term and an energy term,

$$\boldsymbol{k} = (\boldsymbol{k}T/h)\{\exp(\Delta S^*/R)\}\{\exp(-\Delta H^*/RT)\}$$

where ΔH^* is identifiable (nearly) with the activation energy.

In the general expression for a rate constant, $\boldsymbol{k} = A \exp(-E/RT)$, the logarithm of A is a measure of the so-called entropy of activation, and E is the energy needed to take the molecules as it were to the point of no-return : A defines the probability, in respects other than the concentration of energy, that they should reach there. Thus many of the subtler details of chemical kinetics appear as a reflexion of the great primordial conflict of energy and entropy, order and disorder.

Chemical reactions generally are resolved into simple steps involving, with rare exceptions, one or two molecules only, and the major problems relate, first, to the character of the individual bimolecular and unimolecular steps, and secondly, to the mode of concatenation of these steps into the complete sequence. Each of these various matters has passed through the early stage of over-simplification. A naïve theory of bimolecular reactions served its turn, a primitive theory of unimolecular reactions had its vogue and a rather idealized notion about the sequence of steps in reaction mechanisms as a whole led to the idea that chain reactions involving free radicals must be sharply differentiated from the transformations due to molecules alone.

I shall refer only very briefly to the theory of bimolecular reactions. It began with a fine excess of simplicity on the basis of examples in which the entropy factor could be calculated simply from the probability of collision, $k = Z\exp(-E/RT)$, where Z is the collision number in the appropriate units. The constant A then has a value of about 5×10^{11} l.mole^{-1}sec.$^{-1}$. But examples soon appeared where it ranged from this figure down to one about 10^{-8} times smaller, and others where the entropy factor showed an intriguing functional correlation with the energy factor itself. In some simple reactions the entropy factor has lately been calculated, by Ingold and his collaborators, on the basis of a plausible model of the transition state. But it is premature to say that the essential scheme of things is yet clear.

It is, however, the unimolecular reaction which, on the whole, has been the subject of the most interesting evolution of ideas. In this kind of reaction, molecules receive energy in collisions, and after doing so remain in undisturbed isolation long enough for a considerable redistribution of energy to occur within them. The internal degrees of freedom of the molecule constitute its own energy reservoir from which, at the right moment, the amount necessary for the chemical transformation is drawn. The method by which this draft is made has, I think, a certain mystery about it, as will appear. The state of affairs described has long been represented by the following scheme:

$$\begin{array}{c}\text{normal}\\\text{molecules}\end{array}\ \underset{\substack{1'\\(\text{collisions})}}{\overset{1}{\rightleftharpoons}}\ \begin{array}{c}\text{activated}\\\text{molecules}\end{array}\ \xrightarrow{2}\ \text{products} \qquad (1)$$

At low-enough pressures the rate-determining step must be the transfer of energy by collision, and at high-enough pressures this is replaced by the rate of transformation of the activated molecules, the rate constant k then attaining its limiting value. So far so good. But three major questions have excited attention, and are currently debated: First, what is the limiting value of k? Secondly, does the above scheme adequately express the functional dependence of rate on pressure? Thirdly, what exactly happens in the successive stages of the sequence depicted?

The plausible assumption has usually been made that the decisive chemical act consists in the concentration of a critical energy, E, into one bond the rupture of which entails the transformation of the molecule. This hypothesis leads to the conclusion that the constant A is of the order of magnitude of a molecular vibration frequency, so that $k \sim \nu\exp(-E/RT)$, as follows roughly from general reasoning and in more detail from the exact calculations of Slater. The value of the entropy factor for the unimolecular reaction should be of the order 10^{13}, as indeed it sometimes is; the utility of the naïve picture being thereby in a measure vindicated. But lately a continually growing number of examples have been found where it is significantly and even markedly higher.

Greater entropy of activation means less definition of the transition state, which is specified less and less accurately as the constant A increases beyond the value of about 10^{13}. If the unimolecular reaction occurs in solution, a large release of solvent molecules initially bound in a solvation complex could account for the increased entropy term; but for a reaction in the gas phase the explanation must be sought elsewhere. When the entropy constant A is about the same as a bond vibration frequency it means, as has been said, concentration of energy into a single bond. If the very much greater values are to be believed, then much less restricted distributions must be admissible in the specification of the transition state. If every possible distribution of a total energy E among s degrees of freedom counted equally for this purpose, then the entropy factor ν would be multiplied by a combinatory factor,

$$\frac{(E/RT)^{s-1}}{(s-1)!} + \frac{(E/RT)^{s-2}}{(s-2)!} + \ldots + 1$$

which can assume magnitudes of several powers of ten, and easily explain all the experimental findings.

In the pyrolysis of paraffins, A has sometimes about the ideal value but in a good many examples is several powers of ten higher. The decomposition of di-*t*-butyl peroxide gives $10^{15.6}$. For a series of mercury dialkyls and mercury diphenyl, various observers have found values rising steadily with change in structure from 3×10^{13} to 10^{16}. For various thermal decompositions of compounds of the type R_2X with a relatively weak $R-X$ bond, factors ranging from 10^{14} to 10^{17} have been recorded (Clark and Pritchard). In the case of the mercury alkyl compounds the suggestion has been made that the high values are connected with a mechanism in which two Hg—R bonds are broken simultaneously. Hydrocarbon pyrolysis indeed involves the simultaneous rupture of a C—C bond and a C—H bond.

The steady accumulation of results gives increasing weight to the idea that chemical transformation is possible from a wider range of states than the simple theory supposed. This conception is not without its difficulties. When more than one degree of freedom is concerned in the activation process, it will not do merely to postulate a separately specified amount of energy in each. What is needed is a given sum total with no conditions about the sharing between them. Otherwise there would be no combinatory factor to magnify the entropy term. The theoretical implications of the pooled energy are highly significant.

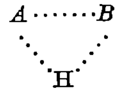
This blurring of the definition of the transition state is the first elaboration of the simple pattern. New complexities are revealed by the fact that there are alternative fates for a decomposing molecule. Sometimes it yields only saturated molecular fragments and the transformation comes to an end. Sometimes it yields free radicals which initiate long chains. Sometimes, however, it would seem, it may yield both.

In the search for simplicity we might well have expected the two mechanisms to be sharply separated, but evidence is accumulating that they are not. Moreover, although in a chain reaction an initial thermodynamic fluctuation is propagated, paradoxically this does not lead to a specially favourable entropy factor, as a simple calculation shows (Appendix 1). The high values of A previously referred to cannot be explained by chain reactions: nor have we any reason to say in advance whether the chain or the molecular mode should predominate. The rate constant of a chain reaction is a composite quantity representable as the product or quotient of unimolecular and bimolecular constants belonging to the various individual steps, and the order of magnitude of the overall entropy can easily be shown to equal in order of magnitude that of a single unimolecular or bimolecular reaction (or something in between). The length of the chain is governed essentially by the fact that the very large activation energy of the initial step appears in the final expression divided by a factor of two. Thus, a long chain reflects not a favourable entropy situation but a greatly lowered activation energy.

A reaction of the general chemical form

$$ABH \longrightarrow AH + B$$

often occurs by a chain mechanism in which initially a bond is ruptured with absorption of energy E_1. The effective activation energy of the whole process, however, works out at $\frac{1}{2}E_1 + \Delta$, where Δ is in general a much smaller term. The same reaction products may be formed by a molecular process through the transition state



without liberation of radicals. Although, unfortunately, the present resources of valency theory do not permit the calculation of the activation energy E_{mol}, this value is evidently much smaller than E_1, and whether E_{mol} is greater than or less than $\frac{1}{2}E_1 + \Delta$ is a nicely balanced question.

Thus, neither entropy nor energy considerations decide clearly whether the chain mechanism or the molecular mechanism predominates, or whether both compete. (One general consideration operates in favour of the non-chain mechanism. At or below atmospheric pressure, $A_{\text{uni.}}$ is greater than $A_{\text{bi.}}$ in the ideal case. The common deviations of $A_{\text{uni.}}$ are upwards by several powers of ten, while those of A_{bi} are downwards. Since A_{chain} involves factors of the type $A_{\text{bi.}}$, there is good chance that the entropy factor of the chain reaction may even be considerably less favourable than that of its molecular competitor.)

Corresponding to the ambiguous state of the theory, the experimental situation provokes some differences of opinion. It is, however, I think becoming increasingly difficult to do justice to the whole mass of facts without accepting the conclusion that in reactions such as the decomposition of paraffins or of ethers, chain reactions and molecular reactions do compete on more or less equal terms.

There are, then, alternative outcomes to the process of activation, and, as we have seen, there may be a sort of spectrum of activated states. Nor is this the end of the story. The final elaboration is provided by the facts about the dependence of rate constants on the pressure, whether of the reacting substance itself or of added foreign gases. In the scheme already given (scheme 1), the activation process (1,1′) is dependent on collisions, while the transformation of the activated molecules is spontaneous. The consequence is a gradual and continuous rise of the rate constant, k, with pressure from zero up to a constant limiting value. A change in the direction of the curve giving k as a function of pressure occurs where one rate-determining process supersedes the other.

Now the form of this curve has long been a subject of discussion, and appears to be a good deal less simple than was at first thought. In particular, certain examples show not one but two, or even three, changes of direction. These are most probably to be interpreted as indications of yet other potentially rate-determining steps in the whole train of events by which normal molecules are converted finally to products.

The piecing together of a complex mosaic of observations seems to suggest the following scheme:

$$\begin{array}{c}\text{normal}\\\text{molecules}\end{array} \underset{1'}{\overset{1}{\rightleftharpoons}} \begin{array}{c}\text{molecules with}\\\text{sufficient store of}\\\text{energy}\end{array} \underset{2'}{\overset{2}{\rightleftharpoons}} \begin{array}{c}\text{critically}\\\text{activated}\\\text{molecules}\end{array} \xrightarrow{3} \text{products} \qquad (2)$$

to which must be added a complete parallel sequence, corresponding at each stage except that in the end there emerge not saturated molecules but free radicals to propagate a chain reaction. (The evidence on which this view of things is based is given in Appendix 2.)

One factor which tends to unify the scheme, while at the same time providing for the striking apparent contrasts between individual examples, and yielding valuable experimental clues to what is happening, is the fact that every step of these sequences is subject to varying degrees of disturbance by the force fields of other molecules. In other words, communication of energy, redistributions of energy and the disruption of activated molecules are all specifically modifiable by collisions, with the result that the dependence of the rate on the pressure, whether of the reacting substance or of added foreign gases, is curiously complicated and puzzling, yet, it seems, always falls within the scope of the general mechanism outlined.

Do the rough fragments thus unearthed fit together into an intelligible design? This is a matter of opinion, but I think they do begin to do so.

The activated state is sometimes ill-defined in that a given total energy may be made up in many ways. Perhaps then this very fact makes more natural the occasional intervention of an extra step before the final crisis in the existence of the molecule. What this new step consists in is not at all certain. But suppose that the electrons of a bond uncouple to give the analogue of a triplet state. This process would not be describable by the crudely mechanical model of the primitive theories. It would occur when the total energy balance was correct and it would be sensitive to the perturbations of the fields of colliding molecules. The normally high energy of promotion to a true triplet state might be greatly reduced by compensating interactions between atoms in the bonds about to be formed.

According to this picture, the molecule in the last phase before decomposition would consist of radicals held together by less than the normal chemical bonds. Whether these radicals escape from one another to initiate a chain or whether they satisfy their affinities by an internal shift of atoms becomes a delicately balanced matter, and largely an affair of total energy. Qualitative differences between the radical reaction and the molecular reaction would tend to vanish and the essential similarity of the two main sequences would be explained. The molecular reaction itself could be envisaged as a kind of internal chain reaction.

If these reflexions should prove to have any validity, the system would regain something of the symmetry it seemed to have lost. It would have indeed a less obvious kind of order, and one allowing room for much diversity of detail but within an essentially uniform framework.

The foregoing may have strayed rather far into the technical details of physical chemistry, but the theme itself required the reference to a set of facts in some confusion. Examples might be chosen from many other fields.

Subatomic physics had its primitive period when plausible interpretations of many important phenomena were provided by the simple idea of a nucleus containing protons and electrons. The simplicity has certainly vanished, and has been succeeded by the phase of complications and contradictions. But the third phase may well be at hand.

Many examples could be quoted from biology and indeed from outside the natural sciences. Men and angels are no longer separate creations, and neither statesman nor ecclesiastic, nor man of science either, dares maintain the crude simplicity of this antithesis. Yet their true relation is still far from clear. To find it is a major need.

Perhaps in these reflexions I have built too much upon some trivial observations, exaggerating their importance and over-straining the analogies which they suggest. But to reflect on the background, the setting and the general implications of the work we do is, I trust, consistent with the philosophical temper with which the Society began and which I like to think it will long preserve.

APPENDIX 1

A common type of chain can be represented by the general scheme :

$$ABH \rightarrow A + BH \qquad (1)$$

$$\overset{(n)}{ABH} + A \rightarrow \overset{(x)}{AB} + AH \qquad (2)$$

$$AB \rightarrow \overset{(y)}{A} + B \qquad (3)$$

$$A + \overset{(y)}{AB} \rightarrow ABA \qquad (4)$$

If steps (2) and (3) are repeated many times the net result is

$$ABH \rightarrow AH + B$$

with minute amounts of ABA from (4) and of H_2 from the decomposition of BH.

In the steady state

$$dx/dt = k_1 n - k_2 n x + k_3 y - k_4 x y = 0$$

$$dy/dt = k_2 n x - k_3 y - k_4 x y = 0$$

whence $$x = \frac{k_1 k_4 + (k^2_1 k^2_4 + 8 k_1 k_2 k_3 k_4)^{1/2}}{4 k_2 k_4}$$

If $k_2 k_3 \gg k_1 k_4$, as it must be for a long chain,

$$x \sim (k_1 k_2 k_3 k_4)^{1/2} / \sqrt{(2)} k_2 k_4$$

The reaction rate is $k_2 x n$, so that

$$k_{\text{chain}} n = \left(\frac{k_1 k_2 k_3}{2 k_4}\right)^{1/2} n$$

k_1 and k_3 are characteristic of unimolecular reactions and may be written

$$k_1 = A_{\text{uni.}} \exp(-E_1/RT) \quad \text{and} \quad k_3 = A_{\text{uni.}} \exp(-E_3/RT)$$

A_1 and A_3 being assumed to have the standard value $A_{\text{uni.}}$

Similarly,

$$k_2 = A_{\text{bi.}} \exp(-E_2/RT), \; k_4 = A_{\text{bi.}} \exp(-E_4/RT)$$

Thus

$$k_{\text{chain}} = A_{\text{chain}} \exp(-E_{\text{chain}}/RT) = \left(\frac{A_{\text{uni.}} A_{\text{bi.}} A_{\text{uni.}}}{2 A_{\text{bi.}}}\right)^{1/2} \exp(-E_{\text{chain}}/RT)$$

where $$E_{\text{chain}} = \tfrac{1}{2}(E_1 + E_2 + E_3 - E_4)$$

and $$A_{\text{chain}} = A_{\text{uni}} / \sqrt{2}$$

Apart from the trivial factor $1/\sqrt{2}$, the entropy factor of the chain reaction is therefore that of an ordinary non-chain unimolecular reaction.

The chain-length is given by k_{chain}/k_1. That it may be considerable is almost entirely due to the fact that $E_2 + E_3 - E_4$ is $\ll E_1$, so that the ratio is mainly determined by $\exp(-\tfrac{1}{2}E_1/RT)/\exp(-E_1/RT)$.

Similar results are found for calculations with other types of chain.

APPENDIX 2

In quite varied examples the curve representing k as a function of initial pressure shows more than one region where the change of slope indicates the replacement of one rate-determining process by another (pyrolysis of paraffins, decomposition of nitrous oxide). This can be accounted for by the introduction of the pair of processes 2 and 2′ of scheme 2. Furthermore, the variations of k with the pressure of the reacting gas or of added foreign gases are such that the best explanation seems to be provided by the assumption that the different gases intervene specifically and in varying degrees in processes 1, 2 or 3, according to the particular reaction. In the decomposition of ether, for example, the molecular reaction left after the suppression of chains is characterized by a value of k which exhibits an initial rapid rise with the pressure, either of the ether or of added hydrogen, and then a rapid reduction in the rate of increase as though a limit were being approached. No limit, however, is observed, but a steady and almost linear increase continues at a much slower rate over a wide range. In contrast with this, addition of many inert gases to the ether causes an initial increase in k to steady limits, well below values which can be reached by raising the pressure of the ether itself (G. R. Freeman). Similar phenomena are met with in the pyrolysis of paraffins, and in the decomposition of di-*t*-butyl peroxide (F. R. Birss). On the other hand, various foreign gases added to nitrous oxide give initial rapid increases in k followed by long-continued and slower rises of a nearly linear kind.

NEWS and VIEWS

Anthropology at the Australian National University: Prof. J. A. Barnes

Prof. J. A. Barnes has been appointed to the chair of anthropology in the Research School of Pacific Studies, formerly occupied by the late Prof. S. F. Nadel. Prof. Barnes, who will take up his new post in June, 1958, graduated from the University of Cambridge and received a doctorate of philosophy from the University of Oxford. In 1951 he was awarded the Wellcome Medal in Anthropology. Before going to Australia in 1956, to the chair of anthropology in the University of Sydney, Prof. Barnes had occupied posts as research officer with the Rhodes-Livingstone Institute; lecturer in the Department of Anthropology, University College, London; Fellow of St. John's College, Cambridge; Simon Research Fellow, University of Manchester; and reader in anthropology in the London School of Economics. Prof. Barnes' research has ranged widely, from the analysis of Ngoni social and political structure through the study of divorce rates in simple societies to a study of a Norwegian fishing parish. His book, "Politics in a Changing Society: A Political History of the Fort Jameson Ngoni", is both a historical study of an African people and a sociological analysis of changes in social structure. The Norwegian study makes use of the techniques of social anthropology in a sophisticated Western community.

British Internal Combustion Engine Research Association: Dr. W. P. Mansfield

Dr. W. P. Mansfield has been appointed to the post of director of research of the British Internal Combustion Engine Research Association, Slough, with effect from March 1, 1958, in succession to Engineer Rear-Admiral D. J. Hoare, the first director of the Research Association, who is retiring. Dr. Mansfield, who is at present chief research engineer of the Association, graduated in engineering in the University of London in 1933. He was awarded the degree of Ph.D. in 1954 for his work on the scavenging process in two-stroke engines. He carried out research on gas and dual-fuel engines with the Erren Engineering Co. during 1934–37. In 1937 he joined Sir W. G. Armstrong Whitworth and Co. (Engineers), Ltd., Slough, as research engineer, and was engaged in research and development of two-stroke engines. In 1944 Dr. Mansfield was appointed by the British Internal Combustion Engine Research Association to take charge of its research section.

National Science Foundation, Office of Scientific Information: Dr. B. W. Adkinson

Dr. Burton W. Adkinson, director of the Reference Department of the Library of Congress, has been appointed head of the Office of Scientific Information of the National Science Foundation. His service with the Library of Congress began in 1945 when he was appointed assistant chief of its Map Division. He became head of the Map Division in 1947, and the following year assistant director of the Reference Department. Before going to the Library of Congress, Dr. Adkinson was assistant chief, Map Intelligence Section, Office of Strategic Services, during 1944–45; research associate and later assistant director of the Board of Geographic Names, during 1943–44; and regional research assistant in the Office of the Geographer, during 1942–43. Prior to his association with the United States Government, he lectured in geography at the University of Washington, and earlier, in climatology at Clark University. He was a teacher in the public schools of Washington State during 1929–39. Dr. Adkinson is a graduate of the University of Washington, and received the degree of Ph.D. in geography from Clark University in 1942. He is the author of papers in fields of geography, glaciology and cartography.

Royal Society: Officers

At the anniversary meeting of the Royal Society on November 30, Sir Cyril Hinshelwood was re-elected president. Prof. W. V. D. Hodge, Lowndean professor of astronomy and geometry in the University of Cambridge, was elected physical secretary in succession to Sir David Brunt. The other officers re-elected for the ensuing year were: *Treasurer*, Sir William Penney, director of the Atomic Weapons Research Establishment, Aldermaston; *Biological Secretary*, Sir Lindor Brown, Jodrell professor of physiology at University College, London; and *Foreign Secretary*, Dr. H. G. Thornton, lately head of the Department of Soil Microbiology at Rothamsted Experimental Station. Other members of Council elected were: Brigadier J. S. K. Boyd, lately director of the Wellcome Laboratories of Tropical Medicine; Dr. G. E. R. Deacon, director of the National Institute of Oceanography, Wormley; Sir Charles Dodds, Courtauld professor of biochemistry, University of London; Prof. N. Feather, professor of natural philosophy, University of Edinburgh; Prof. G. Gee, Sir Samuel Hall professor of chemistry, University of Manchester; Dr. H. Godwin, reader in quaternary research, University of Cambridge; Prof. R. D. Haworth, Firth professor of chemistry, University of Sheffield; Sir Bryan Matthews, professor of physiology, University of Cambridge; Prof. W. T. J. Morgan, deputy director of the Lister Institute and professor of biochemistry in the University of London; Prof. D. M. Newitt, Courtauld professor of chemical engineering, Imperial College of Science and Technology; Prof. A. C. Offord, professor of mathematics at Birkbeck College, University of London; Prof. R. E. Peierls, professor of mathematical physics, University of Birmingham; Prof. L. Rosenhead, professor of applied mathematics, University of Liverpool; Lord Rothschild, assistant director of research, Department of Zoology, University of Cambridge; Dr. K. M. Smith, director of the Virus Research Unit (Agricultural Research Council), Molteno Institute, University of Cambridge; Prof. L. R. Wager, professor of geology, University of Oxford.

Scientific and Industrial Research in Britain

Several questions about scientific and industrial research have been asked in the House of Commons in recent weeks. Replying to Sir Wavell Wakefield, Mr. H. Nicholls, Parliamentary Secretary to the Ministry of Works, representing the Lord President of the Council, said that solar radiation is not at present being used in Britain to produce high temperatures for research purposes. Replying to a question from Mr. A. Allen regarding arrangements being made to increase the availability of translations of Russian scientific papers and books, Mr. Nicholls said that the Department of Scientific and Industrial Research has started a comprehensive collection of translations of Russian scientific and technological literature in all fields, except clinical medicine. This material is being made available through the Department's Lending Library Unit, which also lends Russian technical literature to research organizations, industrial organizations, universities and colleges and Government departments. Microfilms of several thousand translations of Russian scientific papers have also been ordered from a library in the United States. In conjunction with the Scientific Library and Technical Information Committee of the Advisory Council on Scientific Policy, the Department is considering what additional measures are required to improve the volume of translations of Russian scientific papers and books being undertaken in the English-speaking world.

In answer to further questions, Mr. Nicholls said that the Department has undertaken to consider proposals for contracts designed to promote developments of particular ideas or in particular industries, in the public interest, when these are outside the scope of, or unacceptable to, the National Research Development Corporation. The suggestion in the last annual report of the Advisory Council on Scientific Policy that British firms might make arrangements to interview British scientists and engineers in North America has been referred for consideration to the appropriate committees of the Federation of British Industries, and the Department of Scientific and Industrial Research is considering what action could be taken to encourage more British scientists and engineers to undertake postgraduate work in Europe.

Progress in Technical Education

ANSWERING questions in the House of Commons about technical education on November 28, Mr. Geoffrey Lloyd, Minister of Education, said that since the publication of the White Paper in February 1956, eighteen new technical colleges and seventy-nine major extensions of existing colleges have been started. In addition, final plans for five more new colleges and seventeen further major extensions with a total value of £5 million have been approved, and sketch plans prepared for a further fourteen new colleges and twenty-eight major extensions, to the value of more than £8 million. There were 31,700 part-time day students of higher technology in Britain in 1955–56.

Nigerian Geographical Journal

IT is a sign of geographical progress that the geography of regions that were literally being explored by Europeans only two or three generations since is now being written from the inside. Europeans and Americans may still write books entitled "Africa" and they will still have value because of their external and comparative points of view. But a day must come when the geography of Africa is written from within, and of that day the first number of *The Nigerian Geographical Journal* is a harbinger (1, No. 1; April 1957. Pp. iv+20. Per volume of two numbers, 15*s*. Ibadan: University College, 1957). Its first function is to be a means of communication, giving the members of the two-year-old Nigerian Geographical Association—still fewer than a hundred all told and scattered over a vast territory—a sense of community and common endeavour. Its second is to afford a means of self-expression for Nigerian geography. Of the articles in this issue the first is, understandably enough, the text of an address given by Prof. B. J. Garnier, of the Department of Geography, University College, Ibadan, to the members of the Association on the importance of their subject. Another, by a Nigerian teacher in a Government secondary school, says some homely and helpful things about geography teaching to his fellow-teachers. Of more interest and significance, however, are two articles that describe parts of Nigeria. The longer and more sophisticated of these is from the sympathetic pen of the vice-principal of the Government Teacher Training College, Ibadan; the shorter is a description of his home district by a Nigerian undergraduate. Here is the beginning of an African geography written by those who alone can truly understand the human element in the man–land equation in Africa.

British Museum (Natural History)

AMONG the more important recent acquisitions to the British Museum (Natural History) is a gift by Mrs. P. Harwood of the very fine collection of British insects amassed by the late Philip Harwood, formerly of Kincraig, Inverness-shire, and latterly of Wimborne, Dorset, during a life-time devoted to specialized collecting. In addition to his own collecting there are many specimens from the collections of his father and his brother. It was Mr. Harwood's special wish that the Hymenoptera and the Hemiptera should go to the British Museum and the remainder to the University Museum, Oxford. The collection has not yet been counted, but it is estimated that it contains many thousands of specimens, including some of very rare and valuable species which will fill long-vacant gaps in the Museum's collections, and many individuals on which were based the first records of the occurrence in the British Isles of the species concerned.

The Botanic Gardens, Singapore

AN encouraging account of the work done at the Botanic Gardens, Singapore, during 1956 has been prepared by the former director, J. W. Purseglove. Besides the usual meteorological records and the extensive activities connected with the herbarium, the staff made many contributions to botanical knowledge through collections and research. One marine green alga, collected at Mersing, was found to be *Acetabularia crenulata*, a new record for Malaysia. Considerable horticultural work was also carried out despite depredations by monkeys and human beings. The former learned to respect the electric fence which was put up around the orchid enclosure; but this did not prevent intrusions by human beings. As a result of thefts it is no longer possible to display valuable orchids in the plant house. The staff continued to advise many schools and other government institutions during the year. Copies of this interesting report may be obtained from the Government Publications Bureau, G.P.O., Fullerton Buildings, Singapore, price 1.50 dollars.

Root Nodules of *Casuarina*

G. BOND has reported that young plants of *Casuarina cunninghamiana* and *C. equisetifolia*, growing in water culture, developed macroscopic nodules in 26–35 days from inoculation, the nodulation being most successful at pH near neutrality and falling off much more rapidly at lower pH than in other non-legume nodule-forming genera. The distinctiveness of the *Casuarina* organism is thus confirmed. The roots springing from the nodule lobes are shown to be characterized by upward growth and in this to resemble remarkably closely the corresponding roots of *Myrica*. Nodulated plants of *Casuarina* are able to grow vigorously in culture solutions free of combined nitrogen, showing that fixation of atmospheric nitrogen occurs, amounting in *C. cunninghamiana* to 50 mgm. per plant during six months of active growth. The evidence indicates that the fixation occurs in the nodules, and that these have exactly the same functional significance as those of legumes (*Ann. Bot.*, N.S., 21, 373; 1957).

Annual Variation of Sporadic Meteors

In a paper on the theory of the annual variation of sporadic meteors (*Pub. Astron. Soc. Japan*, 8, Nos. 3–4; 1956), Tadayoshi Murakami, of the University of Hiroshima, explains that his reduction of the annual variation was undertaken to verify his drift motion hypothesis of interstellar meteoric particles, published under the title "On the Drift Motion of the Interstellar Meteors in the Vicinity of the Solar System" (*Mem. Oriental Astron. Assoc.*, No. 152; 1954). In the present paper the author admits that most of the meteoric particles for sporadic meteors move together with the solar system, the variation being governed mainly by the altitude of the apex of the Earth's way. A comparison between the meteor rate deduced from observation and the altitude of the meteor apex shows that the relation is simple, and a theory is developed to explain this fact. While admitting that there is a discrepancy between theory and observation, it is pointed out that this can be ascribed to the irregular distribution of the density of the meteoric particles. The relation between the number of meteors m_0 and the zenith distance of the meteor apex can be expressed by the empirical formula $m_0 = 12{\cdot}6 \cos \zeta + 6{\cdot}3$, where $76° < \zeta < 104°$. The number of meteors calculated from this formula shows a satisfactory agreement between the observed and calculated variations (*Pub. Astron. Soc. Japan*, 8, 87; 1956). Although the true distribution of meteors is very different from uniform, as shown by the work of Lovell, Prentice, Hawkins and Aspinall, the author contends that, for a first approximation, uniformity of distribution must be postulated, irregularities of distribution being considered in the next step. On this assumption he derives a formula similar to that derived by Davidson (*J. Brit. Astron. Assoc.*, 24, 352; 1914). The value of the heliocentric velocity obtained is 58·5 km./sec., which does not agree with modern determinations of meteor velocities. It is admitted that the subject requires further consideration but the results suggest that there is unevenness of density distribution of meteoric particles.

University News: Exeter

The following appointments in the University of Exeter have recently been made: Mr. A. Stuart, to the newly created chair of geology; Dr. K. E. Grew, to be reader in physics; G. A. Duller, as assistant lecturer in mathematics; Dr. H. P. Mulholland, as senior lecturer in mathematics; D. J. Stone, as lecturer in mathematical statistics; Dr. R. J. Williams, as lecturer in physical chemistry.

Announcements

Sir Solly Zuckerman, Sands Cox professor of anatomy in the University of Birmingham, has been awarded the Cross of Chevalier in the French national order of the Légion d'Honneur.

The Castner Gold Medal of the Society of Chemical Industry has been awarded for 1958 to Dr. R. Holroyd, deputy chairman of Imperial Chemical Industries, Ltd. The Medal was instituted to commemorate the work of Hamilton Young Castner and is one of the Society's senior awards. It is awarded every two years.

Trinity College, Cambridge, offers entrance exhibitions to male students of universities in the British Commonwealth to enable them to read for the degree of B.A. or LL.B., or for a diploma. Further information can be obtained from the Senior Tutor, Trinity College, Cambridge.

The *New Zealand Journal of Science and Technology* is to be replaced at the beginning of 1958 by the *New Zealand Journal of Agricultural Research* (bi-monthly), the *New Zealand Journal of Geology and Geophysics* and the *New Zealand Journal of Science* (both quarterly).

An exhibition of laboratory apparatus and techniques will be held in the College of Science and Technology, Sackville Street, Manchester, on December 18, during 2–8 p.m., and on December 19 during 10 a.m.–8 p.m.

A half-day conference on "Production Control", organized by the Industrial Applications Section of the Royal Statistical Society, will be held on December 13 at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1. The conference starts at 2 p.m. Further information can be obtained from A. N. James, Wynyates, Church Road, Watford, Herts.

The Institute of Physics has arranged a three-day conference on "Nuclear Fuel Cycles", to be held at the Institution of Civil Engineers during January 15–17, 1958. Further details can be obtained from the Institute of Physics, 47 Belgrave Square, London, S.W.1.

The 128th course of six Christmas lectures "adapted to a juvenile auditory" is to be delivered at the Royal Institution on December 28 and 31, 1957, and January 2, 4, 7 and 9, 1958, at 3 p.m., by Dr. Julian S. Huxley and Mr. James Fisher on the subject of "Birds". The lectures will deal with "Birds in the Animal Kingdom", "Birds and Flight", "Birds Past and Present", "Birds Rare and Common", "Bird Migration and Navigation", "Bird Watching". The first lecture will be given by Dr. Huxley and the remaining five by Mr. Fisher. Applications for tickets (juveniles, aged 10–17, £1; adult non-members, £2) should be addressed to the Royal Institution, 21 Albemarle Street, London, W.1.

Erratum. We regret to find that mistakes have occurred in numbering the axes of the graph which accompanied the communication entitled "Vitamin B_{12} in Marine Ecology" by M. R. Droop, in *Nature* of November 16, p. 1041. The ordinate graduations (number of cells per ml.) should be 10^5, 10^6 and 10^7 (reading upwards); the abscissa graduations (vitamin B_{12} (μμgm./ml.)) should be 0·1, 1·0 and 10 (reading left to right) and these numbers should appear immediately below the marks on the horizontal axis.

THE POST OFFICE RESEARCH STATION

THE Post Office Engineering Research Station at Dollis Hill held an open day on September 27, when several hundred visitors from the universities, industry and Government departments were able to see some of the work in progress or recently completed. Some exhibits were of exploratory work, but most were of new apparatus or systems. The contributions made by the Station to several notable developments in telecommunications since the last open day (in 1954) were reflected in the exhibits; only that to the development of electronic telephone exchanges, now being undertaken jointly with industry, was not given prominence.

Submarine telephony was represented by several diverse exhibits, including some of the equipment and techniques used for the first trans-Atlantic telephone cable which had celebrated the first anniversary of the opening of its service a day or so earlier; others were intended for future use. A length of the new light-weight deep-sea cable proposed by the Post Office was exhibited; its cross-section is shown in Fig. 1. The placing of the strength members inside the inner conductor reduces the size and cost of the cable and renders it nearly kinkless. A full-scale deep-sea trial is planned. The technique developed for jointing lengths, by swaging a steel ferrule over the steel strands, retains at least 94 per cent of the intrinsic strength of the cable. Only one repeatered submarine cable is necessary for a system designed by the British Post Office, because the amplifier is so associated with directional filters as to be able to amplify sixty conversations in each direction simultaneously. The complete repeater is bulky and rigid, however, and its laying has hitherto presented difficulties; it cannot be passed over or around the normal laying drums. A method of laying is being developed, in which the repeater by-passes new cable-laying equipment; it will not require the ship to be stopped. It was demonstrated by a scale model in the new hydraulics laboratory, where visitors could see also the large pressure vessels and machinery for testing repeaters and their glands at pressures up to the highest reached on the ocean bed, 6 tons/sq. in. The plant for making the glands which seal the repeater against the ingress of water at such high pressures, and the portable low-voltage X-ray apparatus for inspecting joints and glands were on show. The Station has long undertaken the supply of thermionic valves for submerged repeaters and has recently completed the design of a new valve, which is, mechanically at least, a big advance on earlier types. The heater, a wire helix of rectangular cross-section and electrically double-ended, fits inside a tube of sintered alumina which in turn fits closely inside the platinum core of the cathode. The design of the other electrodes had to take account of the restricted anode and screen grid voltages imposed by the need to limit the overall voltage which has to be applied to the ends of the cable—the repeaters are fed in series from the ends—and had to prevent ions formed in the anode/screen grid space from reaching and damaging the cathode. Only very little mica is used in the valve.

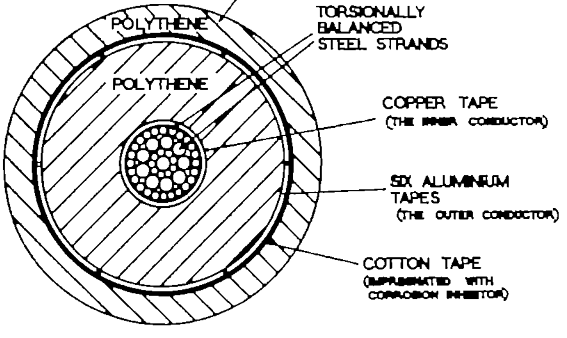


Fig. 1. Cross-section of proposed light-weight deep-sea cable

Work has continued on techniques and equipment for radio communications using frequencies around 4,000 Mc./s. Frequency control has been obtained by extending conventional multiplication to micro-wave frequencies; the starting point is an oscillator with quartz resonator, operating at about 50 Mc./s., and the higher intermediate stages use cavity resonators and triode valves with very close electrode spacings. Long-term stability is better than one part in 10^6 and short-term better than one part in 10^8. For work involving measurements over the band 3,800–4,200 Mc./s. a method of launching signals, aperiodically, at the short-circuited end of a wave-guide has eliminated all controls except that of the frequency of the test oscillator. The joining together of wave-guides of different rectangular cross-sections has been improved by the use of symmetrically stepped transforming sections. A rapid method of measuring the voltage standing-wave ratio in wave-guide, using a rotating loop, was demonstrated; the ratio can be displayed as a function of frequency over a width of band up to 50 Mc./s. A new modulator, electrically balanced but using only one non-linear element, has been developed for frequency changing between the intermediate (70 Mc./s.) and micro-wave frequencies.

The Post Office uses correction by artificial echoes on long-distance television links to reduce the linear wave-form distortions which are not removable by conventional equalization. The standard echo wave-form corrector combines the input signal with an adjustable array of advanced and retarded echoes over a range of 3 microseconds. A new corrector uses doublet, or differentiated, echoes in a novel circuit which enables the range to be extended to suit the requirements for individual links. A unit-block construction provides for extensions in steps of 2 microseconds. The cost and size are much less than those of the standard model. Fig. 2 shows the response, of a 200-mile cable link, to a pulse (sine-squared in shape and of duration one-third microsecond at half amplitude) before and after echo correction.

Big savings have been obtained in the United States by converting amplified loaded cables from four-wire to two-wire working—thereby doubling the traffic handling capacity—following the development of negative-impedance, valve amplifiers having only

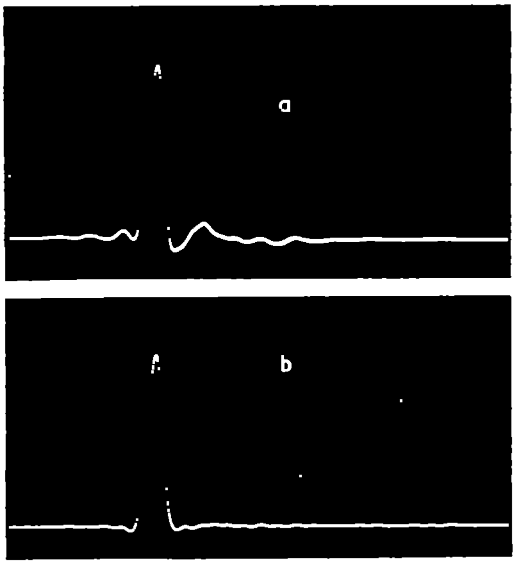

Fig. 2. Response of 200-mile cable link to 1/3-μsec. sine-squared pulse: (*a*) as received; (*b*) after echo-correction

two terminals. But the reduction of attenuation obtained by the insertion of one negative impedor, whether in series or in shunt with the conductors, introduces a serious mismatch and hence loud echoes. If two are inserted at the same point, one in series and one in shunt, and are suitably related to one another and to the cable impedance, echoes can be very much reduced. Such a pair of elements, each using one transistor, have been designed and models are undergoing field trials.

Radio-telegraphy over long distances is being studied in order to minimize the errors in the received messages which arise due to fading, noise and interference. Current practice uses frequency-shift telegraphy, the demodulator in the receiver having a limiter and frequency discriminator; errors arise if signals on either the frequency of the 'space' or that of the 'mark' fade into the noise. The complete message is, however, available on each frequency separately and an improved method of demodulation has been developed which fails only if the signals on both frequencies are simultaneously seriously affected by noise—a rare event because fading is usually frequency selective. Both this study and work on more conventional systems were facilitated by two new equipments, an automatic counter of errors and a fading machine which gives a close approximation to natural fading by combining six signal components in substantially random phase.

Among the larger exhibits was a letter-facing machine, to which attention has been particularly directed since the completion of the design of a letter-sorting machine now going into production. The postal mechanization laboratories were showing also a method of classifying information based on the keying of the first few letters of, say, the name of a town.

Some features of speech interpolation were demonstrated on equipment being built to enable technical studies to be made. The idea uses the fact that at no time during a telephone conversation need both a 'go' and a 'return' channel be provided. If a group on n trunks is available, it may sustain m conversations ($m > n$) without detriment to the conversations, provided terminal equipment can allocate free one-way trunks to speakers the moment they are needed. A practical equipment may need to be complex, but even so it may be economic if, for example, it can effectively double the capacity of a long oversea trunk route.

A sound spectrograph developed for the study of speech transmission systems based on formant coding is capable of analysing any audio-frequency signals. It indicates on 'Teledeltos' paper the energy contained in the recorded signal being analysed in the frequency band $f - \frac{1}{2}\Delta f$ to $f + \frac{1}{2}\Delta f$, where Δf can be selected between 20 and 500 c./s. and f is scanned from zero to a maximum value of 5 kc./s. The level range has been extended, from the 8 db. obtainable with the conventional constant-current excitation of the stylus which marks the paper, to 40 db. by the use of width-modulated pulses of constant amplitude. Among other new apparatus for laboratory use was one for measuring the thickness of tarnish films to within 10 A.

The prize-winning numbers of Premium Savings Bonds are produced by apparatus 'ERNIE' designed at the Station. The key elements, the generators of random digits, are duplicated and their outputs so combined that failure of one does not upset the randomness of the sequences produced. Several electrical and statistical tests are used for checking the randomness. One of the statistical analyses uses some of the conventional tests for randomness, namely, frequency (of individual digits), serial (the frequency of pairs of digits), gap (intervals between successive appearances of the same digit), poker (classification of blocks of four as 'all alike', 'all different', etc.), and coupon collector (size of block containing at least one of each digit). The analysis is carried out automatically on the Pegasus electronic digital computer, the input tapes for the computer being produced automatically (in the Pegasus code) by auxiliary equipment.

A new rolling mill, coupled with the application of powder metallurgy to nickel iron alloys and with closely controlled annealing schedules, has made possible very thin magnetic tapes of consistently high permeability (for example, 40,000). The two work rolls of the four high mill are less than ¼ in. in diameter and are supported along their entire lengths; the plane containing their axes is inclined to that containing the axes of the backing rolls. After the final roll, which may be to a thickness as little as 0·0002 in., the tape is slit in another new machine which uses a flexible disk the cutting edge of which is so shaped and deflected as to provide correct cutting clearances.

The Station has of recent years supplied further quartz resonators to many of the leading observatories of the world. A new resonator—a short bar approximately square in cross-section, with a volume of about 2 c.c. and vibrating torsionally—is under development. It may prove an alternative to the Essen ring, compared with which it is more robust and easier to make; but it has yet to be shown to have quite as high a stability.

Several exhibits dealt with the technology of germanium and components made from it. Sections of junction transistors made by alloying indium to the two faces of a thin wafer showed the accurately plane and parallel junctions obtained when sufficient care is paid to crystal orientation, wetting of the germanium by the indium, alloying and cooling. The kinetics of the gas-phase erosion of germanium are being studied by observations of changes of pressure and weight. Fast junction diodes are being made by heavily doping the germanium with nickel; their performance was demonstrated.

Collectively, the exhibits showed three broad features of progress in telecommunications. First, an increasingly large part is played by electronic engineering, backed by improved materials and new components. Secondly, the role of mechanical engineering is changing as fewer new components have moving parts or require fine clearances; it may lie rather in the machines making the components or assembling them. Thirdly, reliability has to be studied more intensively than ever before, and in good time, if applications of new scientific discoveries are to be successful.

COLOURS AND FLAVOURS

The first of a series of four meetings under the general title of "Some Nutritional and Allied Problems confronting the Food Manufacturers", arranged by the Nutrition Panel of the Food Group of the Society of Chemical Industry, was held in the Society's rooms at Belgrave Square, London, on October 23. These meetings are concerned with food additives, the first dealing with "Colours and Flavours" and the subsequent ones with "Antioxidants", "Emulsifying and Dispersing Agents" and "Chemical Preservatives". Interest in food additives has increased considerably since the end of the War, especially in view of pending legislation in this field, and the first meeting was very well attended.

The first paper at this meeting, under the chairmanship of Dr. F. Aylward (Borough Polytechnic), was read by Dr. B. R. J. Thomas, of A. Boake, Roberts and Co., Ltd., on the "Technological Aspects of Colourings". Dr. Thomas pointed out that the arguments for the use of colours in food were well known and well founded and were accepted by all authorities. The main object of his talk was to deal with the present British list of permitted colours, indicating the problems it raised for the food colour supplier and the food manufacturer. In view of the importance of appearance in the selection and appreciation of a food, the manufacturer is anxious to obtain the right shade for a particular use to which a colour is put, although public taste can be schooled to accept minor departures from previous standards. From the point of view of cost, colour is not an important item to the manufacturer as long as he has not to change it frequently. Thus, speaking in approximate terms, 1 lb. of amaranth will colour 2,000 gallons of raspberryade or 4,000 gallons of ice cream. This means that the cost of colouring raspberryade is approximately 0·09*d*. per gallon or 0·045*d*. per gallon of ice cream, assuming a price of 15*s*. per lb. for the dye.

The desirable properties of an ideal colour were then enumerated. Such a colour must be without suspicion of carcinogenic activity and must be obtainable in a pure form free from carcinogenic impurities. It must also be stable to a temperature range of − 10° to 100° C., and also to *p*H's of 2–8 and to light during storage. It should be resistant to oxidation and reduction and to preservatives, especially sulphur dioxide, and there should be no colour variation from batch to batch. The colour should also be obtainable in oil-soluble and water-soluble forms. On the basis of the above properties, the British list[1] was examined, the discussion being confined mainly to the so-called *A* colours (colours which, from the available evidence, would seem unlikely to be harmful when consumed in foods in the customary amounts) and vegetable extracts.

Reds. The British list[1] contains seven red *A* colours (Ponceau 4*R*, Carmoisine, Amaranth, Red 6*B*, Red *F.B.*, Ponceau *SX* and Fast Red *E*) which conform to most of the points mentioned above, although not one of them is oil-soluble and not one of them is absolutely satisfactory from all points of view. Rhodamine *B*, and Erythrosine of seaside rock and canned cherry fame, are now classified as *C* and *B* colours, respectively, yet for the specific purposes mentioned they are irreplaceable. (*B* colours are those for which the available evidence is deficient or conflicting although there is no apparent reason on structural or other grounds to expect them to be harmful in the amounts ordinarily consumed. *C* colours are those which have been shown, or are suspected, to have harmful effects.) Not one orange colour has been given an *A* rating, and this means that the manufacturer has to use a blend of other *A* colours, which at once raises all kinds of difficulties as a result of the differing stabilities of the constituent colours of the blend. The absence of satisfactory red and orange oil-soluble colours is a serious limitation in the coloration of dairy products and frying oils.

Yellows. The three *A* colours, Tartrazine, Naphthol Yellow *S* and Sunset Yellow *F.C.F.*, cover most of the needs of the colour user, but the alkali stability of these water-soluble dyes is not high enough for all applications. Again, there are no oil-soluble yellows in the *A* list.

Green and blue. The British list[1] is very deficient in these colours, two blues only, Indigotin and Blue *V.R.S.*, being available. The former is very unstable, and when green is needed the manufacturer is reduced to the unsatisfactory course of using blends of other dyes. Of blacks, there are no *A* colours, but Black *B.N.* is on the permitted list as a *B* colour, although Black *B.N.*, has a definite blue tinge, which is a disadvantage.

After reviewing the British list[1], Dr. Thomas suggested that an intensive study is needed of higher wave-length colours both from the point of view of use and of carcinogenicity. Furthermore, he pointed out that the British list differed from those of other countries, and this raised difficulties if a food manufacturer wanted to export. Thus, Naphthol Yellow *S* was on the British list but not on the American list, while Britain and Australia were the only countries which permitted Blue *V.R.S.* Light Green *S.F.* Yellowish was permitted in the majority of countries except Britain. There was therefore a strong argument for some international agreement upon colours permitted as food additives.

A reference was made to vegetable colours which may find increasing use in the future in view of the dearth of synthetic oil-soluble colours. These colours are difficult to produce and standardize. There are ten vegetable extracts in the British list[1], but apparently only five of these appear in the lists of other countries.

Mr. G. R. A. Short, of W. J. Bush and Co., Ltd., spoke about the "Technological Aspects of Flavouring", and introduced his subject with a brief mention of the important function of added flavours to make food more attractive and to create a desire for more. Knowledge of added flavours is very old. Cassia bark is mentioned as far back as 2700 B.C. and cloves from 266 B.C. onwards by the Chinese, who eat otherwise monotonous rich dishes. Wood smoke for fish and meat is also a very old practice.

When a food processer decides on a new flavour, he has many problems to solve. For clear beverages or table jellies a soluble essence is needed; for cloudy beverages an emulsion flavour will be best. In sugar confectionery work, fondants and chocolate centres, a delicate essence in a volatile solvent is needed, while for boiled sugars there is need of a more powerful essence in a high-boiling solvent. Whether a natural or a synthetic flavour is to be used depends on cost, for natural fruit flavours are of low flavouring value, difficult to standardize and are needed in large quantities. The use of a fruit juice concentrate in a table jelly crystal would not be satisfactory since it would produce an unsaleable sticky mass. Synthetic flavours, however, are obtainable in a pure state which maintain the strength and quality of the flavours they contain. To-day many moderately priced essences are blends of natural and synthetic ingredients. There are also the problems of public taste; one peculiar difficulty facing the flavour industry is to decide whether public taste favours the flavour of fresh fruit or of the cooked variety. Thus the public is more familiar with the flavour of cooked than fresh raspberries, and it often demands a flavour remote from that of the natural product, such as amyl acetate as the major constituent of pear-drop flavour.

Natural flavours are extremely complicated. Thus, raspberry juice has been found to contain acetic, *n*-caproic and benzoic acids, ethyl, phenethyl and benzyl alcohols, benzaldehyde, diacetyl, ethyl acetate, γ-methyl-*n*-butanol, and many other unidentified substances, including lactones, phenols, aldehydes, ketones and acids. The number of constituents contributing to the aroma of coffee is as many as seventy and include hydrogen sulphide, methyl and furfuryl mercaptans, dimethyl sulphide, acetaldehyde, furfural, methyl-furfural, vinyl guaiacol, methylpyrrole, etc.

The flavour chemist has at his disposal, in addition to natural extracts and essential oils, a very wide range of synthetic materials which include alcohols, acids, esters, aldehydes, phenols, phenolic ethers, ketones and lactones. The flavour value of most of these synthetics is so great that less than one to three hundred parts per million are necessary to flavour food or beverages. Thus, only 5–6 parts per million of diacetyl added to a fat are needed to impart a flavour similar in strength to that of butter. So far, very few of the flavours have been found to be harmful, but we still know very little about the effects of flavouring materials on the human organism.

Prof. R. T. Williams (St. Mary's Hospital Medical School) then discussed the biochemical and pharmacological aspects of colours and flavours. It was pointed out that some of these additives were potentially toxic and in some cases carcinogenic. There was no doubt that, in the future, colours and flavours would be subject to close scrutiny from a biochemical, toxicological or pharmacological point of view.

Ideally the information needed before a substance could be used as a food additive would consist of data concerning acute and chronic toxicity, carcinogenicity, absorption from the alimentary tract, biochemical transformations and the toxicity of metabolites, elimination from the body and accumulation in the body. Much time and labour will be involved in obtaining this information; and therefore, in deciding on the suitability of a substance as a food additive, attention should also be paid to past experience, a general knowledge of metabolism and common sense so that decisions are not too long delayed.

From a structural point of view, most of the permitted food colours are sulphonic acids and azo compounds. Sulphonic acids are usually strong acids, and strong acids are either not absorbed from the intestine, or if they are absorbed then they tend to be rapidly excreted in the urine. It would therefore be of advantage if a food additive were a water-soluble strong electrolyte, since it would tend to be rapidly eliminated. However, dyes are complicated molecules, and it would be an over-simplification to regard them simply as strong acids.

Some azo dyes have been shown to be carcinogenic, and this effect can be due either to the dye molecule *per se* as in the case of butter yellow or because it gives rise to carcinogenic metabolites. Azo compounds are potentially capable of being split enzymically in the body into two amines, and any azo compound (for example, 2-naphthylazo dyes) potentially capable of giving rise to β-naphthylamine, a known carcinogen, is to be suspect[2,3]. On the other hand, 1-naphthylazo dyes have not been regarded with as much suspicion as 2-naphthylazo dyes, because the carcinogenicity of α-naphthylamine is in doubt. Sunset Yellow *F.C.F.*, Amaranth and Ponceau 4*R* are examples of 1-naphthylazo dyes which have an *A* classification. It is to be noted that these dyes contain sulphonated ring systems on both sides of the azo link. Ponceau *MX* is also a 1-naphthylazo dye, but it is sulphonated only on one side of the azo link and presumably this is why it has a *B* classification. Some oil-soluble dyes have a *C* classification because they are cathartics[4], for example, Oil Yellows *AB* and *OB*, Oil Oranges *TX* and *XX*.

Most synthetic flavouring agents appear to be compounds of low toxicity, and since they are used in minute quantities little apparent harm is likely to follow from their use. Prof. Williams showed with a series of slides that the body has detoxication mechanisms for dealing with the esters of aliphatic and aromatic alcohols with fatty acids, alcohols, aldehydes, phenols, ketones and acids which are used as flavouring agents. However, this is no reason for not being on the alert for potential toxic agents among flavouring material. Thus, coumarin is a flavouring agent which has recently fallen into disrepute and is no longer used in the food flavouring industry, since feeding experiments on animals have shown that it produces liver damage[5]. Some doubts have also been expressed about citral since it may act as a retinene competitor[6]; but in this case a thorough investigation of its biological properties is needed.

In the discussion which followed, Mr. A. L. Bacharach commented on Prof. Williams's suggestions regarding the general tests which might be needed to pronounce a food additive as safe. It may not be necessary always to carry out all the tests on every substance investigated. By arranging them in suitable order, one test can be made to act as a 'screen' for the next. Furthermore, studies on absorption, metabolism and excretion should be directed more towards substances which appear to do no harm rather than those showing toxic effects, since the former are the ones which might find industrial uses. The question of whether the examination of food additives by isolated enzyme systems would yield useful information was put by Dr. A. Bender. It was agreed by Prof. Williams that useful information could be obtained in this way if care were taken in the interpretation of the results. Since a food additive is usually taken by mouth, it may not be absorbed, and if it is absorbed it does not necessarily follow that it will reach the location in the body where a particular enzyme is found. It is thus possible with foreign compounds that *in vitro* experiments will not always yield the same results as *in vivo* experiments. *In vivo* experiments are considerably more important with foreign compounds than with the body's natural metabolites, which are now largely studied in *in vitro* systems.

The possibility of reproducing natural flavours was also discussed by Dr. V. L. S. Charley (Carters). Since lists of organic compounds that have been found in fruit juices had been recorded in the literature, could not a true flavour be made from a blend of the compounds given in these lists ? According to Mr. Short, experience had shown that mixtures of the constituents reported do not reproduce the true flavour of fruit for the reasons that some constituents remain unidentified, while others, particularly aromatic compounds, decompose during extraction.

R. T. WILLIAMS

NEW LABORATORIES AT UPPINGHAM SCHOOL

THE new Science Laboratories at Uppingham School, which were inaugurated by H.R.H. Prince Philip, Duke of Edinburgh, on November 8, owe their existence to the imaginative and far-sighted generosity of British industry.

The old Science School, built in 1897 and partially modernized and extended in 1927, was proving inadequate even before 1939 because of the increasing number of boys who were specializing in science. The great impetus given to the teaching of science during and since the War had made the provision of additional laboratory accommodation imperative. The buildings could not have been modernized satisfactorily, and space for their extension on the existing site was inadequate. Plans were therefore drawn up for the building of a new Science School, but these could not have been carried out without the generous financial help of the Industrial Fund for the Advancement of Scientific Education in Schools and many firms, which contributed a large proportion of the £100,000 needed for the building.

The new Science School was designed by Messrs. Easton and Robertson, of London, and built by Messrs. E. Bowman, of Stamford. It has the shape of the letter H and consists of two floors.

The Chemistry Department includes two large chemistry laboratories (1,100 sq. ft), one specialist laboratory (540 sq. ft.) and two lecture theatres on the ground floor. Each of the large laboratories is fitted with three island benches (16 ft. × 4 ft.), which can comfortably accommodate twenty-four boys (4 ft. bench space a boy), and there is additional space on the benches which extend down the two long sides of each laboratory. A special feature of these laboratories, apart from their spaciousness, is the generous provision of cupboards and drawers, so that all the apparatus which is in general use can be kept in the laboratories. There are large fume chambers at one end and a raised demonstration bench at the other.

The specialist laboratory has been designed mainly for third-year sixth-form work. It can accommodate twelve boys and contains a thermostat and the more expensive apparatus that is needed for advanced work. It is separated from the senior (sixth-form) laboratory by a balance room, which contains concrete shelves on concrete pillars. This arrangement has proved most satisfactory, because there is no noticeable vibration from the traffic on the main road which passes within 70 yd. of the building.

The two lecture theatres contain tiered benches, a well-equipped demonstration bench and a fume chamber, and blinds so that they can be blacked out for the showing of films, etc. Like the laboratories, they are within easy reach of the chemistry store and preparation room. Although the maximum size of a form is usually twenty-four, these theatres can accommodate fifty boys, which is very useful for the showing of films to two forms simultaneously.

The Biology Department consists of two laboratories, a preparation room, a greenhouse, a small botanical garden, and upstairs a large lecture theatre and small museum.

The laboratories are fitted with working benches each specially designed in rows to accommodate four boys. Each working space is 4½ ft. long, with a bench top 30 in. deep. There is a sink between each pair of places, and beneath are drawers. All positions have gas and mains electricity, and face the main windows to facilitate microscope work in daylight.

Special features of the elementary laboratory include built-in racks for aquarium tanks, a galvanized tank alongside the main wash-up sink for preserving specimens used for dissection, and spacious glass-fronted cupboards.

The advanced laboratory, used primarily by boys taking botany and zoology as separate subjects at Advanced Level of the General Certificate of Education examination, is equipped for both lectures and practical work. It has black-out and facilities for projection. It also contains a light-proof cupboard similar in construction to a standard fume chamber, in which plant physiology experiments can be carried out in the dark.

The preparation room is designed to enable the staff and assistants to prepare specimens, microscope slides, etc., without interference, and for senior boys to set up long-term experiments. There is adequate storage space for reagents and equipment.

The greenhouse communicates directly with the elementary laboratory and is large enough to provide the Department with adequate plant material, and also give space for growth experiments, etc. The garden will lie between the greenhouse and the chemistry wing, facing west, and will include a water garden.

The lecture theatre has accommodation for an audience of 120 on tiered benches; but for class teaching only the front rows are used, and these have tops broad enough to take the drawing boards and books required for normal class-work. Black-out is fitted, and the room is equipped for cinema-, still- and micro-projection.

The museum is intended to house teaching collections of animals, the school herbarium collection and the results of work done on the annual Easter expeditions.

The Physics Department (together with a staff room and library) occupies the rest of the first floor, and comprises two large laboratories, one for elementary work up to Ordinary Level of the General Certificate of Education examination and the other for more advanced work. As annexes to the latter, there are an advanced laboratory proper and a dark-room for optical experiments which will between them accommodate about twenty boys, and in which the apparatus for a lengthy piece of work can be left undisturbed. There are also two tiered lecture rooms, each with 16-in. dial ammeter, voltmeter and centre-zero galvanometer mounted above the blackboard, and one containing a 'dry' cupboard for electrostatics apparatus. The electrical installation provides d.c. variable between 4 volts and 108 volts, from lead–acid cells charged by a rectifier unit; and also low-voltage (12-volt or 24-volt) 50-cycle a.c. Sufficient working points are available for class experiments on alternating current. The physics workshop, with wood-working bench, lathe, power-drill and glass-blowing table, is equipped for the making of most ordinary pieces of apparatus, as well as for routine repair and maintenance work.

SPATIAL ASYMMETRIES IN π–μ DECAY

SOME interesting observations on the decay of pions at rest in a nuclear emulsion, made by a group of physicists at the Institute of Atomic Physics at Bucharest, were recently presented to the French Academy of Sciences*. The emulsion was exposed to pions produced by the large synchro-cyclotron at the Institute of Nuclear Research near Moscow. The π–μ decay events were classified into two groups, depending on whether the muon momentum was directed forwards or backwards with respect to the pion momentum immediately before stopping. In a total of 3,595 events, 2,199 backward and 1,396 forward decays were seen. If the angular distribution is of the type $(1 + b \cos \theta)$, where θ is the angle between the two momenta, then b is found to be $-0{\cdot}447 \pm 0{\cdot}032$. Such a large asymmetry parameter b, differing from zero by more than 14 standard deviations, clearly cannot be ascribed to a statistical fluctuation.

An asymmetry in π–μ decay could mean that the pion has a finite spin (most plausibly 2 units of $h/2\pi$) with which to 'remember' its direction of motion before stopping. Such a conclusion would be quite contrary to all previous ideas about pion phenomena, which are easily and consistently interpreted on the basis of zero spin for the pion. It should also be noted that a longitudinal polarization of the pion beam used in the experiment would almost certainly mean that parity was not conserved in the production process, although it is possible to imagine an unusual magnetic-field arrangement which would invalidate this conclusion. Non-conservation of parity in a 'strong' process such as pion-production would be hard to reconcile with the observed conservation of parity in nuclear forces.

Alternatively, and much more drastically, the effect could mean that current ideas about space, which lead to connexions between angular momenta and spatial probability distributions, are false. This would be an extremely fundamental conclusion, but recent experience with the parity hypothesis has taught physicists to be cautious about rejecting all idea of changes of this kind.

At the International Conference recently held in Padua and Venice, several groups working with nuclear emulsions reported finding various kinds of anisotropy in π–μ decays. In each case, however, the experiment had been extended to the electrons afterwards emitted in μ–e decay. The angular correlation in the μ–e decay is well known and comparatively small in nuclear emulsion (asymmetry parameter numerically smaller than $-0{\cdot}20$). It follows that the π–e correlation, through two decay processes, should be much smaller than the simple π–μ correlations. This was not found to be true, indicating that the effects observed were not physical, but due rather to hitherto unsuspected distortions or scanning biases in nuclear emulsion work.

At the same conference, Prof. L. M. Lederman, of Columbia University, New York, reported some work using counters and electronic recording of the events (Garwin, Gidal, Lederman and Weinrich, unpublished). In the horizontal plane, they find an asymmetry parameter in the π–μ process of $0{\cdot}025 \pm 0{\cdot}025$, essentially a zero result. The up-down asymmetry parameter was $-0{\cdot}016 \pm 0{\cdot}012$, again showing insignificant deviation from isotropy.

A GEOCHEMICAL HYPOTHESIS OF THE EARTH'S STRUCTURE*

By A. F. KAPUSTINSKY

Corresponding Member, Acad. Sci. U.S.S.R., Institute of General and Inorganic Chemistry, Moscow

GOLDSCHMIDT'S view that the interior of the Earth resembles the hearth of a smelting furnace and that the Earth is zonal in its structure, with each zone characterized by certain dominant elements, has long prevailed in geochemistry. In recent years, however, these views have been critically examined, and many scientists, such as V. N. Lodochnikov, consider a chemically homogeneous, non-zonal globe much more probable.

In two recent papers[1] I have examined this problem in detail and here I would like to give a brief summary of the conclusions I have reached.

---

* Summary of a paper read at the Symposium on Geochemistry held in Paris in July 1957.

In the first instance, in my opinion, we cannot accept Goldschmidt's views, as they are based on a conception of ordinary behaviour of matter. As we shall see later, the properties of matter and the properties of atoms remain constant only in the crust of the Earth, whereas under pressure of hundreds of thousands of atmospheres, the properties of matter change so much that the very nature and direction of physical and chemical processes become altogether different.

On the other hand, the Earth cannot be regarded as homogeneous. The Earth's core, for example, is probably rich in iron, and modern seismology supports very strongly the existence of geo-zones having different physical properties. But at the same time, it is clear that classical chemistry, based on the Mendeléeff periodic law and the Pauli exclusion principle, cannot be applied to matter composing the Earth as a whole. The study of the Earth requires a new and more fundamental approach, based on new findings relating to the behaviour of matter under very high pressure.

It is now known that with increasing pressure the outer electrons of the atoms are forced into the lower quantum-levels, a process eventually leading to the occupation by the electrons of all the unfilled positions in quantum-levels. For example, while under ordinary conditions calcium has two outer electrons at the level 4*s*, and the level 3*d* is unfilled, under pressure we may expect an 'isomerization' and the transformation of ordinary calcium into '*iso*-calcium', in which the two 4*s* electrons are displaced into the 3*d* level. Since the chemical properties depend primarily on the electron quantum characteristics, this new atom would have completely new properties.

According to R. Sternheimer's[2] calculations, the pressure under which the outer electrons are pushed into the lower quantum-level, for caesium, for example, is of the order of 45,000 atm., which corresponds to a depth of about 100 km. of the Earth's crust. Allowing variation among different elements one may assume this depth to vary from 60 to 120 km., being the lower boundary of a geo-zone called by me the 'perisphere' and which corresponds to the well-known Mohorovičić discontinuity. The 'perisphere' is followed by the 'intersphere' to a depth of 2,900 km. This zone is made of atoms with 'degenerate chemical properties'. Finally, at the centre of the Earth is the 'centrisphere', which is the region of 'squashed' atoms.

In my two papers[1] I have discussed a concept which I have called 'periodicity function'—a mathematical expression, based on empirical data, which shows at what pressure all of the elements are modified to such a degree as to lose their property of periodicity; in other words, at what pressure all atoms will become identical in respect of their chemical properties. According to my calculation such a pressure will be of the order of 1,400,000 atm., corresponding to a depth of 2,900 km. Certain works by Ramsey, Kuhn, Wigner, Huntington and others have a bearing on the development of this idea, as well as my own researches on the thermodynamics of compressed crystals, which represent further expansion of the idea of Lewis that the entropy of a highly compressed crystal tends to zero.

Thus I assume that at the high pressure prevailing in the 'centrisphere' all atoms will be in a 'metallized' state, in which matter will be made of atomic nuclei immersed in a homogeneous electronic 'plasma'. Having no specific electrons attached to them, atoms will cease to be separate elements with definite atomic numbers, definite chemical properties and reactions in this region of 'zero chemistry'. On the other hand, in this state matter will be characterized by such a high electrical and thermal conductivity that the temperature of the whole of the 'centrisphere' will remain constant.

The geochemical hypothesis of the structure of the Earth briefly expounded here requires verification and amplification. It finds its support in certain thermodynamical considerations and seems to agree with the seismological data. In any event, such a hypothesis may stimulate further research and point to new concepts of Nature.

DEPENDENCE OF HEAT CAPACITY OF CERTAIN CRYSTALS ON THEIR THERMAL HISTORY

By R. G. S. MORFEE AND L. A. K. STAVELEY
Inorganic Chemistry Laboratory, Oxford

DURING a study of the heat capacities of ammonium and alkali stannihalides, designed to throw light on the motion of the ammonium ion in these salts, we have encountered a phenomenon for which, so far as we are aware, there is no precedent. This is that the heat capacity over a considerable range of temperature becomes less after the sample has been cooled to low temperatures, and only reaches steady, reproducible values after repeated cooling. The effect was most fully investigated for potassium stannichloride, some results for which are shown in Fig. 1. In this figure, in which the molar heat capacity C_p is plotted against absolute temperature in the range 270–300° K., the open circles represent the first values obtained after the calorimeter had been filled and assembled. When these measurements were made, the sample had not been cooled to below ~245° K. The full circles show the values obtained three weeks later, during which time the calorimeter had been repeatedly cooled (on two occasions to 20° K.) and heat capacity measurements made from 20° K. upwards. A week later, during which period the calorimeter had been cooled several times (though not below 195° K.), a redetermination of C_p gave the values plotted as crosses. After another week, during which the calorimeter was cooled to 90° K. four times, and allowed to warm slowly to room temperature after each cooling, the C_p values (shown as triangles) did not depart significantly from the curve through the crosses. Further experiments

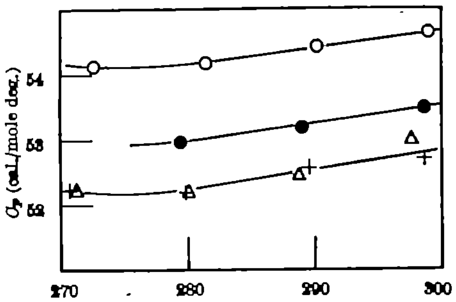

Fig. 1. Molar heat capacity, C_p, of potassium stannichloride in the range 270–300° K., showing the decrease in C_p with repeated cooling of the salt

confirmed that these final values were reproducible. The overall drop in C_p amounted to about 4 per cent.

It must be stressed that the results shown in Fig. 1 were obtained with the same sample throughout. The calorimeter used was that described by Davies and Staveley[1]. Similar effects had never been obtained with it before, and there was no reason whatever to suspect misbehaviour on the part of the platinum resistance thermometer or the heating circuits. Since progressive desorption of, say, water vapour from the surface of the calorimeter would produce a drop in its heat capacity, particular attention was paid to the evacuation of the space around the calorimeter before any measurements were started. A possible source of a changing heat capacity could be chemical reaction between the salt and the copper calorimeter, and after the experiments on potassium stannichloride the sample was removed from the calorimeter and analysed, and the inside of the calorimeter thoroughly washed out to see if any such reaction had taken place. It was found that, in fact, there had been a slight attack on the copper, but analysis showed that, at the most, not more than 0·2 per cent of the salt could have been affected. Furthermore, such a reaction would not lead to a marked decrease in heat capacity. Thus, a mixture of potassium chloride, stannous chloride and cupric chloride—the most probable reaction products—would have a total heat capacity at room temperature within a few per cent of that of equivalent amounts of potassium stannichloride and copper; as a rough estimate, reaction of 0·2 per cent of the potassium stannichloride in this way would not have changed the heat capacity by more than ~ 0·01 per cent. Clearly the observed decrease of about 4 per cent was not due to reaction or decomposition of the salt. Evidence to support this is provided by (1) below.

A full understanding of the phenomenon must await a detailed examination of the properties of the salt before and after cooling, but the following observations are relevant, and would have to be considered in any attempted explanation:

(1) The change in C_p is due to cooling, and not simply to ageing. In another series of experiments on potassium stannichloride, C_p was measured between about 267–300° K. without cooling the salt below about 260° K., using a sample which had been standing at room temperature for 15 weeks. After allowing the calorimeter to stand for a further three weeks at room temperature, C_p was measured again over the same range and, within the precision of the measurements (± 0·2 per cent), was found to be unchanged. The sample was then cooled to 90° K. and allowed to warm to room temperature. This was repeated five times in a week, and C_p was then redetermined. The values obtained were lower by about 2 per cent at 300° K.

(2) The effect was also observed with ammonium and rubidium stannichlorides, and potassium stannibromide. Some of the experiments on these substances were carried out before we had become fully aware of the phenomenon, and the initial measurements of C_p at higher temperatures were sometimes made after the sample had been cooled at least once to liquid-oxygen temperature. Consequently the observed drop in C_p with further cooling was not as marked as with potassium stannichloride. The decrease in C_p at room temperature between the first values and the final steady values was ~ 1 per cent for ammonium and rubidium stannichlorides and ~ 2·5 per cent for potassium stannibromide.

(3) With each salt, the change in C_p was only apparent in roughly the upper half of the temperature-range covered (20–300° K.). Thus for potassium stannichloride all C_p values obtained below about 115° K. follow the same curve, regardless of the stage in the history of the sample at which they were measured. From about 115° K. upwards, a curve through the first values of C_p diverged more and more from the curve through the points accepted as the 'final' values. (See Fig. 2.) The corresponding temperature for ammonium stannichloride was about 200° K.

(4) Extensive X-ray diffraction studies have been made of these and similar salts of the type R_2MX_6, where R is a univalent cation and X is a halogen. With the possible exception of potassium stannibromide, they are all said to have anti-fluorite structures, with the M–X bonds directed along, or parallel to, the sides of the cubic unit cell. Potassium stannibromide was considered to have the same structure by Ketelaar, Rietdijk and Staveren[2], but Markstein and Nowotny[3] concluded that it is tetragonal, with a and c parameters differing by about 1 per cent. The samples used in the calorimeter were prepared by slow evaporation at room temperature from solutions containing the stannic halide, the alkali or ammonium halide, and free halogen acid to avoid hydrolysis. All four salts gave satisfactory analyses. The crystals were usually large and well formed, some being several millimetres across. In order to be introduced into the calorimeter they had to be lightly crushed. They were then sieved, and the

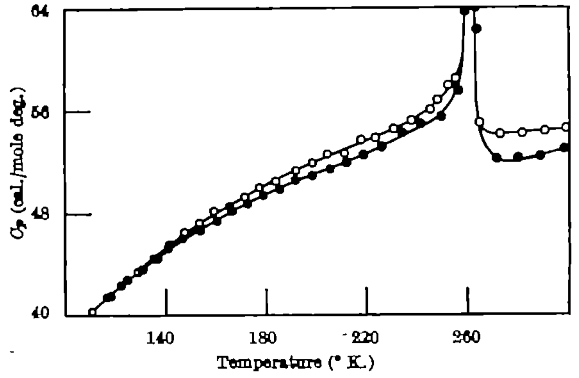

Fig. 2. Molar heat capacity, C_p, of potassium stannichloride. open circles, first measurements; full circles, measurements on the same sample after repeated cooling

fines rejected, so that the measurements were made on crystals of size roughly 0·5–1 mm.

(5) Potassium stannichloride was found to have a λ-point with C_p reaching its maximum at 262·1° K. (This means that the crystal structure of this salt at lower temperatures, at least, is not so simple as the previous crystallographic work has suggested.) The decrease in C_p with repeated cooling was apparent both above *and* below the λ-point. This is shown in Fig. 2.

It may be that the phenomenon we have described arises because the crystals are formed with a higher proportion of defects than they eventually possess when equilibrium has been achieved. Although nothing appears to be known about defect concentrations in salts of the type R_2MX_6, it is possible that such salts, even at room temperature, contain a relatively high proportion of Frenkel defects. The inter-ionic forces must be weaker than in salts composed solely of monatomic ions, and there is a considerable difference in size between anion and cation. Moreover, the nature of the lattice is such that cations might be accommodated in the octahedral interstices between the anions. Such defects must in principle affect the heat capacity. Thus, they could give rise to a greater coefficient of expansion[4] and an enhanced (C_p–C_v) term. It is possible, too, that the considerable contribution made to C_p by the internal degrees of freedom of the stannihalide ions might be significantly altered if the environment of some of these ions is changed by neighbouring defects. However, if it is true that the proportion of defects in the crystals studied was initially higher than that reached eventually, it is remarkable that the approach to equilibrium should be favoured by cooling.

The final heat capacity results will be reported in detail elsewhere. It will be obvious that the effect we have described, whatever its cause, could lead to considerable discrepancies between the heat capacity results of different observers for substances subject to it.

We are grateful to Prof. F. C. Frank for a helpful correspondence, and to Imperial Chemical Industries, Ltd., for financial assistance.

HERMAPHRODITISM WITH SELF-FERTILIZATION, AND THE MONTHLY EXTRUSION OF UNFERTILIZED EGGS, IN THE VIVIPAROUS FISH *LEBISTES RETICULATUS*

By DR. H. SPURWAY

Biometric Unit, Indian Statistical Institute, Calcutta, 35

THIS communication is a preliminary report on two independent phenomena: first, functional hermaphroditism, resulting in self-fertilization, has been observed in a fish and eighteen of her descendants; secondly, in all but two families in which more than one female became adult, one or more fish has extruded groups of unfertilized oocytes into the surrounding water. Such extrusions have occurred in fish unrelated to the hermaphrodites. Both kinds of abnormal parturition were discovered by keeping virgin females alone in small glass vessels (usually in 600 c.c. of water). The baby fish were always isolated before puberty and usually within 24 hr. of birth.

Tables 1 and 2 show that the ages of both the extrusion of the first group of oocytes and the first fatherless birth are not only variable, but also often higher than the median ages of death. Also some fish (not chosen at random) are removed from the populations either to be mated for genetical experiments or killed for histological examination. Therefore a meaningful estimate of the frequencies of fish which perform either of these two abnormal parturitions, and comparison of these frequencies between families, involves statistical procedures the assumptions of which require discussion. A full analysis was delayed until the population here discussed and kept in the Department of Biometry, University College, Gower Street, London, was discarded in July 1957.

Lebistes reticulatus is a typical poeciliid fish in which internal fertilization is effected by copulation. The anal fin of males develops into an intromittent organ

during the first eight weeks of life. Sperm from a single copulation can sire up to eight litters[1]. These are born at approximately monthly intervals[1,2] (but see also Fig. 4), and the young are 5–6 mm. long at birth.

Lebistes males are bright coloured and variable; wild-type females are monomorphic and have a typical teleostean shape. Usually the males are heterogametic (or *XY*) and the females homogametic (or *XX*). *XX* and *YY* males and *XY* females can be functionally normal[4].

Nineteen individuals all related to one another have produced fatherless offspring. Eighteen of these were superficially normal females. The anal fin of the nineteenth developed into an intromittent organ coincidentally with the birth of its first litter. With this it made courtship movements but did not sire any young on unrelated females. It was found to contain testicular tissue by M. J. Hollingsworth, now of the University College of Ghana, Achimota, who failed to discover any testicular tissue in two other self-fertile mothers, *P*8 and β7. However, Prof. J. Z. Young, of University College, London, discovered testicular tissue in the self-fertile females *S*7 and μ7 (Figs. 1 and 2). I wish to thank both these colleagues, and their assistants, for this histological co-operation.

The self-fertility is, therefore, assumed to be due to hermaphroditism and not to parthenogenesis, as was stated previously[5].

The self-fertile proposita *D*9 occurred in an inbred aquarium stock given me by Maurice Wilson, now of Queen Mary College, London. This was segregating for alleles of the loci *Flavus*[4], *blond*[6] and *gold*[6], all affecting pigmentation and scorable on females. These were used for diagnosing paternity when self-fertile or related females were mated. The sex ratio among certainly sired offspring was normal. There

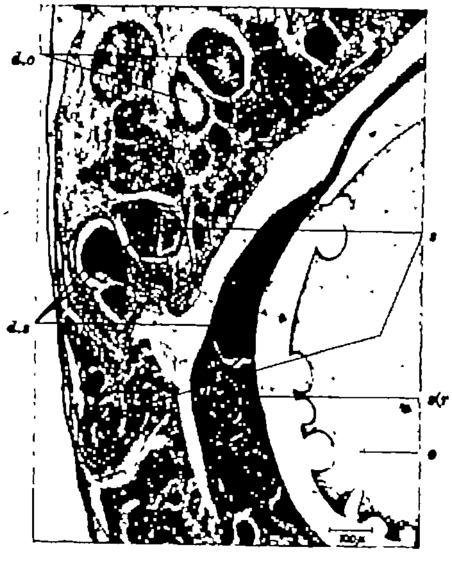

Fig. 1. Section of ovotestis of μ7

Key: *d o*, developing oocytes; *d.s*, developing seminiferous tubules; *o*, yolk of mature oocyte; *s*, seminiferous tubules containing mature sperm; *s(r)*, ruptured seminiferous tubule liberating sperm (this rupture is not certainly an artefact of preparation and it may be by such means that the sperm and the oocytes come into contact)

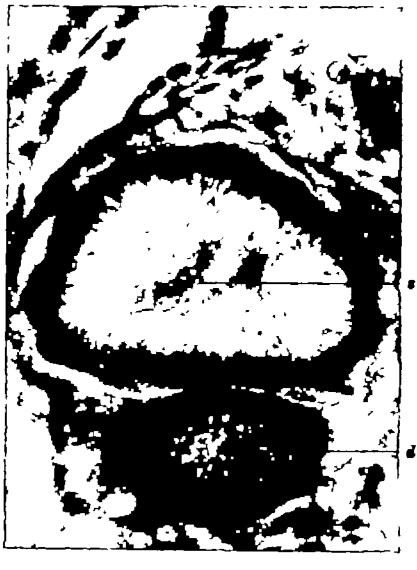

Fig. 2. Another section of the ovotestis of μ7. Key as for Fig. 1

is no evidence for self-fertilization first occurring in an animal after it had been in the company of a male.

Table 1 shows the incidence of the self-fertility and oocyte extrusion in the animals born in the collection. The first column gives a classification of the animals in terms of parentage.

Sired and fatherless females are classed together as the original 'stock' (excluding twenty-one females including the proposita, because they were kept in aquaria where young, but not oocytes, could have been detected). Females (self-fertile, and fatherless and sired daughters and grand-daughters of self-fertile females) were outcrossed to males from two stocks, for which I wish to thank Dr. Caryl Haskins, of the Carnegie Institution of Washington. Stock *B* was descended from a recent capture in Trinidad; the *Maculatus* stock was a subculture of that produced by Winge, and thus $X_0 Y_{Ms}$ in his nomenclature[4]. Sons, both fatherless and sired, of self-fertile females derived from outcrosses to *B* were crossed to females from the *Maculatus* stock, that is, $X_0 X_0$.

In Table 1, column 2 shows the number of families in each of the six groups, and column 3 the number of females who survived 100 days. Column 4 is a rough estimate of their median age of death. The families within a given group are not homogeneous among themselves.

Column 5 shows the number of females which have been self-fertile. The absence of self-fertile females among the progeny of *Maculatus* males, compared with the progeny of stock *B* males, is significant after allowance has been made for the detailed longevity of the females tested. Column 6 gives the number of females which extruded oocytes (excluding six which extruded them synchronously with full-term young, two which had previously given birth to fatherless litters and four which had previously given birth to sired litters).

Table 2 shows some details about the self-fertile mothers and their fatherless litters, and the extract from the pedigree given in Fig. 3 shows the relationship of the parents of the five sired families (*D*, *DD*, *P*, *S* and *Z*) in which self-fertile individuals have segregated.

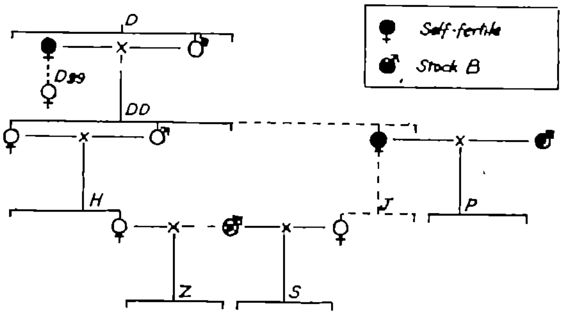

Fig. 3. Part of pedigree showing relationship of parents of the five fathered families in which hermaphrodites segregated

The range of the mothers' ages at the birth of their first fatherless litter means that some apparent females must die before they become old enough to manifest their hermaphroditism by a parturition, and perhaps before any testicular tissue has developed. Such variation in expression would prevent any Mendelian ratios being observed even if the hermaphroditism were due to a change of allele at a single locus. It also makes it difficult to compare such a change with the non-functional hermaphroditism which seems characteristic of the development of lower vertebrates[7,8].

The third column shows the age at which the mother was removed from the population either by death (*d*), killing (*k*) or introducing a male (*m*+ if producing sired offspring, or *m*− if subsequent litters were recognized as products of self-fertilization on the evidence provided by their alleles for the three pigment genes).

Within the fatherless families there is positive correlation between the number of litters, the size of these litters, and the number of miscarriages and deaths before puberty; that is, as would be expected, the greater the development of the testis tissue the greater the number of conceptions but also the greater the disturbance of the follicular pregnancies.

*DD*20, the one certain fatherless offspring born to *D*9 after it had been mated, was in its second sired litter born when *D*9 was 594 days old. The second litter of X8 was produced when the mother was 293 days old, an extrusion of unfertilized oocytes having

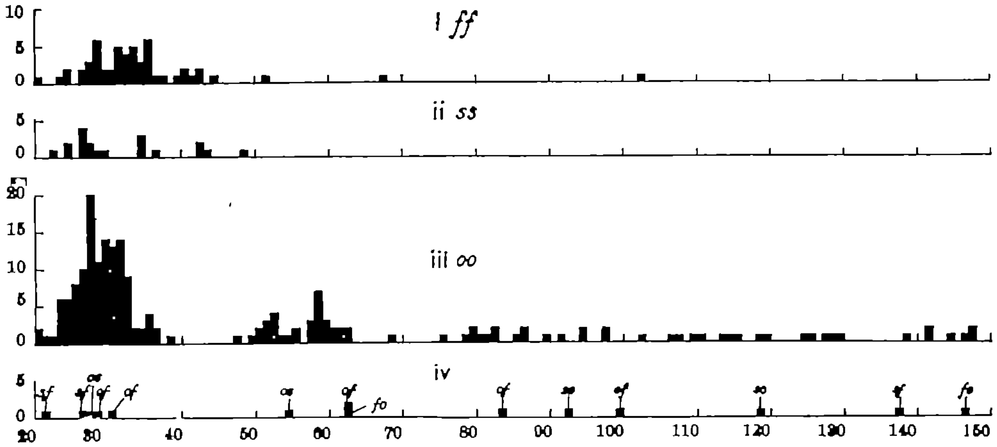

Fig. 4 Distribution of intervals between births

Abscissae, length of interval in days. Ordinates, number of intervals. *f*, fathered litter; *s*, fatherless litter; *o*, oocyte extrusion (for omissions see text) intervened at 265 days. All other intervals between fatherless litters are shown in histogram ii of Fig. 4. This distribution is statistically indistinguishable from that observed for the production of sired litters (histogram i). This confirms the histological findings that the testis tissue is transitory and usually does not re-develop.

I have discussed elsewhere[9] the significance of the increased expression of self-fertility in the F_1 generation between two inbred stocks which is unexpected on certain interpretations of heterosis. Table 2 corrects several previously published errors in addition[9].

The last three columns of Table 2 give the superficial sex of the adult products of self-fertilization. Among the animals scored as females, many more than the five who were self-fertile must be presumed to be actually or potentially hermaphrodites. This sex ratio suggests that the hermaphrodites are XX, which is supported by the phenotypes and the sexual history of the four males. All were under-coloured, and no Y chromosome empty of alleles for male epigamic patterns has yet been reported. Three were sterile, though one of these had histologically normal testes. The fourth provided evidence for its XX constitution by siring only females, sixteen of which were by a *Maculatus* stock female.

Among fatherless fish, the three colour alleles segregated in the 3 : 1 ratio characteristic of selfing in hermaphroditic plants.

The hereditary factor responsible for making XX zygotes develop into hermaphrodites is not X-linked, and is not an autosomal recessive allele either with or without a delayed zygotic effect. Because the crosses were made with the *Maculatus* stock which suppresses their penetrance, we do not know whether the determiners are inherited differently through males or females; that is, I have not discovered whether hermaphroditism is dependent on an autosomal allele with dominant but variable penetrance, or on a cytoplasmic factor comparable with those influencing hermaphroditism in some species of plants[10].

Histogram iii of Fig. 4 shows the distribution of 200 of the 222 intervals observed between two extrusions of oocytes. The 22 omitted intervals ranged in length from 165 to 447 days. The distribution of these intervals is significantly different from that of the intervals between births. 126 (that is, more than half) ranged between 21 and 39 days, and this group did not deviate significantly from the normal distribution. Its mean was 29·4, and its standard deviation 3·4. This is significantly lower than the mean observed for sired litters, which is 33·0, with standard deviation 5·16 even when the three extremes are neglected. The next group of thirty-five intervals between oocyte extrusions ranged from 48 to 69 days, again normally distributed among themselves with a mean of 57·1 and standard deviation of 4·6. These groups are called 'single' and 'double' intervals, respectively. The range of the single intervals is too great for groups to be apparent if higher multiples of these do occur among the longer intervals between extrusions.

Table 3 shows that (except for the oldest two fish) the greater the age of a fish at its first extrusion of oocytes the greater the mean number of its subsequent extrusions. Omitting from consideration inadequately tested animals, 73 females first extruded before 300 days but not one extruded more than five times; though of the 64 which began later, eight produced six to ten groups of eggs. This is unexpected, because the earlier in its life a fish extrudes oocytes the longer is the expected (and observed) period before its death in which subsequent extrusion could occur. This correlation is partly explained by the observation that the greater the age of a fish at its first extrusion of oocytes, the higher is the proportion of single intervals between consecutive extrusions to all such intervals.

Table 3

Age at first extrusion	Mean No. of extrusions	Ratio of single intervals to all intervals
100–199	2·18 ± 0·19	0·450 ± 0·076
200–299	2·41 ± 0·22	0·433 ± 0·064
300–399	2·20 ± 0·34	0·567 ± 0·090
400–499	2·30 ± 0·68	0·714 ± 0·121
500–599	3·5 ± 1·5	0·615 ± 0·135
600–699	3·6 ± 0·44	0·609 ± 0·104
700–799	4·5 ± 1·18	0·657 ± 0·076
800–899	3·25 ± 0·62	0·800 ± 0·089
900–999	1·5 ± 0·5	0·0 (1 interval)

Extrusion reveals a failure of the follicles to re-absorb unfertilized oocytes. In the females which begin this extrusion late in life and then extrude regularly, this failure may be described as a senility and is then mainly dependent on a monthly rhythm of oocyte maturation[3]. In the animals that extrude earlier, and afterwards extrude intermittently or not at all, other causes of ovarian inadequacy must be suspected, some of which seem transitory. In some families, perhaps in all, the females which extrude oocytes live longer (for example, a mean increase of more than 300 days) than their sisters who do not. This suggests that extrusion itself compensates for failure of other processes, and prevents the animals becoming 'egg bound'.

Histogram iv of Fig. 4 shows the distribution of the intervals between two different kinds of parturition. Two *fo* of 201 and 740 days and 3 *sf* of 210, 340 and 385 days are omitted. This histogram reveals that oocyte extrusion is not evidence that the ovary has become incapable of pregnancy. Also, when it is borne in mind that the interval before a sired birth depends on when the male was introduced as well as on the mother's receptivity, and that the senile oocyte extrusion may not occur until many months after sperm has been exhausted, it is seen that oocyte extrusion coincides reasonably well with the rhythm of other births. It has also occurred six times with them. Therefore, the breakdown of the follicular walls may be a failure of an incipient pregnancy because the oocyte was not fertilized; that is, the extrusions seem more comparable to the menstruation than to the ovulation of mammals.

The gross synchronizing regulations which take place in the follicles just before term[8] provide an explanation of the significantly longer intervals observed between fertile parturitions and perhaps for the positively skew distribution of these intervals.

A Significant Error in the Determination at Low Pressures of the Virial Coefficients of Vapours

THE differential method[1] which we have developed and which has been applied successfully to the accurate measurement at low pressures of the deviations from ideality of a number of gases has, with vapours, been found to give unreliable results. Usually, with these the *PV/P* isothermals show a curvature concave towards the pressure axis. This effect was noticed by Casado[2] with benzene vapour, and the literature contains references to curved low-pressure isothermals with several easily liquefiable gases. Hamann and Pearse[3] noticed this behaviour with methyl chloride and methyl bromide. Since, on theoretical grounds, it is very unlikely that a third virial coefficient could produce an effect of the magnitude observed even in benzene, it is clear that an experimental error of some significance is involved. This error is due to adsorption, which hitherto has been neglected by other workers in this field.

Now that a careful investigation of adsorption on 'Pyrex' glass of a series of vapours at various temperatures has been made by one of us[4], it is possible to define the conditions in which this error is at a minimum and to make reliable corrections in volumetric work. It was found that only when the glass surfaces in the volumeters were scrupulously clean and the mercury in contact with them entirely free from even traces of grease that minimum and constant values for adsorption could be obtained.

It was hence imperative to redesign the differential compressibility apparatus so as to avoid entirely the passage of mercury through greased stopcocks. This has now been done by using magnetically controlled mercury valves which permit the necessary fine adjustment[5], and results obtained for benzene vapour at 22° and 35° C. between the pressure limits of 60 and 20 mm. The *PV/P* graphs, after correcting for adsorption, are very closely linear and the deviations of the experimental points from a mean square line do not exceed 2 parts in 10^5. The virial coefficient at 22°, deduced from the slope of the line, is $-B = 1{,}525$ c.c./mol. In the particular apparatus used the increase in surface on expansion is nearly balanced by the decreasing adsorption, so that the total adsorption correction is small and even at the lower temperature does not exceed 30 c.c./mol., or about 2 per cent; at 35° it is still smaller.

As a check to these results, we have compared the balancing pressures of benzene vapour and nitrogen by means of the microbalance. Originally, Casado, Massie and Whytlaw-Gray[6] compared benzene vapour with oxygen and obtained a value for the molecular weight from the limiting value of the pressure ratio very close to the accepted figure, but for the virial a high degree of accuracy was not claimed and we had reason to suspect that the balance used might not have been sufficiently compensated for adsorption. Imperfect compensation would affect significantly the value of the virial coefficient but would have little influence on the molecular weight. Using a more certain method of compensation for adsorption, we now find, as the mean of two sets of experiments, $-B = 1{,}537$ cal./mol. in good agreement with that found with the modified compressibility apparatus. At 35° C. also a satisfactory agreement between the two methods has been attained. Although with the microbalance the accuracy of the results is not as great as with the compressibility method, the agreement supports the view that systematic errors have been avoided.

From the form of the adsorption curves on 'Pyrex' there is a great increase as the saturation point is approached, and on silica at 22° C., although the adsorption is not so great as on 'Pyrex' glass, it increases nearly threefold between 68 and 90 per cent, so that measurements made near the latter point are likely to be adversely affected unless adequately corrected.

It is likely that some of the published data on compressibilities at low temperatures may be in error unless adsorption is taken into account.

Travelling Disturbances in the Ionosphere : Changes in Diurnal Variation

IN an earlier communication[1] it was reported that the direction of horizontal movement of travelling ionospheric disturbances observed at Sydney, Australia, had a consistent diurnal variation during winter months in the years 1950–52; but no significant diurnal variation was then apparent in the summer. These conditions continued until 1955; but in the summer of 1955–56 a definite change appeared which was even more marked in 1956–57, the main feature being a marked change of direction from the south-east to the south-west quadrant about midday. The contrast is clearly evident in Fig. 1, which shows the mean diurnal variation in January for the years 1951–54 as compared with the variation for January 1957. The consistency of the results of 1951–54 is shown by the dotted lines, which indicate maximum deviation from the mean. It will be noted that the change from south-east to south-west quadrant in 1957 is quite sudden. This sequence is also found on a number of individual days, though not on all days. There was no significant change in mean speed over this time interval.

Examination of past records starting from the summer of 1949–50 shows that there was a tendency for a similar sequence to occur on occasional days in that year but not sufficiently often to affect the mean curve for the month. This tendency, however, decreased in succeeding years to a minimum in 1953–55. It then increased noticeably in 1955–56 and markedly in 1956–57.

It seems likely that these changes are associated with the sunspot cycle, which showed minimum

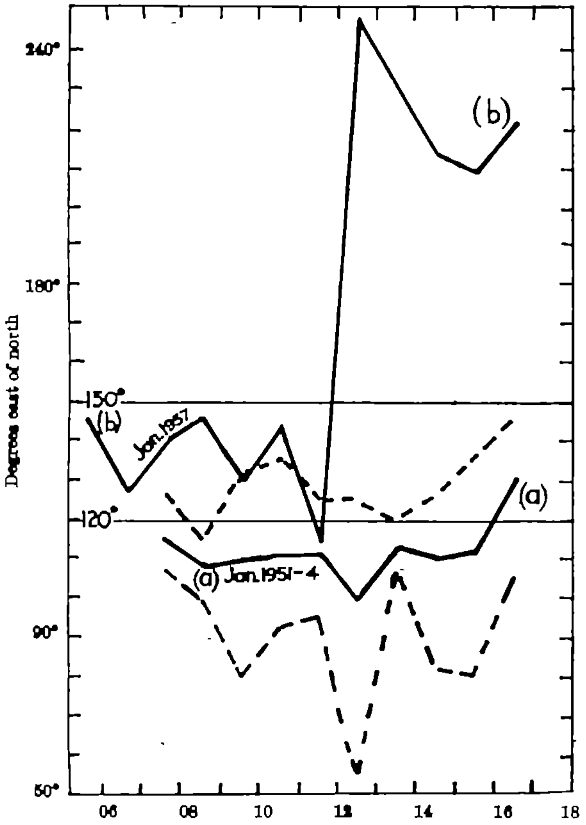

Fig. 1. Diurnal variations in direction of travelling ionospheric disturbances: (*a*) January 1951–54 (peaked curves show extreme values); (*b*) January 1957

activity in 1954, and which had already reached a record high value in the (southern) summer of 1956–57.

Radio Noise from Planets

The reception of high-frequency radio noise from the planets Jupiter and Venus[1-3] has led to speculation on the nature of the causative disturbances. One suggestion is that the noise originates in electrical discharges analogous to terrestrial lightning, and Kraus[3], from consideration of the total energy in lightning discharges, has concluded that a source on Venus, of comparable size to those on Earth, would be sufficient to explain the noise. Before the analogy is pressed too far, however, it is desirable to compare the characteristics of the noise in more detail.

One feature of terrestrial lightning is that while the greater part of the energy, and in particular the electromagnetic radiation at very low frequencies, emanates from the high-current stroke to ground, noise at high frequencies has its origin mainly in discharges in the cloud. These cloud discharges are often associated with ground strokes, but are of different form and much lower energy. Any derivation of the high-frequency radiation from consideration of the total energy of the lightning flash may, therefore, be grossly in error. A more satisfactory basis of comparison is the observed form of high-frequency radiation from terrestrial lightning.

Typical noise from a single flash, as observed in a bandwidth of 500 c./s. at 10 Mc./s., consists of a burst lasting up to one second and of peak amplitude about 1 mV./m. at a distance of five kilometres from the flash. These are approximate figures, but only orders of magnitude are being considered. On this basis a similar flash on Venus would give a burst, received on Earth with a power flux of 10^{-26} watts/m.^{2}/c./s., and the corresponding figure for Jupiter would be 5×10^{-28} watts/m.^{2}/c./s.

The measured amplitudes of the noise bursts from Venus and Jupiter are 9×10^{-22} and $2 \cdot 6 \times 10^{-21}$ respectively, at 27 Mc./s. (ref. 3 and private communication from J. D. Kraus). Since a terrestrial atmospheric would have lower power at 27 Mc./s. than at 10 Mc./s., perhaps by a factor of ten, the discrepancy between the measured noise power and that which would be expected from a flash of terrestrial form is of the order of 10^6 and 5×10^7 respectively for Venus and Jupiter.

It must be considered, however, that lightning flashes on Earth do not occur in isolation; it has been estimated that about one hundred flashes per second take place over the world as a whole. Since each disturbance lasts an appreciable fraction of a second, the fields are superimposed, and the total field at a distance may greatly exceed that from a single flash. It is reasonable to assume that a similar state of affairs would exist on the other planets, and this may be a partial explanation of the amplitude discrepancy, particularly for Jupiter, where the storm areas might be much larger than those on Earth. However, it seems necessary also to assume that the scale of the disturbances greatly exceeds that of terrestrial discharges, or that they are of different form, with much more high-frequency energy, or that some form of focusing takes place.

If the noise originates in a multiplicity of storms, its character is difficult to understand. To an observer in outer space, terrestrial noise would be continuous, owing to the integrated effects of a large number of storms. The noise from the planets is reported to consist of bursts, with durations similar to those of typical atmospherics from single lightning flashes. Before the analogy with terrestrial discharges can be accepted, an explanation for the occurrence of discrete bursts must be found. Perhaps these bursts are introduced by fluctuations in the condition of the propagating medium rather than in the activity of the source.

The atmospheric noise observations on which these remarks are based are part of the programme of the Radio Research Board, and this communication is published by permission of the Director of Radio Research of the Department of Scientific and Industrial Research.

Variation of Elastic Constants of Hardened 1 per cent Carbon Steels on Tempering

It was shown some years ago that changes in elastic constants accompany the hardening process in steel[1] and can be measured by ultrasonic techniques. More detailed experiments have been made recently on two commercial steels containing about 1 per cent carbon. The steels were quenched in oil from 780° C. and then tempered for one hour at temperatures between 100° C. and 650° C., in steps of 50° C. Young's modulus, E, and the rigidity modulus, G, were measured after each heat treatment by the ultrasonic-pulse method. The rigidity modulus was also measured by static loading, the same specimens being used.

The specimens were 7 in. long and 0·5 in. in diameter with enlarged ends of square section for the application of the static torque. The square ends were used for the ultrasonic tests in which the phase velocities for pulses in the longitudinal and transverse modes were measured. The values of E determined from these velocities are estimated to be accurate to within ± 0·2 per cent and those for G to be within ± 0·1 per cent.

The static values of G were measured in a special rig designed to apply a pure torque and the maximum shear stress did not exceed 4,000 lb./in.^{2}. The twist was measured over a length of 3 in. by means of two mirrors which were observed simultaneously with an autocollimator. The static values of G are considered to be accurate to within ± 0·3 per cent.

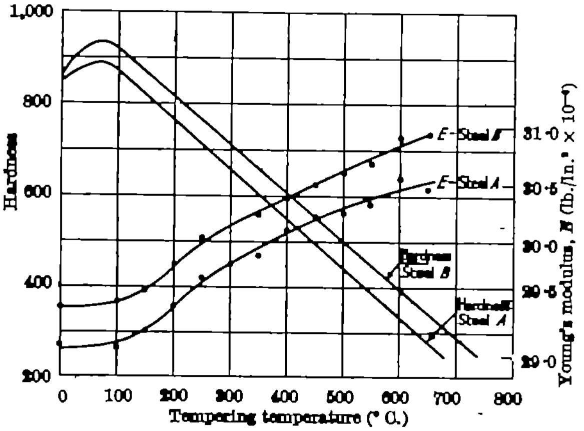

Fig. 1

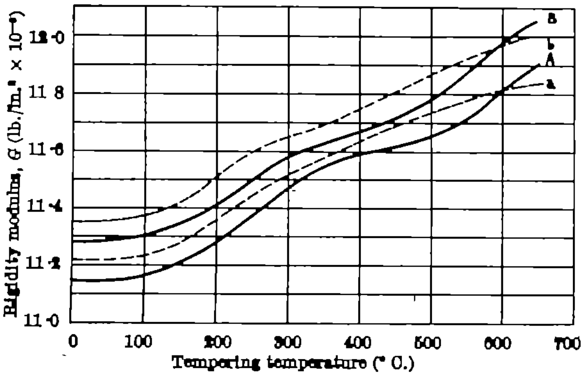

Fig. 2. Rigidity modulus *vs.* temperature of tempering. For steel A: (a) by the ultrasonic method, (A) by the static method; and for steel B: (b) by the ultrasonic method, (B) by the static method

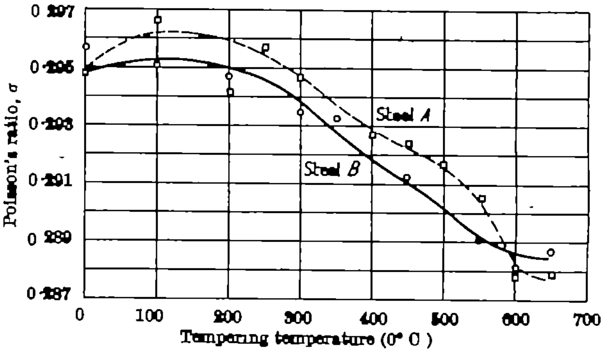

Fig. 3

Fig. 1 shows the ultrasonic values of E for the two steels as a function of tempering temperature, the corresponding values of the hardness being also plotted. Fig. 2 shows the values of G determined by ultrasonic and static methods, again as a function of tempering temperature. In Fig. 3 the values of Poisson's ratio derived from the ultrasonic figures are given. It can be seen that the total increase from the hardened to the fully tempered state is about 4·5 per cent for E and 6 per cent for G.

The static values of G are about 1 per cent lower than the ultrasonic values for hardened steel for tempering temperatures up to 450° C. At higher tempering temperatures the difference is insignificant.

A possible explanation is based on the supposition that the bars were not fully quenched through their thickness. If the surface were harder it would have more effect on the static measurements because of the stress gradient, whereas the ultrasonic tests are based on the average wave velocities in a radial direction. Further work would be needed to prove the validity of this effect.

This work has been carried out as part of the research programme of the National Physical Laboratory and is published by permission of the Director.

A Surface Electroluminescence Effect in Diamonds

Thin diamonds, all of type I, have been found to luminesce with bright green spots of light when a potential difference is applied to them. The luminescence is often intense enough to be seen in daylight. This effect was first noticed while investigating some aspects of the counting properties of the diamonds, and only after the diamond had been coated with a thin layer of graphite and annealed in this condition.

All the stones so far tested are of the conventional rhombohedral form and with a maximum dimension of about 1 mm. Before being coated with 'Aquadag', the diamonds were good insulators with a resistance greater than 10^{12} ohms: after coating, the resistance between opposite faces fell to 10^6 ohms or thereabouts.

SCIENCE AND SOCIETY

The Poverty of Historicism

By Prof. Karl R. Popper. Pp. xiv+166. (London: Routledge and Kegan Paul, Ltd., 1957.) 16*s*. net.

THIS book is an enlarged, revised version of some articles published in *Economica* thirteen years ago. Their reappearance in book form is very welcome, for in these writings Prof. K. R. Popper adds to the considerable debt already owed to him by all students of the natural and social sciences.

Popper's intentions are both polemical and constructive. He wishes to expose the fallacies which underly a certain theory, or group of theories, about both the subject-matter and the methodology of the social sciences. This doctrine, 'historicism', is roughly that the task of the social sciences is both to discover the 'laws' or 'trends' exemplified by the development of societies in time, and to predict the future course of history. In criticizing this, Popper makes a large number of illuminating and subtle observations, particularly in connexion with the crucial difference between a trend, such as may be established by statistics, and a universal law, of the kind desiderated by physics. This logical analysis of laws and theories in physics is not only of considerable importance in its own right, but it also conclusively shows that there can never be a holist or historicist 'science of society'. As against this, Popper defends a piecemeal approach to both social investigation and reform; this he calls "social engineering" —a phrase with unfortunately mechanistic overtones, which, however, Popper is at pains to disavow.

There are three topics whose treatment by Popper is, I think, open to question.

(1) The notion of historicism is qualified in so many ways that in the end the term has a very wide meaning indeed, perhaps too wide to be very useful. Historicism, we are told, is both the theory that large-scale social changes can be predicted, and that they can be controlled. As Popper shows, predictability and controllability are not the same, and so we have two distinct varieties of historicism. Further, a distinction is drawn between what are called pro-naturalistic historicists, who regard the methods and objectives of the social sciences ('social dynamics') as essentially the same as those of the natural sciences, and anti-naturalistic historicists who reject this on the grounds that the complexity of society vitiates the experimental method, and that historical development precludes generalization. This gives us a fourfold classification of types of historicism, and there are doubtless others, for Marx, Plato, Comte, Spengler, Toynbee, Mill and Mannheim are all said to be, in their various fashions, historicists. However, the reason why Popper gives to 'historicism' such a wide meaning is that he very properly wishes to state these theories in their most plausible form before setting out to demolish them.

(2) According to Popper, the essential difference between the natural and social sciences is that the latter permit the adoption of a method of logical construction in which a model of behaviour is set up on the assumption of complete rationality on the part of the individuals concerned, so that we can estimate the deviation of actual behaviour from model behaviour by using the latter as a zero coordinate. This technique, which in this application is derived from Weber's *verstehende Soziologie*, is of great importance in the social sciences; but the employment of this type of idealized model is also important in the natural sciences, although admittedly here no reference is made to rationality. There seems no difference in principle between, for example, an economist's use of the concept of perfect competition and a physicist's employment of the notion of 'free motion' in a Newtonian system.

(3) In discussing the conditions of scientific and technological progress, Popper rightly insists that the scientific community is a social institution whose standards of objectivity make possible the growth of science. He associates this with a different doctrine which, although widely accepted, is in my view both mistaken and dangerous—it is that "science is based upon free competition of thought; that is, freedom" (p. 159). In fact, the only social requisite for the development of science is free interchange of ideas *on scientific issues*; this might co-exist with complete absence of freedom in respect of other matters. Although liberal humanism made the sciences possible, we cannot assume that it is essential for their preservation. This supposition is one of the reasons why it is still difficult for many to recognize the achievements of Soviet science. We can all think of individuals who combine scientific sophistication with political superstition, though to what extent a whole society can succeed in maintaining the departmentalization is a question that cannot as yet be answered. But its answer must not be begged.

It would be misleading, however, to conclude on a critical note. This is an important and original book which makes valuable contributions towards the solution of a number of difficult and fundamental questions.

C. K. GRANT

ARCHÆOLOGY AND THE BIBLE

What Mean These Stones?

The Significance of Archæology for Biblical Studies. By Prof. Millar Burrows. (Meridian Books.) Pp. xvi+306. (London: Thames and Hudson, Ltd., 1957.) 12*s*. 6*d*.

THE Bible is a library of books, not all of the same literary or historical importance. In some cases (especially in the Old Testament) the books themselves are composite and contain ancient fragments embedded in a more recent framework. When, therefore, Prof. Burrows suggests that archæological researches in Palestine back up statements appearing in the writings, it must be clearly understood that in no sense can the verbal accuracy of the whole be demonstrated; all that can be said is that many topographical descriptions can be shown to be reasonably correct, and some of the ideas underlying the outlook of the people can be shown to be in agreement with the written records. Prof. Burrows knows his material and is not at all one of those verbal inspirationists who still hanker for proof that every word of the written text is a scientifically accurate statement. The only fault in his book—and for some of us older folk it is a real one—is the small print. Why the publishers did not produce a better and larger volume I cannot imagine.

Prof. Burrows first discusses what archæology can teach us and how its finds must be interpreted. He then deals with the texts. He continues by trying to show how far in the long story of Israelite development the archæological evidence seems to reinforce the written accounts. The last chapter deals with the religious and ethical background. In this connexion it can be recalled that some of the patriarchal legends and indeed the beginnings of an ethical religion seem to have already been evolved in the Bronze Age Ugarit Kingdom of northern Syria long before the Hebrews infiltrated into Palestine. It would appear that when Egypt was strong she kept open the high road to Damascus whence came her supplies of wood. When Egypt was weak, Canaan was controlled by a number of cities which organized the defence of the countryside. With the arrival of the Pharaohs of the eighteenth dynasty these cities were destroyed and the great road re-opened. During the times of the 'Heretic King', once again the Egyptians retired and the road was blocked. But owing to the recent destruction of the cities the countryside could not be defended. It was just then that the Israelites infiltrated into the region. Only Jericho (destroyed by an earthquake similar to that which in 1927 caused the banks of the Jordan above Gilgal to cave in and so ponded back the water for a few days—permitting the invaders to cross dryshod) and Ai (obtained by fraud) were taken, but the countryside was occupied; and this because the Pharaohs of the eighteenth dynasty had first destroyed the ruling towns and then left the country. Now turn up Joshua xxiv, 12: "And I sent the hornet before you, which drove them out from before you . . .". The symbol of the Pharaohs of the eighteenth dynasty was a winged wasp! Just a sentence of real history. M. C. BURKITT

ROMAN ROADS

Roman Roads in Britain

By Ivan D. Margary. Vol. 2: North of the Fosse-Way—Bristol Channel (including Wales and Scotland). Pp. 288+24 plates+6 maps. (London: Phoenix House, Ltd., 1957.) 50*s*. net.

THIS is the second and concluding volume of Mr. Margary's survey of the Roman road system of Britain. The first volume was very generally and rightly acclaimed by Sir Mortimer Wheeler, for we have had to wait nearly half a century for anyone to take up the heavy task of bringing Codrington into line with the modern knowledge of this subject (see *Nature*, 176, 3; 1955).

It is a curious fact that although the Roman road system of Britain has attracted the almost passionate attention of antiquaries for more than two hundred years past, the subject still awaits really adequate treatment. On various occasions of late, when research projects in archæology have been discussed, a systematic study of our Roman road system has been proposed, always in vain. Now this would certainly be a very large project which could only be undertaken on a team basis, and it would be hampered by the fact that a good proportion of the system in Britain is buried under modern roads. All the same, there are many hundreds of miles of road quite free of modern encumbrance, but it is still only occasionally and locally that we can speak with knowledge derived from actual testing in the field about the width of the road, its composition, its ancillary features, and its date within the period.

We cannot expect this information from Mr. Margary, for he is but one man, and here collates for us all that is known. He has himself shown the way in his own more detailed researches into the Roman road system of the Wealden region. But the whole field of British archæology can show no more really comprehensible subject than this, provided that enough properly organized work is done. It may be objected that the time is not ripe for such a project even now. It is certainly true that the full tale of Roman roads in Britain is far from being made up, as Mr. Margary will be the first to acknowledge, as exemplified by the appendix to this volume which records progress in this field south of the Fosse Way–Bristol Channel line in the short time since his first volume appeared. It becomes more evident every year that the network of properly constructed and maintained Roman roads in Britain is far greater than we suppose. It is possible for important links in the system, like the roads connecting Silchester with St. Albans and Gloucester with Bath, to be only appearing now, as Mr. Margary's study sees the light, and it would be rash to prophesy what will come out of Wales and the Midlands in the next decade.

Roads, whether they are Roman or of later date, make a coherent system in relation to the population pattern of their time. In the case of several parts of Roman Britain, and in particular the Midlands, this pattern is now beginning to take more definite shape and density in areas which used to be almost blank, and the recognition of many lesser roads there is following suit. The need now is for a study section by section of every Roman road in the country, which will establish the exact line, the date of construction and of any major modifications, the make-up of the road with reference to local and other materials, the engineering features of difficult tracts, all recoverable information about bridges, viaducts, and culverts, and, last but not least, the related human settlements, whether actually on the line of the road or in the more immediate region through which it passes. There is also the important question of survey methods used in the lay-out of the original line.

In some parts of the country, notably in East Anglia, there is reason for believing that some roads were of only temporary military importance, while others were more enduring and related to the developed economic and administrative life of the regions through which they pass. Here once again Mr. Margary has shown the way with his Wealden studies; but the process requires extension to the whole country. Locally the details of suburban roads and by-passes in relation to towns also need more intensive study where conditions still permit this.

Therefore, while we welcome the completion of Mr. Margary's great task and applaud the skill which he has shown in handling and presenting a great body of material in convenient form, it must be made plain that this is not the end. These two volumes come at a time of growing public interest in archæology. They are passing into the hands of a wider public than was the case of archæological books even twenty years ago, and they will certainly play a great part in promoting this long-established line of study. They are at once a landmark and a point of departure. C. W. PHILLIPS

THE ESSAYIST OF THE BRITISH COUNTRYSIDE

Field and Farm

Essays now First Collected, with some from MSS. By Richard Jefferies. Edited with an Introduction and Notes by Samuel J. Looker. Pp. 191. (London: Phoenix House, Ltd., 1957.) 15*s*. net.

RICHARD JEFFERIES was one of the most highly gifted writers about the English countryside in the whole of our history. He was born in 1848 at the little village of Coate near Swindon; his father was a small farmer, unpractical but a keen observer of Nature and natural phenomena, and also a great reader with a considerable library of the best authors. He introduced Richard to Homer, interested him in the neighbouring Roman encampments, and trained him in the habits of the naturalists. Richard did not, however, follow his father on the farm, but at the age of seventeen became reporter for a local paper and afterwards joined the staff of the *Wiltshire and Gloucestershire Standard*. Some twelve years later he moved to Surbiton and became a free-lance journalist, writing articles on the countryside for *The Times*, the *Pall Mall Gazette*, and some of the agricultural journals, especially the *Live Stock Journal*. He also wrote three indifferent novels and other books which were not all appreciated. Two, issued by Longmans, "The Story of my Heart" (1883) and "Red Deer" (1884), had been failures; Longmans consequently refused "The Life of the Fields", which, however, was later published. "Amaryllis at the Fair" was rejected by Bentley but afterwards accepted by Sampson Low (1887). His clientele was highly esoteric.

Jefferies started collecting his scattered writings into volumes but died before the task was completed. Many would have been lost; they were mostly unsigned or were under a variety of pseudonyms, and no complete list could be found. By prodigious efforts, for which all admirers of Jefferies must be profoundly grateful, Mr. S. J. Looker has unearthed a number of them. He issued some in 1948 under the title "Chronicles of the Hedges" and now a further group in this volume, "Field and Farm".

The essays are short, compact, full of close observation and very attractively written. They cover one of the most interesting periods in the history of the British countryside, the 1870's and 1880's, when the brilliantly successful golden age of British farming was giving place to the terrible depression that lasted until about 1900, and his vividly recorded reminiscences of older people take the story back into the period when farms and villages were largely self-contained and had little personal contact with the outside world. It was the milk traffic with London that first brought news-sheets—weeklies, not yet dailies—into his country: the most popular items were local squabbles, slashing attacks on established institutions, murders and other crimes spicily related. He tells of other new troubles: of town trespassers breaking farm fences, trampling down crops, and allowing their dogs to chase sheep; except that there is no mention of litter, all this might have been written to-day. He is heavily down on some of the newfangled innovations: the newly introduced lunch which broke up his day and spoiled his dinner, the "heathenish Tories" with their Primrose League seducing the villagers, the parson that refused burial to a Nonconformist baby, and the growing power of money.

Most of his writing, however, is about the common things of the countryside: the birds, the flowers, the trees and the fields. His descriptions are not simply accurate—for he was a sound observer—they are expressed in delicately appropriate language conveying something of the elusive beauty of the things he saw. He was essentially a solitary figure, spending his years, especially the later ones, not in the quest for personal advancement but in communing with Nature, trying to see beyond the mystery of which he was conscious and yet could never penetrate; it is this that gives the special quality to his writings.

His last five years were darkened by illness: he died in 1887 at the age of thirty-nine. He lies buried at Broadwater, Worthing, near W. H. Hudson, the one who comes nearest to him in quality though writing a little later in time. Mr. Looker is to be congratulated on his discovery of these essays, and the Phoenix Press on presenting them so well.

E. JOHN RUSSELL

INSTINCT IN MAN

Instinct in Man in the Light of Recent Work in Comparative Psychology

By Dr. Ronald Fletcher. Pp. 248. (London: George Allen and Unwin, Ltd., 1957.) 40*s*. net.

THERE seems to be a pendulum-swing in our thinking about some of the more general aspects of human behaviour. At one time they are regarded as a product of biological forces inherited by every member of the species; at another, the environment is held to be all-powerful.

During the past thirty years or so we have moved out to the environmental extreme. Even in the clinical field, where the biologically oriented theories of Freud have gained wide acceptance, the part of psychoanalysis that has been most influential relates to the effects of the early environment. The pendulum is now beginning to swing back.

Recently the ethologists, Lorenz, Tinbergen, Thorpe and others, basing their studies mainly on animal behaviour, have shown that instinct is not an outmoded concept, and may even be of value at the human level. In so doing they have confirmed, as well as improved upon, the pre-1920 work of Lloyd Morgan, McDougall and Drever.

Dr. Fletcher has given a general account of the whole cycle, with particular reference to the systematic importance of the biological approach to the sociologist. The treatment is discursive but readable. It suffers from a lack of first-hand experimental or clinical experience and from a rather amorphous theoretical background. On the other hand, it is important that social scientists should have brought to their notice once again evidence from animal behaviour which they might tend to neglect. It is also of value to have put into historical perspective for the first time our recent thinking on some aspects of motivation.

SIDELIGHT ON A MODERN ARCTIC EXPEDITION

High Arctic

The Story of the British North Greenland Expedition. By Mike Banks. With four chapters by Angus Erskine. Pp. xii+276+17 plates. (London: J. M. Dent and Sons, Ltd., 1957.) 25s. net.

This book is good evidence of the truth that, if we are to get something approaching the whole story of a major expedition, it is necessary that several of its members should contribute individually to the written record. To a reviewer, himself a survivor from Antarctic exploration half a century ago, this has been a fascinating book to read, far more so than could be any carefully edited official narrative. Its interest is much enhanced because it is, in effect, the work of two authors, differing in temperament and experience and both conveying their experiences in an uninhibited manner. To one who has himself written in an amateur way on psychological aspects of polar exploration, it is particularly intriguing to be given a glimpse of the old pattern repeated under such very different conditions: alternations of exhilaration and depression; the formation of cliques; the deepening of loyalties and prejudices—all the kaleidoscopic responses to team life in a harsh environment can be detected, substantially unchanged in spite of the impact of radio and the application to polar exploration of mechanical aids and air support.

The more isolated Antarctic sojourners even of to-day will envy the variety provided by the more prolific Arctic flora and fauna; the contact with trappers and the men of the Danish patrol (even at the expense of an occasional parking fee) and American airmen dropping, among other things, condemned pork and hamburgers for under-privileged dogs. Survivors from a past less-sophisticated age will be impressed by the increased fire risk caused by the introduction of petrol as an essential of polar travel, especially when combined with the intervention of the 'Commando' type who is trained to live dangerously as a matter of course.

To the non-mechanical mind one of the most amazing and creditable facets of modern exploration is the thousand and one improvizations successfully carried through in the maintenance of 'weasels' and their like in the field. Mike Banks's remark "on rough going give me my flat feet" is a modernized version of McClintock's flat that set the pattern of sledging technique for the Scott and Shackleton expeditions. One thing very different from their regime is the much more lavish use of alcohol nowadays, which perhaps reflects the Service habits of a more indulgent and less disciplined age than those of Victoria and Edward VII. It is arguable that, in this particular respect, the old practice had more to recommend it both from the physical and psychological points of view. There is some piquant phraseology here and there, of which as examples I would choose two references to the "white-out" which has become so important since aircraft are used: Angus Erskine's description "like the inside of a ping-pong ball" and that of the observer who looked out of a tent and could see "two-fifths of one-third of dam-all".

Raymond Priestley

CHEMISTRY OF SIGHT

The Visual Pigments

By Dr. H. J. A. Dartnall. Pp. vii+216. (London: Methuen and Co., Ltd.; New York: John Wiley and Sons, Inc., 1957.) 30s. net.

In 1878 Kuhne published his classic treatise on visual pigments. The same year, it appeared in England in a translation by Michael Foster entitled "On the Photochemistry of the Retina and on Visual Purple". Kühne's book laid the foundation for much that has since been learned about visual pigments. The intervening years have, however, brought many new discoveries—the elucidation of the role of vitamin A in vision, and hence nightblindness; the discoveries of retinene, and of vitamin A_2 and retinene$_2$; the characterization of several new visual pigments; and many others. Dr. Dartnall has successfully met the challenge of writing the first book on visual pigments since Kuhne. He is an authority on the chemistry of visual pigments, and his book fills a need which has long been felt by teachers, students and research workers in the field of visual physiology.

The book starts with a description of methods of preparing visual pigments and of measuring their absorption properties. It goes on to a classification of visual pigments and a discussion of their chemical reactions, particularly the intermediates and end-products of bleaching. Dartnall next discusses the physical chemistry and photochemistry of rhodopsin, and reviews critically proposed structures for the rhodopsin chromophore. A chapter is devoted to the *cis-trans* isomerism of the retinenes and vitamins A in relation to the chemistry of the visual pigments, and another to methods which test the homogeneity of various preparations of visual pigments. A final chapter summarizes the interesting results obtained recently from the study of visual pigments in visual cells *in vitro* and in the living eye. Each chapter ends with a list of references. The book can therefore be read as an integrated introduction to the field, or as a series of semi-independent reviews. It will be useful to the general reader as well as to the person interested in some specific aspect of the field.

A number of minor errors have inevitably crept into the condensation of such a wide range of information into about two hundred pages. Thus the discussion of resonance (p. 101) reveals a misunderstanding of the concept of the hybrid bond. There is also some trouble involving terminology. For example, Dartnall uses the term 'isorhodopsin' in two senses, sometimes in the same sentence (as on p. 53), to denote 'regenerated rhodopsin', now known to be a mixture of two molecular species (the sense in which the term was originally proposed by Collins and Morton); and for the specific pigment formed by the combination of the iso-*a* isomer of retinene$_1$ with rod opsin (the sense in which the term is currently used). More serious errors are contained in the summary diagram on p. 54. Such diagrams are potentially more instructive than several pages of text. It is unfortunate that this one contains hypothetical and actual reactions mixed in a way which is likely to mislead readers unfamiliar with the details of the field.

A final word on the extraction of visual pigments. The methods given in this book have on the whole not yielded the purest preparations of visual pigments. Dartnall therefore describes various ways of correcting for coloured impurities. Unfortunately the preparation of pure visual pigments is still something of an art. However, in general, carefully purified visual cells yield spectroscopically pure solutions of visual pigment, which need no further correction; while visual cells contaminated with other tissue debris yield impure visual pigments. Since paper and pencil corrections introduce errors as often as they eliminate them, every effort should be made to prepare solutions of visual pigment which are sufficiently pure to need no correction. Such preparations are being made in several laboratories by methods which should have been included in the present volume.

However, these are minor criticisms of a book which offers excellent discussions of the photochemistry of the visual pigments, their synthesis, and their possible role in stimulating vision. The biochemistry of vision is a rapidly growing field, and it is unfortunate that Dr. Dartnall's review spent two years in press. I hope that author and publishers will give us a second edition in the near future.

Ruth Hubbard

COAGULATION OF BLOOD

Human Blood Coagulation and its Disorders

By Dr. Rosemary Biggs and Dr. R. G. Macfarlane. Second edition. Pp. xxv+476+3 plates. (Oxford: Blackwell Scientific Publications, 1957.) 42*s*. net.

To write a reasoned and critical account of the present status of our knowledge of the mechanism of hæmostasis and of the disorders to which it is prone is a Herculean task which few people would care to undertake, and fewer still possess the breadth of view of the subject to enable them to bring such a task to a well-balanced conclusion.

The unequivocal demonstration of the separate existence of factor V and of the general mode of its action by Owren in 1947, closely followed by two other groups of workers, initiated a period of intense activity in the subject of blood coagulation which may only just be levelling off. In 1949–50, nearly 400 papers were published in the field and in 1953–54, when the first edition of this book appeared, the number had risen to 600. The deceptive facility with which experiments on blood coagulation can apparently be conducted has always led to the publication of much ill-considered work, and excessive labour has consequently to be expended to winnow the few grains of truth from the chaff. Latterly in addition, as well-authenticated new components of the clotting mechanism have come to light more or less simultaneously in different laboratories, a multiple nomenclature has arisen further to complicate efforts to appraise the significance of any particular piece of research.

It must have been the cause of considerable chagrin to the authors to find that the first edition of this book was out of date almost immediately after it was published, chiefly on account of developments arising from their own work. The situation was a result of their demonstration in 1953 of the essential mechanism of production of the powerful intrinsic thromboplastin of blood. This was previously believed, erroneously, to be very weak in comparison with thromboplastic extracts of tissues, on account of an unrecognized lag phase in its production. As the book was in the press it at last became clear that clinically recognized hæmophilia could be due to the deficiency of either of two factors now known to participate in intrinsic thromboplastin generation; these are variously referred to, but in the authors' terminology are called antihæmophilic globulin and Christmas factor. There may be other factors, a deficiency of which can evoke a syndrome similar to hæmophilia, but these two alone are established beyond reasonable doubt.

The revision of the book is consequently mainly concerned with the newer knowledge of the components involved in the generation of intrinsic thromboplastin in blood, the probable mechanism of their interaction and the consequent modification necessary to the classical theory of blood coagulation. The development of the thromboplastin generation test has facilitated both diagnosis and treatment of hæmophilia and Christmas disease, and it has further implications.

Naturally the other chapters of the book have been brought up to date. It would appear that the conception of the function of factor VII in the coagulation system is altering; also new mechanisms have been put forward to explain the activation *in vitro* of plasminogen, though the evidence for these does not appear to be definitive.

The book is written essentially from a physiological–pathological point of view. Lest the impression has been given that its only concern is with the blood coagulation mechanism, it must be stated that the overall aspects of hæmostasis are also discussed in relation to platelets and capillary phenomena.

An extensive account is given of the various tests which may be applied to detect deficiencies of the clotting function, and in appendixes adequate details are provided for the laboratory preparation of reagents required.

It is distressing to find a book of such high scholarship marred by faults of production. There are many misprints in the text, and a large proportion of the numerous graphs give the impression of having been drawn on blotting paper. The reviewer found it irritating also to have the bibliography in two sections, one comprising the references of the first edition and another an addendum of references to papers published from 1953 onwards.

In view of the emergence of a phase, mentioned by the authors in their preface, in which more disciplined biochemical work will be necessary for the further advancement of the subject, they might perhaps have given more consideration than they have to the established work in this field.

Though there is still room for considerable variation of opinion in the interpretation of some of the experimental findings, there is no doubt that all who are interested in the subject of blood coagulation will be indebted for many years to come to the authors, for the clarity and wisdom with which they have compiled this comprehensive and most readable monograph.

R. A. KEKWICK

PLANT DISEASES AND HUMAN WELFARE

Principles of Plant Pathology

By Prof. E. C. Stakman and J. George Harrar. Pp. xi+581. (New York: The Ronald Press Company, 1957.) 8 dollars.

THE names of Prof. E. C. Stakman and Dr. J. G. Harrar are in themselves almost guarantee enough that this would not be just another academic text-book, but the fact could well have been emphasized by a title more appropriate to their vivid treatment of the subject. "Principles of Plant Pathology" tends to imply dull reading, of the sort needed to pass examinations, whereas there is nothing dull about this book. The student who has to pass examinations in plant pathology will certainly find much here to help him with this chore, but this is a minor part of the book's value. What is much more valuable is that he will soon realize that he has entered a subject of immense and varied scientific interest, the fascination of which is surpassed only by its economic and sociological importance. A better title, however, is less needed for plant pathologists, for whom the book will be essential reading anyway, but to attract the wider audience that could read much of it with interest and profit.

Its style, theme and contents are most simply illustrated by a few quotations. "Man occupies this planet as a guest of the plant kingdom." "Unless plant diseases are contained, the world's efforts to feed itself cannot be successful." "This problem is by its very nature international in scope." "The health of plants is vital to society and human progress, and this volume is essentially a discussion of the problems and principles involved in protecting the health of domestic plants." The only comment called for is to say that the discussion is excellently conducted and the conclusions amply justified.

Prof. Stakman and Dr. Harrar show that much has been achieved in the short history of plant pathology, but they make it equally clear what a lot still needs to be done before the world's crops reach even a moderate state of health. Their unique international experience, first at the famous school of plant pathology in Minnesota and later through the Agricultural Division of the Rockefeller Foundation, allows them to write with equal authority on present and future problems. Although they have no doubt that what needs to be done could be done, they are far from complacent; indeed their awareness that present research is inadequate gives an impelling sense of urgency to much of their writing. Food is far from plentiful in some parts of the world, mainly those where losses from pests and diseases are greatest, and with human populations increasing rapidly, more than is now harvested is soon going to be needed everywhere. There is some comfort to be gained from the fact that man need not starve provided he stops sharing his crops with pests and diseases; but the reaping of full instead of part harvests will not come about automatically. Those responsible for deciding what proportion of scientific endeavour should go to different subjects seem often not to put first things first, and biology tends to become an increasingly poor relation of other sciences. To reach the Moon may be a laudable ambition, but its fulfilment will butter no parsnip, and surely it should wait until both the Moon visitors and those left on Earth are assured of enough to eat. This assurance will not be gained unless agricultural research is much increased. The cost would be small, not only in relation to the gains, but also relative to what is spent on less essential problems.

But this book is far more than an eloquent plea for increased research. It deals adequately with all kinds of diseases, and describes the conditions that affect their prevalence and how they can be combated. Considering its scope, it contains few errors, and these on minor matters that do not affect the general conclusions. The text is matched by many excellent photographs, and the whole book is finely produced. Each of the eighteen chapters has a selected list of references; there are three appendixes listing books on plant pathology and the principal pathogens and insects cited in the text, and there are a subject index and an index of names.

F. C. BAWDEN

LAVOISIER'S LETTERS

Oeuvres de Lavoisier

Correspondance. Recueillie et annotée par René Fric. Fascicule 2: 1770–1775. Pp. 251–536. (Paris: Éditions Albin Michel, 1957.) 2,750 fr.

THE second fascicule of Lavoisier's correspondence covers the years 1770–75, one of the most interesting periods of his life in which he was beginning his investigations into the phenomena of combustion. This volume contains 160 letters and documents, seventy of which are by Lavoisier himself. They give an intimate picture of his varied interests in these years and, thanks partly to the biographical footnotes, of the personalities with whom he was in contact. However, the most important and fascinating documents are a number of Lavoisier's own drafts of his notes and letters which reveal the meticulous care that he took in their composition.

Of the thirty-seven letters written in 1770, twenty-six deal with Lavoisier's responsibility as a 'farmer-general' for administering the control of the processing and sale of tobacco. Most of them were written to his father-in-law Paulze, under whose direction he was working, and they show Lavoisier's conscientious devotion to the details of his task and his efforts to prevent the adulteration of tobacco. His shrewd comments and his appraisals of the characters of his officials show his sound business acumen. During his annual tour of his district he reported almost every day on what he had seen and done.

One of Lavoisier's earliest interests had been the improvement of the water supply of Paris, and some of the letters of 1770 deal with this and with a comparison of the efficiencies of the primitive steam engines used to pump water in Paris with those used in the supply of water to London.

There are only eleven letters dated 1771 and they are mainly concerned with the geological atlas of France in which Lavoisier was assisting Guettard. They show the active interest that he was still taking in this project and how much thought he was giving to geological problems. Geikie said of him that he might have become one of the great founders of geology if he had not given himself up to chemistry.

The early letters of 1772 again deal mainly with geology, but on August 31 Lavoisier, writing to an unknown correspondent, tells him of his unanimous election by the Academy as an *associé chimiste* in the place of Macquer who had become a *pensionnaire*. It was a prophetic change in Lavoisier's life, as ten days later his first experience of burning phosphorus led to the investigation described in the first note to the Academy, which he deposited with de Fouchy on October 20. His second note, which was deposited with the Academy on November 1 and opened and read on May 5, 1775, is reproduced in facsimile in this volume. It contains a brief statement of the 'discovery' that the gain in weight of sulphur and phosphorus during combustion is due to the fixation of a large quantity of air.

In the previous July he had received through Trudaine a letter from Magelhoens (Magellan), a son of the Portuguese navigator, who was living in London in close touch with British scientists. It describes a number of investigations of fixed air (carbon dioxide) and gives an abstract of Priestley's proposal to the Admiralty for its use in making mineral waters. This was the first of a series of letters from Magelhoens to Lavoisier, who sent him from time to time copies of Priestley's papers.

There are only four letters dated 1773, perhaps for the very good reason that Lavoisier's time was almost entirely occupied with his study of the evolution of gases during chemical reactions and with careful analysis of the results of previous investigations. Lavoisier's account of the work was published in a separate volume "Opuscules Physiques et Chimiques" in January 1774. He sent copies to a number of learned societies and fortunately the drafts of some of the letters that accompanied them have been preserved.

The first two were addressed to the Royal Societies of London and Edinburgh with copies for Priestley and Black. The letter sent to the Royal Society acknowledges his debt to British chemists: "Cest dans le Sein de langleterre que la doctrine de la fixation de lair dans le Corps a pris naissance. . . ." The letter to Edinburgh shows his realization of the debt he owed to Joseph Black, and his conviction of the importance of the line he was following: "Cest dans votre ville et dans le Sein meme de votre illustre Societié que S'est presquentierement formée une theorie nouvelle qui Semble preparer une revolution dans le phisique et dans le chimie . . ."

Most of the correspondence in 1774 is connected with the publication of the "Opuscules", and later in the year came a letter from Beccaria pointing out that he had anticipated Lavoisier's work on the calcination of tin fifteen years earlier. Lavoisier sent this letter to Rozier to be published with his own paper in Rozier's Journal.

In October of 1744 Priestley had directed Lavoisier's attention to mercury *precipité per se* (mercuric oxide) and in March 1775 Lavoisier deposited a note with the Academy describing briefly his own experiments. It is interesting to compare his original draft with the shortened form in which it was communicated, both of which are printed in this volume. But it was not long before these researches were interrupted by another decisive change in Lavoisier's fortunes. His quick eye had noticed the inefficiency of the operations of the financial syndicate entrusted with the manufacture of gunpowder, to which he had directed the attention of the controller-general, Turgot. A letter from D'Ormesson, one of Turgot's officials, on June 13 informed Lavoisier that he had been appointed with three colleagues to manage the powder factories of France, which also involved responsibility for the collection and purification of nitre. Turgot wrote later to say that lodgings would be provided for Lavoisier in the Arsenal, which was to be his home until almost the end of his life. Lavoisier immediately switched his attention to the urgent problems of his new post, with which most of the later letters in 1775 are concerned.

Undoubtedly Lavoisier must have written many more letters in these years which have been lost or destroyed, so that it is dangerous to generalize from those that have survived. It is strange, however, that there are no letters to his scientific colleagues, except for one to Guyton de Morveau, about the main pre-occupation of his mind from 1772 onwards, his conviction that the investigation of the part played by gases in chemical reactions would solve the riddle of phlogiston and give chemical theory a new basis.

The publication of the correspondence under the ægis of the Academy has had financial support from the University of Delaware and from French industry. Chemists will be very grateful to them for this volume, but it whets one's appetite again for a sight of the as yet unpublished notebooks, without which it is impossible to follow all the twists and turns of Lavoisier's impulsive mind which ended in the chemical revolution.

HAROLD HARTLEY

PLEISTOCENE GEOLOGY

Glacial and Pleistocene Geology

By Prof. Richard Foster Flint. Pp. xiii + 553 + 5 plates. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1957.) £5 net.

IN the preface Prof. Flint states that this book started as a revision of his earlier work, "Glacial Geology and the Pleistocene Epoch", published in 1947; to a certain extent, therefore, some chapters are revisions of that excellent book. So much new work, however, has been done in the years since that volume was written that this book rightly claims to be a new one, bringing his assessment of the various problems up to date.

The book is divided into two major parts of about equal size; the first considers problems of glacial geology, the second deals with Pleistocene stratigraphy. There is one feature of the book which is most helpful: at the end of many sections and chapters there is a short summary underlining the conclusion the author draws from the existing evidence on the point under discussion. In a book of this size, covering such a wide subject, it is more or less inevitable that one interpretation is given greater weight than other views, but the very full bibliography enables anyone who wishes to evaluate other interpretations to do so, if he is within reach of a good library.

There is a very useful summary of the present state of knowledge on 'frozen-ground' phenomena without the use of the jargon which has tended to grow up around this subject. Prof. Flint deals in Chapter 13 with the problems of fluctuation of lakes in non-glaciated regions; here he takes a world-wide survey and suggests correlations of lake-levels with the various episodes of the glacial advances.

It is perhaps in the second half of the book, the stratigraphical part, that most workers will find what is not to be found easily in other works. After dealing with the special problems of Pleistocene stratigraphy and giving a most useful summary of the history of the nomenclature, he concludes that there is no justification for a Quaternary Period and that the "Pliocene–Pleistocene boundary cannot justifiably have 'system value', but only 'series value'". He would also consider that the Pleistocene series includes all post-Pliocene time.

It is natural to expect that the stratigraphy of North America receives the 'lion's share'; Chapters 18–21 deal with North America. It is most valuable to have his authoritative account of the present state of knowledge of this vast area. The correlation charts given are marked 'tentative', showing that Prof. Flint is far from being dogmatic and realizes that new work will necessitate modifications in the schemes.

The glaciation of Europe is compressed into Chapters 22–23. In these, naturally, the details of the succession in the British Isles can only receive a few pages in each chapter, but those few pages give a clear and fair account of the distribution of the various deposits of the Older and Newer Drifts. Prof. Flint concludes that the evidence shows that in the Newer Drift times the Scandinavian ice-sheet made contact with the British ice off the east coast of England, although Fig. 22-2 does not show it as doing so and this figure and Fig. 22-3 vary considerably on the east coast position of the boundary of the Newer Drift.

The correlation table for the British Isles gives a valuable summary of the position as it is at the present time. This table has been drawn up by Prof. Flint after visiting most of the critical sections and discussing the problems with many workers when he visited England a few years ago. Like the North American tables it is labelled 'tentative'. That the complexities of the British glacial succession can be compressed into about two pages of print and a correlation table shows that Prof. Flint is a master at sorting 'corn from chaff' in glacial matters.

Some may find the chapter on the records of Pleistocene fossils rather disappointing after the masterly summaries of the stratigraphy. The final chapter, on the problem of causes, contains much of interest and the general conclusion reached is that the most hopeful theory is a combination of the effect of uplift with solar variation as the primary cause of glacial periods.

An excellent bibliography, covering thirty-four pages, ends the book. Some of the maps are rather disappointing, the stippling at times is at fault and at others reduction from the original drawings has brought lack of clarity; these are very minor criticisms of a work which should be on the bookshelf of every worker on the Pleistocene. W. B. R. KING

QUANTUM CHEMISTRY

Quantum Chemistry

An Introduction. By Walter Kauzmann. Pp. xii+744. (New York: Academic Press, Inc.; London: Academic Books, Ltd., 1957.) 12 dollars.

THIS is a book on which opinion will be very sharply divided. This division will be at the deepest level: How should we teach quantum chemistry? Should we regard the mathematical equipment as of such central importance that we must get it clear and thoroughly established before we allow ourselves the pleasure of seeing just how and where it fits chemistry? Or should we think of it as interpreting chemistry to us, and point out to our satisfaction (or perhaps our surprise) that there is an almost perfect correspondence between familiar chemical concepts and (to a chemist) less familiar mathematical techniques? Dr. Kauzmann belongs to the former class of expositors. So this is why it comes about that the first 150 pages are concerned with determinants, operators, matrices and water waves on a hypothetical earth, with never a mention of atoms or molecules or chemical bonds. Chemistry does not really begin until Chapter 11, on p. 375. But by the time that it does begin, we are already familiar with ideas of eigenvalues, quantized functions, degeneracy, perturbation theory, correlation diagrams and other topics.

There is much to be said for this line of attack. It separates the concepts from the techniques, and so simplifies the student's job. But there are things to be said against it: it uses up valuable time, and there is a danger that the characteristic concepts of chemistry are lost in the mathematical formalism. When we read on p. 1 of "chemistry as a branch of mathematics", or on p. 117 that "much of quantum chemistry depends on the possibility of expansions of this kind" (in a complete set), we can see the author's position clearly.

Let it be said at once that he has carried out his policy in an excellent fashion. The book is clear, exceedingly well illustrated, and with a good number of interesting exercises for the student. Further, it manages to include a lot of material not so commonly found, such as nuclear quadrupole coupling, adiabatic and non-adiabatic transitions and chemical shifts in nuclear magnetic resonance, which greatly enhance the value of the book. From time to time, as in the discussion of the relative values of certain exchange integrals, a real physical insight appears, as an aid to understanding the mathematics. But emphasis on the mathematics, while very salutary to those chemists who are given to loose and woolly thinking, does lead to some unsatisfactory points of view, in which there occur "idealizations, not capable of experimental verification because of the uncertainty principle"; and an account of resonance in the H_2^+ ion (pp. 378 and 535) which leans so heavily on the classical mechanical analogy that it seems to the reviewer to be not quite correct. Nor will anyone be surprised that one conclusion of the book is that most of the familiar chemical concepts such as hybridization, ionic character, bond energy, valence, are so vague as to be ultimately almost meaningless.

This is not a book for a beginner who wants to pick up his quantum chemistry quickly. But if he has already learnt a good deal of it, this book really will help him to see the essential validity of what he has been doing, and will warn him of pitfalls. It will also give him great satisfaction in seeing that the mathematics which he needs for his chemistry is not so very dissimilar to that used in other branches of applied mathematics; and at the end he is likely to say that a better title might have been "Molecular Physics".

C. A. COULSON

RÉAUMUR ON STEEL

Memoirs on Steel and Iron

By R. A. F. de Réaumur. (A translation from the original printed in 1722, by Anneliese Grünhaldt Sisco. With an Introduction and Notes by Cyril Stanley Smith.) Pp. xxxiv + 396 + 17 plates. (Chicago: University of Chicago Press; London: Cambridge University Press, 1956.) 45*s.* net.

TWO hundred years ago (October 17, 1757), the death occurred of René Antoine Ferchault, Seigneur of Réaumur, "whose name is to-day widely known only in connexion with a thermometric scale and a station on the Paris Métro", to use the words of Prof. C. S. Smith in his excellent introduction to this volume. The main work of his life was his biological researches, and from his investigations on the nests of wasps he might perhaps be regarded as the father of the modern wood-pulp industry. It is, however, as a result of his work on metals, confined to the ten years between 1716 and 1726, that his chief claim to posthumous fame really depends, work from which the malleable cast iron industry directly originated. The volume under review contains the collected memoirs, first of his investigations into the production of steel by carburizing wrought iron, and, secondly, the reverse process, the decarburization of white cast iron, in his attempts to produce steel from that material.

Like so many scientific investigators of his day, Réaumur saw no line of demarcation between the discovery of new knowledge and the putting of such knowledge to practical use, and as a direct corollary of his investigations, which were for the first time strictly scientific, he introduced, although at first somewhat unsuccessfully, a new industry to France and later to the world.

Réaumur lived and worked before the age of modern science; an age which had not divorced itself from the alchemical. His thinking, as is shown throughout this book, still centred on the alchemists' 'salts' and 'sulphurs', and it is a most illuminating example of the way in which a prevailing fashion of thought can blind the researcher to what later would appear to be quite self-evident conclusions—a warning which perhaps is not altogether inappropriate in certain directions even at the present day. In his work on the mechanism of converting wrought iron into steel, for example, he showed beyond doubt that materials, such, for example, as lime or bone ash, which do not contain carbon, have no influence, and that the only constant factor to be found among those which did effect the change was carbon in some form or other. He also discovered, however, that the rate at which the conversion of iron into steel takes place may be accelerated by the presence of a salt. This fact, in view of his habits of thought, so completely blinded him to the obvious conclusion that the difference between the original iron and the final steel lay in the carbon content of the latter, that this, one would have thought, self-evident deduction escaped him completely. It is to the 'salt' as much as to his 'sulphur' that he ascribes the effects observed, a fact which so complicates his thinking both in connexion with carburization and decarburization that the essential simplicity of the processes is completely lost.

Although the age of microscopic metallography was still in the comparatively distant future, Réaumur, with the slender facilities available to him, makes the first serious attempt to correlate structure with properties. The structure he could examine was merely that of the fractured surface, but he repeatedly makes it clear that he realizes that behind what was visibly observable lay some deeper and finer structure on which the real nature of the material ultimately depended. He was, however, able to examine in some detail the effects of carburizing wrought iron and of decarburizing white cast iron, and although the meaning of his observations so frequently escaped him, the idea of a composition gradient was clearly in his mind. He speaks, for example, of wrought iron getting into a condition close to steel. That this involved a process of diffusion he obviously realized, and that the rate of such diffusion depended on the temperature was equally clear. So far as the mechanism of the process is concerned, he appears to have believed that diffusion could produce tiny voids into which the diffusing material passed, a conception strikingly similar to the vacant lattice sites hypothesis of the modern metal physicist. It was inevitable that his work on high temperatures should have led him to consider the nature of heat itself. He knew that different metals had different specific heats, latent heats of fusion, and melting points, but heat to him was still a material phenomenon and he speaks, for example, of the introduction into the sample being heated of "torrents" of particles.

Whether looked at as a contribution to the history of technology or as an account of a most interesting phase in the history of science, there can be no doubt that this book is one of outstanding importance. The translation appears to have been done in an exemplary manner and the editor's introduction could scarcely be improved. To translator and editor, and to the funds made available by the American Iron and Steel Institute, we owe a volume which the publishers legitimately claim to be "the first significant book ever devoted to the iron and steel industry".

F. C. THOMPSON

THE *j* OPERATOR

The *j* Operator for Electrical Engineers

By Philip Kemp. Pp. vii + 135. (London: Macmillan and Co., Ltd.; New York: St. Martin's Press, Inc., 1957.) 21*s.* net.

ELECTRICAL engineers calculate the values and 'phases' of alternating currents and voltages in circuits and networks in very much the same way as they calculate steady 'direct' values, except that the values of the quantities are represented by complex numbers $(a + jb)$. They use j instead of the mathematician's 'i' because they use i for current. The basis for this system lies in the representation of sinusoidally varying quantities by radial lines on a clock-face diagram, referred to as vectors, together with the use of complex numbers corresponding with the co-ordinates of the ends of these vectors.

The teacher of electrical engineering is faced with the problem of deciding whether he aims at giving his students the aptitude to use such procedures in the kind of problems to which they are usually applied, with just sufficient explanation to make them plausible, or whether, at the other extreme, he proposes to make use of this topic to develop their understanding of the logical basis of the complex number, which can imply uncovering some of the roots of algebra.

Some kinds of student are unlikely to profit if the time available is devoted to any but the more limited aim. Mr. Kemp has chosen to cater for the needs of this class of student and he has done it very well. His book will help many students, provided that they can afford to buy it, to pass the kind of examination that can be passed by obtaining correct answers to numerical problems about alternating currents. The presentation is very simple, clear and logical within the limitations the author has set himself.

The treatment of the j operator as representing rotation through 90° is followed by short chapters on operators representing rotation through 120°, 60° and 30° respectively, leading to a chapter on the 'symmetrical components' of 3-phase systems, making use of the 120° operator. The exponential form of the complex number A exp $j\theta$ is not mentioned.

The book will be particularly useful to teachers and students in technical colleges. It could have been made useful to a somewhat wider circle if an appendix had been added, to be read by the more mathematically minded, justifying somewhat more rigorously the presumption that the rules of algebra apply to a symbol that is first defined merely as an indicator of a geometrical property. A. TUSTIN

THE ELECTRON PHYSICIST'S VADE-MECUM

Tabellen der Elektronenphysik, Ionenphysik und Übermikroskopie

Von Manfred von Ardenne. Band 1: Hauptgebiete. Pp. xvi + 614. 74 D.M. Band 2: Randgebiete und Hilfsgebiete. Pp. xii + 617–1368. 92 D.M. (Berlin: Veb. Deutscher Verlag der Wissenschaften, 1956.)

IT may be thought unusual, if not extraordinary, to say of a collection of data that, once in the hand, it is hard to put down, that it is fascinating, intriguing and (occasionally) exhausting and infuriating. But this is an unusual work and its author no ordinary man. He is Baron Manfred von Ardenne, inventor of some of the fundamental features of high-frequency amplifiers and cathode-ray tubes, the patents from which enabled him before the Second World War to build a private laboratory near Potsdam which eventually included a betatron and other nuclear physics apparatus, as well as some of the best electron microscopes of the time. In 1945 he went of his own accord (so it is said) to work in the Soviet Union, being flown to Moscow with his family and his universal electron microscope. Rumours of his suicide, after shooting the rest of his household, were confounded when he returned to East Germany in 1955 bringing his family and the universal electron microscope back with him—and the manuscript of this extraordinary book. It was intended to sum up "ten years of fruitful research" in the U.S.S.R., most of which had not been otherwise published, and to prepare the ground for the programme of research in his new Institute in Dresden which had been planned from 1951 onwards and was opened in January 1956. As director of the leading laboratory for nuclear and electron physics in the German Democratic Republic, he is now the best-paid physicist in the Western as well as the Eastern Zone. The "Tabellen", in two volumes totalling nearly 1,400 pages, are on the same grand scale as most of his enterprises. They are much more than a collection of tables such as "Kaye and Laby". They are planned as "a concentrated presentation of the essential content [*geistigen Inhaltes*] of the separate special fields in the form of a co-ordinated collection of formulae, tables, literature references and extracts from original papers", on the lines of the pre-war "Gasentladungs-Tabellen" of Knoll, Ollendorff and Rompe. Vol. 1 contains "the most important formulae, fundamental principles, methods, practical designs, results, technical data and properties of materials" relating to electron and ion physics, and electron microscopy. Vol. 2 contains a similar compilation from the related fields of vacuum technique, heat, optics, high-voltage and high-frequency techniques, magnetism, nuclear physics and mathematics, in so far as they enter into the theory and practice of the main subjects. In other words, a compendium of all the information that a specialized laboratory must have at its command, but which we ordinary folk carry around in our heads, in our day books and our card indexes, stored away in the journals, annual reviews and the American engineering handbooks on our shelves—and in the hands and heads of our glassblowers, mechanics and other assistants. Here you can find tabulated details of the 38 sorts of image converters and intensifiers, the 33 different types of ion source, the 68 nuclear reactors so far built for research purposes and the 38 for energy production; but also the most complete and compact treatment of the properties of electron lenses, and of the design, construction and operation of electron microscopes yet provided.

Only a German could have conceived of such a project, only a man of very wide knowledge and experience could have planned and carried it through, only a von Ardenne could have done so in the Soviet Union, brought the text away with him and had it published on such a sumptuous scale in Eastern Germany. "To achieve uniformity in presentation, the whole work was written by one hand only," he records, and goes on to regret that he has not entirely succeeded, owing to extraneous difficulties, in the task of providing a bird's-eye view of the state of electron and ion physics in the year 1956. As it stands, the work contains as good a survey of it as one will find anywhere. It is inevitable that the German literature should receive more attention than the foreign, but American and English work is widely quoted, up to the second half of 1955, with, however, some unaccountable omissions, such as the work of Haine and Einstein on electron gun properties. It also follows from its individual nature, that the work of the author receives the greatest attention, sometimes to the neglect of more recent or more thorough treatments. In a very detailed author index running to 100 pages, "von Ardenne" occupies 5¼ pages. The inventors of the electron microscope, von Borries and

Ruska, who have been active over an equally long period, rate 1¼ pages between them, and Zworykin, nearest comparable to von Ardenne in versatility, only ¼ page. More seriously, it is often difficult to be sure how much of the author's work is purely paper project and how far it has been proved in the laboratory.

Be that as it may, here is a work of unique character and value—part International Critical Tables, part text-book, part record of ten years individual research, and part history of his subject in the wider sense. If the special nature of its origin and composition is borne in mind, everyone will find much of interest in it and something of value. As a source-book it has no equal in its particular field, the greatest overlap being with the American Institute of Physics "Handbook" (which lists only 38 reactors of all types, but has fuller information on particle accelerators), and with Fink's "Television Engineering Handbook" or Terman's "Radio Engineers' Handbook", both of which are very weak on electron lenses. Taken in conjunction with such other reference works, and here and there with a pinch of salt, it will prove a most valuable addition to the library of every laboratory of electron and ion physics.

V. E. Cosslett

SEMICONDUCTOR PHYSICS

Fizika Poluprovodnikov

By A. F. Ioffe. Pp. 491. (Moscow and Leningrad: Publishing House of the U.S.S.R. Academy of Sciences, 1957.) 20 roubles.

The author of this book has long been associated with the study of the physics of solids. Born in 1880, Dr. A. F. Ioffe became an academician in 1920 and has worked on X-rays and crystal physics in their many aspects. In 1942 he was awarded the Stalin Prize for his research in semiconductors and he is at present director of the Institute of Semiconductors of the U.S.S.R. Academy of Sciences.

The book is a revised and enlarged edition of "Semiconductors in Contemporary Physics" published in 1955. It is essentially descriptive in style and, generally speaking, detailed theoretical treatments are not presented, in order to avoid obscuring the physical argument by analytical complexities.

The introduction traces the history of semiconductors which in the early days were taken to be those materials the resistivity of which lay in the broad no-man's land between 10^{-3} and 10^{10} ohm/cm. Early observations of photoconductivity, rectification and the dependence of conductivity on temperature led to important technological applications long before there existed an adequate theoretical understanding of these processes. To-day the great importance of this field of physics is emphasized by Ioffe's list of sixteen distinct fields of technical application of semiconductors. Furthermore, understanding of the physical bases of the phenomena involved has greatly advanced in the last decade and in some cases may even be said to be complete.

The first three chapters are concerned with electrical conduction in solid electrolytes, metals and electronic semiconductors and provide the background for the later more detailed chapters. Chapter 4 deals with the basic quantum theory of semiconductors and gives a lucid outline of the band theory of crystals and of the factors determining the distribution and occupancy of electronic energy-levels.

Chapter 5 is by far the longest (occupying nearly half the book) and deals with physical phenomena in semiconductors. This commences with a discussion of lattice properties, defects, impurities and the thermal motion of the lattice and thence proceeds to the scattering and mobility of electrons. Consideration is then given to boundary-layer phenomena and *p–n* junctions, and their implications for rectification, transistor action and photo-voltaic effects are briefly described. In passing, Ioffe compares the capital cost of photo-electric and thermo-electric solar batteries for generating one kilowatt of electrical power and arrives at the respective figures of 400,000 and 1,000 dollars. Although the former figure should be divided by about 5 in view of the recent reduction of the cost of silicon cells, and operating factors have to be taken into account, this comparison is still strikingly significant. External electron effects (contact potential, photo-electric effect, emission and secondary emission) and the magnetic properties of semiconductors are reviewed in outline. The chapter then concludes with a section on thermal conductivity and one on thermo-electricity which is a condensation of the author's monograph (1956) on the subject. It provides a survey of the theory of the Seebeck and Peltier effects and an excellent discussion of the design of thermo-electric generators and refrigerators with estimates of attainable efficiencies.

Chapter 6 deals with the measurement of both the fundamental constants and the phenomenological parameters of semiconductors, though not in sufficient detail to enable the experimental procedures to be set up and for their difficulties and precautions to be fully appreciated. The last chapter describes various classes of semi-conducting materials and discusses their properties in relation to existing theory. Deficiencies in these theories and the need to extend our knowledge of amorphous and liquid semiconductors are briefly considered in the conclusion. An addendum dated January 1957 sums up the data about the band structures of germanium and silicon and the energy-levels associated with impurities and defects.

Two features of the book immediately strike a Western reader. The first is the tracing of the historical development of semiconductor physics with particular reference to Russian contributions in the field. Thus the theoretical work of Davydov, Frenkel, Landau, Pekar and Tamm and the experimental work of A. V. and A. F. Ioffe, Juse and Losev among others are mentioned frequently. On the other hand, the names of Mott, Schottky, Shockley and Wilson scarcely receive mention.

The second point is that there are no references to original papers in the text, apart from incomplete references to papers by Telkes and Justi on thermo-electric effects; this is a disadvantage for a reader who wishes to follow up in more detail a topic which may interest him. Instead, there is, at the end of the book, a list of some forty books and review papers—and among those listed under the heading "in the Russian language" are the familiar names of Mott and Gurney, Seitz, Shockley and Wilson, referring to translations of their works. Instead of an index there is a contents list with about 140 entries. The book is well printed and has 155 figures. Only a few minor errors have been detected.

The book would probably be of greatest interest to the non-specialist physicist and to the chemist and metallurgist who wished to perceive the rapid advances of semiconductor physics and technology in the perspective of contemporary science. Some idea of the anticipated demand can be seen from the publication data which indicate a printing of twenty thousand copies.

R. E. BURGESS

ECONOMICS OF ATOMIC ENERGY

Economics of Atomic Energy

By Mary Goldring. (The Atoms for Peace Series.) Pp. viii+179. (London: Butterworths Scientific Publications, 1957.) 15s.

IT may come as a surprise to many people to learn that one of the best places to site a nuclear power station is at Niagara Falls where all available water is now used for generating electricity. The nuclear power station could operate there on almost 100 per cent load factor, and be used for pumping water back up the Falls. The water could then meet the peak demand for electricity in Ontario Province by installation of further hydro-electrical equipment. A somewhat similar concept is in mind in the recent decision to site one of the new Central Electricity Authority nuclear power stations in North Wales.

If the general public feels disturbed at the possible despoliation of the countryside, however, they may perhaps find some comfort in reading the first chapter of this book by Miss Goldring. It gives a delightful account of how a large nuclear power station such as Calder Hall or a large plutonium-producing factory such as Windscale is a most novel and remarkable installation. Virtually nothing goes in through the factory gate after building has finished, nothing appears to come out; there may be chimneys but no smoke emerges. It is remarked even that birds can be seen sitting on the top of the chimneys at Windscale though anybody who has seen these chimneys may feel that some poetic licence has crept in. It is a fact, however, that virtually nothing is brought into a nuclear power station, and only at rare intervals is waste fuel taken out in a lorry. In theory, the factory could be almost automatic in operation. Pictures of recently ordered Central Electricity Authority nuclear power stations show most elegant structures; even chimneys have disappeared. Even grid lines taking electricity from the power station could be placed underground at some extra cost.

Miss Goldring describes in some detail the various atomic factories which exist in the United Kingdom and gives a basic account of atoms, and the problems of using radioactive materials. Following this she discusses, in a most interesting chapter, the scale of investment which a country needs in order to enter the nuclear energy industry on a sufficient scale. She remarks that the United States, Britain and France are all spending about 0·6 per cent of their national income on atomic energy and she points out also that the minimum capital needed to start a nuclear energy industry is about £100,000,000. Much of the expenditure has been for military purposes in the case of the United States, the U.S.S.R. and the United Kingdom, but the fact that this expenditure has been made has enabled these powers to build factories which can have a civilian as well as a military application. The investment is probably not much less even if the military application is foregone. She points out, in particular, that the smaller industrialized countries are likely to have some difficulty in entering the nuclear energy industry entirely on their own; though, for a small country, Sweden is making rapid strides in this field just as it has in the aircraft industry. Although the non-industrialized countries and the comparatively small countries are unlikely to be able to develop atomic power on their own, there is great national prestige attached to the subject of nuclear energy and most of them will form atomic energy commissions. In due course these will be able to discriminate between various reactor designs and advise power companies on the installation in their country of small nuclear power stations. These will have been purchased from highly industrialized countries with a large nuclear energy industry. Miss Goldring notes, however, that it will be much cheaper for a very long time to come to use diesel engines of comparatively low capital cost, except in those cases where fuel is extremely expensive because of high transport costs. This fact is beginning to become more generally appreciated even in those circles where two to three years ago nuclear power was looked on as something which would end all misery and poverty. It is important to remember that the capital needed to exploit electricity or other sources of power is far greater than the capital cost of the power plant itself.

The author comments on the need for atomic power and points out, as many others have done, that atomic energy is very badly needed in Britain and also Japan. In fact it is among the highly industrialized countries, except the United States and the U.S.S.R., where the need is really urgent. The United States has large and cheap sources of coal, oil and natural gas, and the U.S.S.R. has no overall fuel problem. In the extreme west of Russia, however, fuel supplies involve high transport costs and here it may possibly pay to develop nuclear power in the next ten to fifteen years.

The author has a chapter on the cost of atomic power and in general she tends to follow the views that have been expressed by the United Kingdom Atomic Energy Authority; though she does conclude this chapter with the remark, "this is a subject on which it is possible to have more than one opinion". She gives a critical discussion of the costs of natural and enriched fuels.

On the subject of nuclear power station exports Miss Goldring is once again extremely realistic. She recognizes that the actual business is not likely to be large in terms of numbers of large nuclear power stations. Most industrialized countries will tend to build either a complete power station under licence or manufacture most of the components themselves.

Finally, the author gives an excellent review of relations with industry in the field of nuclear power, though she avoids the difficult question of exactly what these relations should be.

This is an entertaining book, and a few technical errors do not affect the main arguments. For the general public as well as the specialist it is well worth reading since the author has studied and appreciated the intricacies of a very complex subject.

J. V. DUNWORTH

Science and Its Background

By Dr. H. D. Anthony. Third edition. Pp. ix+352. (London: Macmillan and Co., Ltd.; New York: St. Martin's Press, Inc., 1957.) 20*s*. net.

TWO former editions of Dr. Anthony's short history of science received favourable notice in *Nature* (175, 962; 1955 and 162, 354; 1948). The present edition, the third, appearing only three years after the second, testifies in itself to the popularity of the work.

The author, a former grammar school headmaster, colonel in the Royal Army Educational Corps and university extra-mural lecturer, has a wide knowledge of the requirements of the earnest student of the history of science in relation to social needs.

In the third edition of the book most of the chapters deal with the work of individual men of science selected not merely as a part of scientific history but also because of the value of their work to-day. Nevertheless, the historical background is that not only of isolated biography but also of the continuous history of human affairs. Even in so comparatively short and straightforward a work the temptation to turn a short history of science into the achievements of a hundred great men has been avoided. In this connexion the various time-charts will be invaluable.

The present edition of the book includes a chapter on the International Geophysical Year (which appeared before the Russian Earth satellites) and two new chapters on the post-war utilization of science and the pursuit of science for its own sake.

The book is an admirable short introduction to the history of science for the sixth-form pupil and the intelligent layman. The social importance of such a book increases every year. W. L. SUMNER

Britain's Nature Reserves

By E. M. Nicholson. Pp. 175+65 plates. (London: Country Life, Ltd., 1957.) 30*s*. net.

THE Director-General of the Nature Conservancy has written this book to explain the objects and scope of the Nature reserves, and especially the functions of the Nature Conservancy itself. The greater part of the book consists of concise descriptions of the more important reserves, indicating the reasons why they are of interest and, sometimes, the character of the work in progress and the way the reserve contributes to the larger scheme. The location of the reserves is clearly indicated and the book is illustrated by numerous well-chosen photographs which further indicate the nature of the work and may well help to enlist co-operation and goodwill as well as the understanding which Mr. Nicholson seeks to promote. The book is not limited to the Conservancy's own reserves, but includes some of the important local reserves and also some of those of other bodies such as Wicken Fen, of the National Trust, Skokholm, of the West Wales Field Society and Field Studies Council, and Minsmere Level, of the Royal Society for the Protection of Birds.

The core of the book, however, is in the introduction. In those twenty pages Mr. Nicholson gives an account that could scarcely be bettered of the Nature reserve movement in Britain, the tasks that confront it and the way it is setting about those tasks. He explains clearly just why it is necessary for access to some reserves to be restricted and the ways in which Nature lovers can help the work, as well as some of the implications of its work for Britain's economy and for the advancement of science. This is a book that was needed, but Mr. Nicholson's introduction deserves to be issued as a reprint at a price which would place it in the hands of thousands whom a 30*s*. book is unlikely to reach.

Art and Analysis

An Essay toward a Theory in Aesthetics. By Prof. Edward G. Ballard. Pp. xv+219. (The Hague: Martinus Nijhoff; London: B. T. Batsford, Ltd., 1957.) 30*s*. 6*d*.

IN this book, Prof. Ballard has performed a valuable duty in discussing the place which æsthetics should occupy in the broad hierarchy of knowledge. Many people have attempted this before; what distinguishes the present work is its emphasis upon the historical development of the subject, and how the persistent effort to 'locate' the beautiful has stimulated contemporary interest. There is no doubt that much æsthetic theory shares a common boundary with philosophy, especially that part of it which embraces experience, as in the work of Whitehead.

But however elusive an æsthetic object seems to any particular generation of thinkers, we come back to the presence of symmetry as an essential, not sufficient in itself (by traditional standards), but coercive. To Plotinus this extra something was a 'shining through', but the concept gained strength centuries later in the *claritas* of St. Thomas Aquinas and other scholastics. This factor is closely related to form, as if to suggest that inanimate shape could achieve sublimation (under the appropriate conditions) in a way not wholly different from human advancement. It is this element of the sublime which sensitive mathematicians have felt in their preference for one approach to a problem rather than another. In brief, Prof. Ballard's theme is analytic rather than synthetic, though he manages to hold a delicate balance with æsthetics nicely poised between metaphysics and criticism.

F. I. G. RAWLINS

Studies on Fertility

Including papers read at the Conference of the Society for the Study of Fertility, Birmingham, 1955. Edited by Prof. R. G. Harrison. (Vol. 7 of the Proceedings of the Society.) Pp. ix+156+28 plates. (Oxford: Blackwell Scientific Publications, 1955.) 25*s*. net.

"STUDIES on Fertility, 1955" is Vol. 7 of the Proceedings of the Society for the Study of Fertility. It contains certain papers selected from those read at the Birmingham conference of the Society in 1955 (see *Nature*, 176, 340; 1955), and a number that report original work. Part 1 deals with the male and includes a lucid account by Clare Harvey of the cytology of abnormal spermatogenesis in subfertile men, and three useful papers, by members of the Department of Anatomy of the University of Liverpool, on testicular physiology in the rat and guinea pig. Among them is a study by R. Harris and R. G. Harrison of the damaging effects of cold on the seminiferous epithelium of the guinea pig. In other papers, Marcus W. H. Bishop discusses the inter-relationship of semen characteristics in seventy-six bulls of seven breeds, and T. D. Glover the effects of scrotal insulation on the semen of rams. Three clinical papers introduce the section of the book dealing with the female, to which A. M. Dalcq, of Brussels, contributes a valuable summary of the information provided by cytochemical techniques about processes of synthesis in the egg of the rat and mouse. The final three chapters deal with the œstrous cycle of the cat; the occurrence of supernumerary spermatozoa in the fertilized ova of rabbits; and fertility in the ewe—all of them accounts of valuable and interesting work.

Twentieth-Century Bestiary

(A *Scientific American* Book.) Pp. xi + 240. (London: G. Bell and Sons, Ltd., 1957.) 13*s*. 6*d*. net.

With 130,000 regular subscribers and many casual sales from news-vendors *Scientific American* has now become one of the most powerful agents for spreading scientific knowledge throughout the United States. So popular have been its non-technical articles that, two years ago, the Board of Editors launched a series of short books on specific areas of science consisting of contemporary articles from the journal. These books have been as successful as the journal and are now being published for British readers. Each is designed to elucidate the new knowledge recently gained by research in a particular field of science and to acquaint the reader with the problems which are at present being investigated.

As its name implies, "Twentieth-Century Bestiary" is concerned with certain aspects of zoological science. These, presumably, have been chosen because of the appeal of the original articles and represent but a small sample of current zoological investigations. The random sample includes two articles on the balance of Nature, three on mating, two on the social insects, two on the origin of species, three on what is aptly called physiological engineering, four on bird flight, one on sonar in bats and others on laboratory entomology and researches on primates. The authors include American, British, Danish and Swiss investigators who are as well known for their abilities to write as for the quality of their researches. Between them they have produced a book the contents of which belie the quaintly chosen title. This is no moralizing treatise but an unvarnished account of how the frontiers of science are being extended by imagination, patience and humility.

The Great Chain of Life

By Joseph Wood Krutch. Pp. xiv + 227. (London: Eyre and Spottiswoode, Ltd., 1957.) 21*s*. net.

In this little introduction to biology a distinguished American naturalist challenges many accepted beliefs. He questions, for example, whether the complexity of a microscopic, one-celled animal can be explained by natural selection or any other logical theory. He believes that joy and other emotions are not confined to man and that animals—even in zoos—develop an awareness of, and an interest in, people of which we would never believe them capable if we knew them only in the wild. . . . "Monkeys are notorious exhibitionists and gibbons, especially, will put on performances at intervals after a preliminary ballyhoo of howls to collect an audience." In his love for, and zeal to promote the study of, animals as individuals, Krutch also argues that laboratory biology, which has tended to become the most earnestly cultivated kind of scientific study, is precisely the kind least likely "to stimulate compassion, love or reverence for the creatures it studies . . . the laboratory scientist is not of necessity drawn into any emotional relationship with animals or plants and the experiments which must be performed are more likely to make him more, rather than less callous, than the ordinary man".

Does Krutch really believe this? Could he produce evidence? Do most biologists believe in a mechanized process of natural selection which is making the animal machine more and more efficient? That man is merely an extrapolated version of the Anthropoidea? That most biologists do not accept that there are varying degrees of 'intelligence' and 'emotion' in all animals? Krutch has written a book which will appeal to many—and especially those who find delight in erecting their own Aunt Sallies to aim at. It is a masterpiece of unsubstantiated assertion.

T. H. Hawkins

The American Arbacia and Other Sea Urchins

By Ethel Browne Harvey. Pp. iv + 298 + 16 plates. (Princeton, N.J.: Princeton University Press; London: Oxford University Press, 1956.) 48*s*. net.

This is the story of an egg, or, to be more precise, an annotated bibliography and summary of the story of an egg. The first sixty pages are devoted to a description of the etymology, history and natural history of sea urchins (still called sea eggs in parts of Britain) in general and *Arbacia punctulata* in particular. The next eighty pages review investigations into the normal and modified development of the egg of *Arbacia*. This is followed by eighty pages of a "compilation of experimental work" arranged alphabetically and set down in note form. The bibliography lists 1,500 titles and is stated to include all the important papers written on *Arbacia* between 1850 and 1954. The index is admirable. The scholarship involved in this work is immense, and the book is a most complete guide to the voluminous literature which has grown up on sea urchin eggs. These eggs are one of the most investigated of biological entities, rivalling even *Drosophila* in popularity.

The extent of the investigations on the American species can be gauged by the numbers used at Woods Hole and the decline in population which appears to have been brought about chiefly by overcollecting. In the summer of 1933, 70,000 were collected. In 1949, although the same number were ordered, only 4,000 could be found. The chief value of this book lies in its use as a reference source, for which it is indeed indispensable. The first half may be used also by students and teachers as an account of the embryological and cytological investigations, but it is rather concentrated.

D. B. Carlisle

Marine Algae of the Northeastern Coast of North America

By Prof. William Randolph Taylor. Second revised edition. Pp. ix + 509. (Ann Arbor, Michigan: University of Michigan Press, 1957.) 12.50 dollars.

The new and revised edition of this important work is especially welcome because of the advances in knowledge of the life-histories and taxonomy of the algæ which have accrued in the past twenty years. The area with which the book deals extends from the coast of Virginia to the Arctic Circle and contains, therefore, elements of the northern flora with subarctic tendencies as well as plants which inhabit warmer waters. The volume, in consequence, will be welcomed by algologists from many locations either for direct or comparative reference. On this account one regrets that, in the new edition, bibliographical references to plants occurring in areas outside North America have been omitted, though admittedly they are now available in other standard works. The information that such references contain has, of course, been incorporated where it affects classification and nomenclature, though the author has exercised commendable caution where facts remain so far unconfirmed. The volume is beautifully produced and the excellent plates, mostly by Dr. Chin-Chih Jao, have been reproduced with some modification to the captions. Prof. Taylor is to be congratulated on the material and presentation of this new edition, which makes his extensive and detailed knowledge of the algae of the area available to workers throughout the world. I would like to suggest that when he gives us a third edition, a map might be included either on the end-papers or as a frontispiece.

Lily Newton

Physical Chemistry for Students of Pharmacy and Biology

By Dr. S. C. Wallwork. Pp. xi+307. (London and New York: Longmans, Green and Co., Ltd., 1956.) 25s. net.

In his selection of those portions of physical chemistry which are particularly the concern of the biological sciences, the author states that he follows the recommendations, and covers the syllabus, of the Pharmaceutical Society of Great Britain, and that he fulfils the requirements of students of pharmacy and biology taking recognized courses in these subjects in technical colleges and universities. The book's eleven chapters deal with: mathematical preparation, the properties and constitution of matter, the structure of atoms, the structure of molecules, chemical reaction, properties of solutions, electrolytic dissociation, electrochemical cells, acids and bases, surface chemistry, and colloids. The book has a bibliography, a table of logarithms, and sets of problems. Dispersed through the text are ten representative instructional experiments with the requisite practical directions. Dr. Wallwork's explanations, clear, well expressed, and given from the point of view of the modern electronic theory, should conduce to an understanding of the subject. He uses mathematics—but not beyond simple calculus—when by doing so he attains the best presentation of the subject in question; and in Chapter 1 he revises and expounds the elements of the mathematics required.

G. Fowles

The Reactive Intermediates of Organic Chemistry

By John E. Leffler. Pp. x+275. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1956.) 6 dollars.

"The objectives of the present book are to provide some of the background of information about stable radicals and ions needed by those interested in organic reaction mechanisms, to point out some of the pitfalls awaiting the unwary, and to show some of the criteria for preferring one type of intermediate over another." These aims, set out by the author in his preface, have been fully achieved, and the result is a book which can be recommended to undergraduate and postgraduate students and working research chemists as presenting an accurate, stimulating and eminently readable account of the role of radicals and ions in organic reactions in solution.

The first chapter begins with a section on the physical properties of free radicals leading to a summary of the preparation, stability and reactions of the triarylmethyl and some analogous radicals. Chapter 2 gives an account of the formation and behaviour of unstable carbon radicals. Biradicals are described in Chapter 3, while Chapter 4 gives an excellent account of the heteroradicals, those radicals in which the unpaired electron is associated with an atom other than carbon. The treatment of free radicals throughout is very good.

The next three chapters are devoted to carbonium ions, being divided according to their formation by reversible or irreversible dissociation or by addition reactions. These are followed by an interesting chapter on analogues of carbonium ions, the common feature being the possession of low-energy orbitals in excess of the electrons available to fill them. Chapters 9 and 10 describe the formation and reactions of carbanions. An account of base-catalysed reactions in Chapter 11 is followed in Chapter 12 by a most useful comparison of radical and polar reactions.

The book is well produced and there are very few misprints. The apt quotations from Mark Twain and other authors are a delight in themselves.

H. S. Turner

Optics

By Prof. Bruno Rossi. (Principles of Physics Series.) Pp. xii+510. (Reading, Mass.: Addison-Wesley Publishing Company, Inc., 1957.) 8.50 dollars.

This is a text-book for university honours and pass degree students. The main emphasis is on the wave theory of light including the electromagnetic theory, and this subject is treated up to the standard of an honours physics degree in Great Britain. Other aspects of optics are briefly reviewed. The optics of lenses and of instruments occupies forty pages, but a good deal of this is used in an exposition of elementary lens theory which would be included in a school course in Britain. Quantum phenomena are discussed in fifteen pages and relativistic optics is just mentioned. The account of wave-theory is theoretical: there is very little description of experimental methods.

Some parts of the book appear to be written for readers who are intelligent and possessed of the mathematical knowledge and ability normally possessed by students who reach the final year of an honours physics course. These parts are incisive, clear and interesting. Not only students but also many lecturers could derive benefit from them. In other parts of the book, and particularly in the earlier chapters, the author attempts to expound difficult mathematical concepts to students with a weak mathematical background. These sections appear to be much less successful.

The author has provided a large number of examples from which a teacher could select those appropriate to his own students.

Relaxation Spectrometry

By Prof. E. G. Richardson. Pp. viii+140. (Series in Physics.) (Amsterdam: North-Holland Publishing Company.) 20 guilders. 40s.

The present book is essentially an exposition of modern experimental methods available for studying stress relaxation in solids, liquids and gases.

The reader is first introduced to the representation of visco-elasticity by means of models of the spring-and-dashpot type, to the equations of such rheological models and their canonical forms, and to their utilization in analysing relaxation in static and dynamic stress fields. The main part of the book is devoted to: subsonic relaxation as typified, for example, by the damping of oscillations of a torsion pendulum; methods of measurement applicable at sonic frequencies, for example, the vibrating reed; and spectrometry in the ultrasonic range. A short account of dielectric relaxation is also given, and the analysis of complex spectra by the linear superposition of relaxation-times, as well as the thermodynamic implications of the spectra, are briefly discussed.

It is clear from the book that, while experimental methods for measuring relaxation spectra are comparatively well advanced, little is as yet known of the significance of the spectra, particularly in solids. Some modern techniques, such as the introduction of a 'blue-shift' into the relaxation spectra by neutron bombardment and, on the theoretical plane, the mathematics of stochastic processes may, however, soon fill some of the major gaps in the science.

Irrespective of the actual pattern of future development, a sound knowledge of what has already been achieved will remain the research worker's indispensable prerequisite for successful work. Prof. Richardson's book provides this information. It is sure to be well received by all concerned with this branch of physics. P. FELTHAM

An Introduction to the Cathode Ray Oscilloscope

By Harley Carter. (Popular Series.) Pp. viii+100. (Eindhoven: N.V. Philips' Gloeilampenfabrieken; London: Cleaver-Hume Press, Ltd., 1957.) 12*s*. 6*d*.

THIS little book explains the general principle of the oscilloscope, and the associated time-base, amplifier, and power-supply circuits. So far as the 'popular' aspect of the book goes, it is written simply and without any mathematical theory, and it should be quite useful to the kind of reader who wants to know merely how oscilloscopes work, and why people use them. But Mr. Carter goes a good deal further than this, and is really writing for the beginner who is prepared to work his way solidly through the book and to go so far as making up various circuits for himself in order to see how they work. He discusses the characteristics of the various standard types of tube, and gives detailed instructions for the assembly of four complete oscilloscope circuits; at least two of these are simple enough to appeal to relatively inexperienced hands. The book is handsomely produced and finished, and while it does seem rather expensive for its size it is not extravagantly so. Indeed, experimenters who are thinking of building an oscilloscope will probably find it very good value.

Probability

An Intermediate Text-book. By M. T. L. Bizley. Pp. viii+230. (Cambridge: At the University Press, 1957. Published for the Institute of Actuaries and the Faculty of Actuaries.) 20*s*. net.

THIS book, designed to meet the requirements of actuarial students, is concerned solely with classical probability theory, although the importance of relating this to statistics is emphasized. The development is elementary, but sound within the limits of an acknowledged incompleteness of discussion of the fundamental nature of probability. The general account of alternative definitions of probability is indeed good, and the subsequent presentation of standard theory of combinations of probabilities is excellent. The solution of certain types of problem by difference equations is well illustrated, and the reader is introduced to the theory of runs and other Markov chains. The final chapter, on continuous variates, is less satisfying, in that it scarcely goes beyond somewhat unexciting geometrical problems. The book, despite the aridity that is perhaps inseparable from its subject, can be recommended to a student skilled in algebraic manipulation, or to a teacher in search of a modern text with a good systematic plan and an abundance of examples. It is unfortunate that so many of the examples, good though they are as exercises in probability calculus, are either explicitly based on random drawings from bags and urns or have the irritating pseudo-realism of relating to people who form random committees and keep large numbers of indistinguishable pairs of gloves in a drawer; more use might have been made of actuarial problems and of applications of probability theory to science and industry.

D. J. FINNEY

Tables of Integrals and Other Mathematical Data

By Prof. Herbert Bristol Dwight. Third edition. Pp. x+288. (New York and London: The Macmillan Company, 1957.) 21*s*. net.

THE fact that a third edition of this collection of formulæ and tables has been called for is an indication of its usefulness. The first 193 pages consist of lists of formulæ, including those of derivatives and integrals, relating to the elementary functions, elliptic and Bessel functions, and surface zonal harmonics (Legendre polynomials). The next two sections consist of a ten-page list of definite integrals and a five-page set of notes on ordinary differential equations. The last 75 pages contain tables of numerical values of elementary functions, complete elliptic integrals, the probability integral and the Kelvin functions ***ber***, ***bei***, ***ker***, ***kei***, in the tabulation of which the author was a pioneer.

For engineers, physicists and practical mathematicians this is an excellent reference book, very well classified. The first sentence of the preface to the first edition is a glimpse of the obvious: "The first study of any portion of mathematics should not be done from a synopsis of compact results, such as this collection". The objection which some teachers have to the existence of such collections seems to result from a misunderstanding of their purpose. After all, it is largely because practical use is made of such formulæ that much mathematics is taught, and no one can be expected to remember them all, or work them out every time they are wanted.

In the third edition there are a few unimportant additions to the formulæ, and useful tables of sines, cosines, tangents and cotangents of angles in degrees and hundredths have been added. It is a pity that the opportunity was not taken to bring the table of references up to date. The most recent reference is dated 1947–48, and many relevant tables have been published since then.

The printing and binding are very good.

G. A. GARREAU

(*Continued from p.* 1254)

A potential difference, applied between two electrodes on the diamond, produces luminescence over a wide range of potential values. Due to the high refractive index the whole diamond appears to luminesce, with a band of wave-lengths in the 5400-A. region, but closer microscopic inspection shows that the luminescence is in fact confined to small spots on the diamond. There may be a dozen of these which are not necessarily in the immediate neighbourhood of the electrodes and seem to be independent of the precise form of the potential probe, but are sensitive to its position. If the graphite layer is scratched off in the vicinity of one of these luminescent centres, the effect is destroyed for that particular one.

The intensity increases with an increase in the applied voltage, and in one particular case could be observed from 30 volts to 1,500 volts. Changing the polarity of the electrodes makes no difference to the locality, colour or intensity of the spots. They are equally unaffected by a temperature variation from that of liquid air to 300° C.; by immersion in oil, or a sprayed plastic sheath; or by ultra-violet or infra-red irradiation.

None of these diamonds exhibits counting properties; only one of them shows fluorescence under ultra-violet irradiation, but all of them show blue luminescence when bombarded by electrons.

Unlike some of the effects reported by Wolfe and Woods[1] the diamonds return to their normal state when the surface is cleaned and display no luminescence. Neither quartz nor glass was found to display luminescence after similar treatment.

The investigation is far from complete; but this communication is prompted by a recent observation of Fischer[2] that when the dielectric properties of the diamond have been broken down by sufficiently high currents and fields, a green luminescence is observed. The breakdown process may produce graphitization of parts of the diamond and the effect may be of the same nature as that reported here.

This research has been supported financially by Industrial Distributors (1946), Ltd., to which we are indebted.

Ranque Vortex-Tube Combustion Chamber

Recent experiments carried out here lead to the conclusion that the vortex tube of Georges Ranque[1] may form an extremely useful compact combustion chamber and also a possible research tool for the investigation of cool flames. Many applications of the vortex tube have appeared during the past fifteen years, as shown by Westley[2], but, so far as it has been possible to ascertain, the nearest approach to the burner described here is due to Moore and Martin[3] and Martin (private communication). Moore and Martin, using a single-outlet vortex tube made of 'Pyrex' glass, discovered the peculiar behaviour of premixed propane-air flames in this burner, together with the extreme flame stability obtained over a wide range of ratios of air to fuel. Owing to the limitations of their air supply, and to the size of the glass tube, they were apparently unable to obtain the rates of flow needed for some of the behaviour described here.

The burner used in this Department consists of a standard vortex tube of the type described by Ranque, with a range of orifices to restrict the flow in one direction. The main tube has an inside diameter of one inch, and was fed by a tangential nozzle, of rectangular cross-section, 0·017 in. × 2·30 in. Orifices of diameter $\frac{1}{8}$ in., $\frac{1}{4}$ in., $\frac{3}{8}$ in. and $\frac{1}{2}$ in. are available, and the burner is also run with both ends open, and with the orifice end closed off, when it resembles that of Martin and Moore. Due to the high temperatures involved, the complete burner is made of steel.

With both ends open, and with all the orifices, the striking-back phenomenon of Moore and Martin is encountered, but it is found to be even more stable when there is a double exit from the tube than under the conditions which they used. When the ratio of air to fuel is increased, however, two further forms of combustion are found to exist. The first, a detonating or howling combustion with a very high heat release occurs at the lower ratios of air to fuel, while the second, a quiet mode of combustion with relatively small heat release and very steep temperature gradients across the flame-front occurs at the higher ratios of air to fuel. The latter flame also produces large quantities of formaldehyde, acetaldehyde and propionaldehyde.

The upper and lower limits of these forms of combustion have been established, the upper limit of the aldehyde-producing flame being complete extinction. It is apparent that the function of the orifice is to allow the induction of a large quantity of air into the system, since the change from one form of combustion to another occurs at lower ratios of air to fuel for the premixed gases as the orifice size is increased. The change from one mode to the next is also affected to a very great extent by the temperature of the tube; as tube temperature increases, so the ratio of air to fuel at which any flame occurs also increases (Fig. 1).

The various aldehydes in the flame were detected by means of the semicarbazide–hydrochloride reaction,

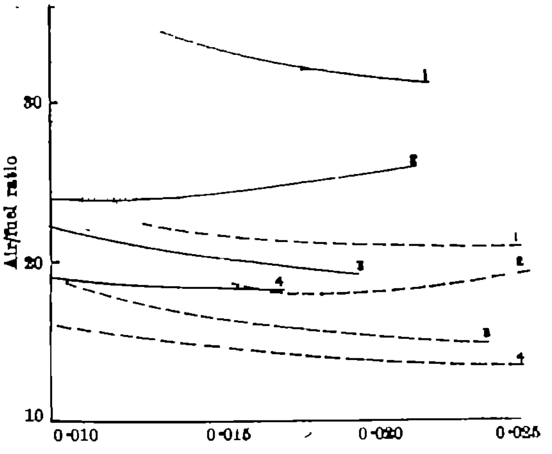

Fig. 1. Sample performance curves: (1) Extinction, tube temperature 1,100° F.; (2) extinction, tube temperature 500° F.; (3) detonation to aldehyde-producing flame, tube temperature 1,100° F.; (4) detonation to aldehyde-producing flame, tube temperature 500° F. Orifice end closed, ———; $\frac{3}{8}$ in. orifice, - - - -

together with a determination of the melting points for the resulting semicarbazones. Current spectrographic work further confirms these results. The work is continuing; it is hoped to publish more information on this combustion chamber.

Spectra of Flames supported by Active Nitrogen

When organic substances are introduced into a stream of active nitrogen, a luminous reaction zone is observed, closely resembling the atomic flames given by hydrogen and oxygen. The spectra of these luminous reaction zones have been photographed on 'Ilford Zenith' plates, using a 'Hilger' medium quartz spectrometer and exposure times of 4–6 hr.

Cylinder nitrogen with less than 0·05 per cent of oxygen was activated in a high-frequency electrodeless discharge. Flow rates of 10–15 cm.^{3}/sec. were used, and the pressure in the apparatus was usually 2–4 mm. of mercury. The organic reactants were introduced into the active nitrogen at a point about 4 cm. beyond the discharge tube, and the luminous zone was viewed through a silica window attached to the end of the reaction tube.

The size and shape of the zone depended largely on the flow rate of the organic reactant. In the present work, the flow rate was adjusted so that the luminous zone was localized on the nitrogen inlet tube, which corresponded to a flow rate of about 0·5 cm.^{3}/sec. in the case of acetylene. The reaction tube had to be cleaned periodically since most substances used formed a polymer on the walls of the tube.

The spectra of flames produced by the following substances were photographed:

C_2H_2, C_2H_4, *cis*-$CHCl{=}CHCl$, $CHCl{=}CCl_2$, $CCl_2{=}CCl_2$, CH_3Cl, CH_2Cl_2, $CHCl_3$, CCl_4, C_2H_5Cl ; C_2D_2

In all cases, the CN-violet system was the most prominent feature of the spectrum, many of the so-called 'tail bands' being present. The CN-red system was also prominent, and appeared to be enhanced by the presence of chlorine in the molecule. All substances containing chlorine gave the CCl-bands in the region of 2790 A., but no bands that might correspond to the unknown molecule NCl could be found. All molecules containing hydrogen gave the CH-band at 4315 A., due to the transition $^2\Delta \rightarrow {}^2\pi$; but the band at 3889 A., due to the transition $^2\Sigma \rightarrow {}^2\pi$, appeared to be absent. These molecules also gave the NH-heads at 3360 A. and 3370 A., the rotational fine structure being visible on some plates. The CH- and NH-bands given by chloroform were very weak, in contrast to the very strong bands given by methylene dichloride. Because of the strength of the CN-red system, it was often difficult to decide whether the C_2 Swan-bands were present or not. They were certainly given by acetylene and ethylene, but were not given by carbon tetrachloride. The nitrous oxide β- and γ-systems were occasionally present faintly, especially in the case of carbon tetrachloride and tetrachlorethylene.

In addition to the above bands, a complex group of heads was observed in the region of 3290 A., degraded to the violet, with all molecules except carbon tetrachloride and tetrachlorethylene, and possibly chloroform. The intensity of these bands correlates quite well with the intensity of the CH- and NH-bands, and because of this and their complex structure, it was thought that the bands were due to hydrogen cyanide, which is known to be the main product in the reaction of hydrocarbons with active nitrogen[1]. Consequently, deuteroacetylene (C_2D_2) was prepared by the action of heavy water on purified calcium carbide, giving a product of 97·5 per cent purity, and the spectrum of the flame produced by passing this into active nitrogen was photographed. The spectrum of an iron hollow-cathode lamp was used as a comparison spectrum. A comparison of this plate with one given by methylene dichloride showed that the structure of the unknown bands was identical, and that the expected isotopic shift was less than 4 cm.$^{-1}$. It therefore seems unlikely that the bands can be attributed to an emitter containing hydrogen, such as hydrogen cyanide.

The fact that the bands are given only by molecules which contain hydrogen may be due to some kinetic requirement, but the bands are not given when molecular hydrogen and carbon tetrachloride are introduced into active nitrogen. It is hoped that further work now in progress will help to clarify the problem.

This work was carried out as part of Contract *AF* 61(514)–1117 with the A.R.D.C. of the United States Air Force. We thank H. W. Thompson for the loan of a spectrograph.

Production of Vibrationally Excited Oxygen Molecules in the Flash Photolysis of Ozone

Previous work on the photolysis of ozone has led to the conclusion that a simple atom-chain mechanism is incapable of explaining the experimental facts. The existence of an energy chain involving excited oxygen molecules has gained wide acceptance due to the work of Schumacher[1], Heidt and Forbes[2], and Ritchie[3]. The nature of the excitation involved in the energy chain was not known, however, most workers assuming it to be the $^1\Sigma_g^+$ state of the oxygen[4]. Experiments on the flash photolysis of ozone[5] have enabled us to show that the excitation is purely vibrational, the oxygen being formed in the ground electronic state with up to 16 quanta of vibrational energy, by reaction (1) which is exothermic to the extent of 93 kcal./mole for $O(^3P)$ and 138 kcal./mole for $O(^1D)$.

$$O + O_3 \rightarrow O^*_2 + O_2 \qquad (1)$$

After allowing for the observed vibrational excitation and considering that spin conservation will be effective, the second oxygen molecule should be produced in the $^1\Delta g$ state according to

$$O(^3P) + O_3(^1A) \rightarrow O_2^*(^3\Sigma_g^-) + O_2(^1\Delta g) \qquad (2)$$

which would reduce the amount of energy available

* The bands are so strongly degraded that the head is only about 0 5 A removed from the origin.

† Taken from Pearse and Gaydon, "The Identification of Molecular Spectra" (Chapman and Hall, London, 1950).

for vibrational excitation of the $O_2{}^*({}^3\Sigma_g^-)$ from 93 to 72 kcal./mole.

The vibrational energy distribution of the oxygen molecules has an apparent maximum at $v'' = 14$ (56·2 kcal./mole) and falls off sharply at $v'' = 12$ and 16 (49·0 and 63·2 kcal./mole). Table 1 gives the details of the observed spectrum of the vibrationally excited oxygen molecule O^*_2. None of these bands has previously been observed in absorption, although most of them have been seen in emission.

In the photolytic decomposition of ozone the primary step might lead to the formation of $O_2({}^3\Sigma_g^-) + O({}^3P)$, $O_2({}^1\Delta g) + O({}^1D)$ or $O_2({}^1\Sigma_g^+) + O({}^1D)$. Formation of the vibrationally excited oxygen in this step is unlikely from various aspects such as the small change in bond-length going from ozone to oxygen. The most conclusive evidence that the vibrationally excited oxygen, O^*_2, results from the secondary reaction (1) is obtained from a study of the reactions given in Table 2. From this we can see that, in an exothermic reaction involving the attack on a triatomic molecule by an atom, the new bond formed has an initial vibrational energy greatly in excess of normal.

Recently, Benson[8] has claimed that the thermal decomposition of ozone can be explained without the necessity of an energy chain. His suggestion that the excited oxygen molecules produced in reaction (1) can dissipate their energy more rapidly than they can transfer it to ozone would be reasonable if the excitation were electronic. We have shown, however, that it is vibrational and that the excess energy can be retained through many collisions, for in a mixture of ratio nitrogen/ozone = 40/1 it was possible for us to detect absorption due to vibrationally excited oxygen molecules, O^*_2, up to 200 μsec. after flashing. It is to be noted that oxygen is a homopolar molecule and that loss of vibrational energy by radiation must be extremely slow, since it is limited to magnetic dipole or quadrupole radiation. Moreover, further analysis of our results indicates that the vibrationally excited oxygen is degraded by ozone more rapidly than by any other deactivating process. This can be due to physical deactivation and by decomposition of ozone, since the excited oxygen has sufficient energy to bring about the decomposition to ground-state molecules and atoms according to:

$$O^*_2 + O_3 \rightarrow 2O_2({}^3\Sigma_g^-) + O({}^3P) \qquad (3)$$

Taking account of the maximum vibrational energy observed, it is of course energetically possible that one ${}^1\Delta g$ or ${}^1\Sigma_g^+$ oxygen molecule is produced, but consideration of spin conservation makes this unlikely.

In view, therefore, of the results reported here, the evidence favouring the energy chain decomposition of ozone by vibrationally excited oxygen molecules would seem to be very strong, and the photon-propagated chain postulated by Benson for the short wave-length photolysis of ozone, if it occurs at all, should be negligible in comparison. This conclusion is further substantiated by the following considerations. Thus the reaction:

$$O({}^1D) + O_3 \rightarrow O_2({}^3\Sigma_g^-) + O_2({}^3\Sigma_u^-) \qquad (4)$$

suggested by Benson is about 4 kcal./mole endothermic whereas the reaction involving the formation of two $O_2({}^3\Sigma_g^-)$ is highly exothermic, and in view of the analogous reactions shown in Table 2 vibrational rather than electronic excitation is indicated. We would also think that the photon-propagated chain would be inefficient, since the chain-length would be seriously decreased by the considerable escape of radiation which must occur, particularly in a vessel the walls of which have low reflectivity.

In further discussions of these points with Dr. B. A. Thrush, he has pointed out that the radiation emitted by the $O_2({}^3\Sigma_u^-)$ formed in reaction (4), going to the ground-state ${}^3\Sigma_g^-$, would not be in the region of 2000 A. suggested by Benson. As stated previously, reaction (4) is endothermic and is unlikely to yield vibrationally excited molecules. According to the Franck–Condon principle, oxygen molecules in the lowest vibrational levels of the ${}^3\Sigma_u^-$ state will radiate to give molecules with high values of v'', and the bulk of the radiation will lie above 3000 A., where a photon chain can be excluded by the extreme weakness of the ozone absorption.

Table 2

Reaction	ΔH kcal./mole	Excited species	Highest vibrational level observed
$O + O_3$[5]	93 $O({}^3P)$ 138 $O({}^1D)$	O^*_2	$v'' = 16$ (63 kcal./mole)
$O + ClO_2$[6]	61	O^*_2	$v'' = 8$ (34 kcal./mole)
$O + NO_2$[6]	46	O^*_2	$v'' = 8$ (34 kcal./mole)
$H + O_3$[7]	80	OH^*	$v'' = 9$ (75 kcal./mole)

The excited species are in the electronic ground state in these reactions.

Quantitative Estimation of Graphite in Refractory Carbon Deposits by X-ray Technique

THIS communication presents two curves (Figs. 1 and 2) which permit a quantitative estimation of graphite by use of an X-ray spectrometer.

The identification of graphite in carbon deposits produced by carbon monoxide attack of refractories by X-ray methods was first mentioned by Rowden[1]; later by Patrick and Sosman[2] and by Davis and

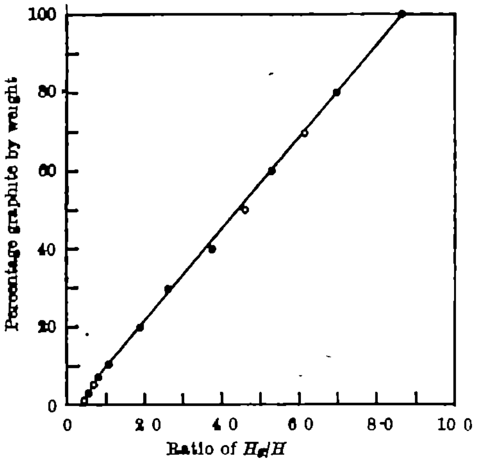

Fig. 1

Rigby[3]. To the best of our knowledge, no quantitative estimation of graphite in such deposits has previously been published. The very recent paper of Davis and his co-workers[4] has prompted submission of these results.

For the preparation of the curves, Dixon's 'Micro-Fyne' graphite was used with Baker's 'Analyzed' fluorite as the internal standard, as in the method outlined by Klug and Alexander[5]. The third component was magnetite. The three materials were reduced to minus-325 mesh by use of an agate mortar. Their diffraction patterns were then obtained by means of a Philips 'Norelco' X-ray spectrometer having automatic recording and covering a 45-degree Bragg angle. The same equipment was later employed to measure the intensity ratios of the working curves and the unknown samples. Agreement between the diffraction patterns obtained with filtered iron radiation, and the American Society for Testing Materials records for graphite, magnetite, and fluorite was satisfactory. The X-ray pattern for graphite was also checked against one obtained from a sample of well-crystallized Ceylon graphite. Fourteen standards containing 100, 80, 70, 60, 50, 40, 30, 20, 10, 7, 5, 3, 0·5 and 0·1 per cent graphite by weight were prepared by use of an analytical balance. The total weight used in all cases was 1·6700 gm. The internal standard, fluorite, was 0·4 of this value or 0·67 gm. The McCreery[6] technique was used in preparing the standards and in operating the spectrometer to minimize erratic results due to the platy nature and preferred orientation of graphite. All compact thicknesses were checked to ensure that 'effectively infinite' thickness[7] had been obtained. Magnetite was included in the standards because qualitative X-ray work had shown that the unknown material contained considerable triferric tetroxide (Fe_3O_4).

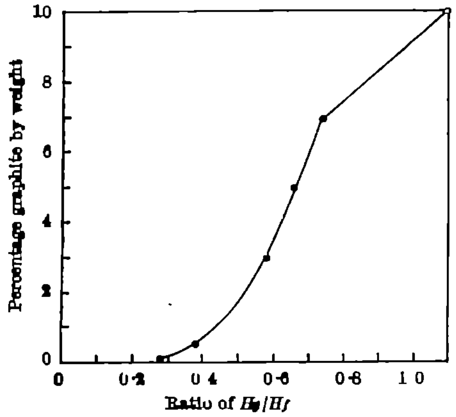

Fig. 2

The working curve of Fig. 1 covers the entire range of graphite content. When work was started on the unknown samples, however, the graphite content was found to be small. Fig. 2 was prepared, therefore, covering the range 0·1–10 per cent graphite by weight. In both curves, the ordinate is per cent graphite (by weight) obtained from the known composition of the standard. The abscissa H_g/H_f is the ratio of the height above background of the strong graphite line H_g at a wave-length of 3·38 A. to the corresponding height of the neighbouring fluorite line H_f at 3·16 A. Each point on the curve represents the average of at least ten separate measurements. The point representing 0·1 per cent graphite weight is the average of sixteen measurements. It was realized that use of automatic recording would limit the relative accuracy of graphite estimation to ±10 per cent by weight, but no counting equipment was available.

The working curves were used to determine the percentage of graphite by weight in eleven large samples of carbon deposits produced by carbon monoxide attack on fired refractory specimens. The ceramic pieces were dry pressed from chemically analysed North Carolina and Florida kaolins to which chemically pure and spectroscopically checked Fe_2O_3 was added. Firing temperatures ranged from 1,110 to 1,260 deg. C. Tests for resistance to carbon monoxide attack were carried out in a cylindrical non-catalytic 'Inconel' chamber in accordance with the procedure recommended by the American Society for Testing Materials[8]. During the carbon monoxide attack, temperatures between 500 and 550 deg. C. were used.

The results obtained showed that the graphite content in the eleven unknown samples ranged from less than 0·1 to 9·4 per cent by weight. Magnetite was estimated on a semi-quantitative basis by comparison of the height above background of the 2·53-A. line for triferric tetroxide in the unknown with the height of this same diffraction line in the fourteen standards. The magnetite content ranged from less than 20 to approximately 100 per cent by weight. Because the powder compacts were required to have 'effectively infinite' thickness, it was necessary to use a minimum weight of carbon deposit of 0·375 gm. This requirement severely limited the number of samples which could be analysed.

Two other features of this method deserve brief mention. The first is the estimation of graphite in amounts as small as 0·1 per cent by weight. It is a fundamental principle that a good reflector of radiation is a poor absorber. The mass absorption coefficients calculated from data in Internationale Tabellen[9] for the three materials are: graphite, 10·73; magnetite, 59·55; and fluorite, 178·05.

The second feature is the departure of the working curve from a straight line below a value of 7 per cent graphite by weight. The internal-standard theory predicts both this departure and the curvature observed. The curvature is due mainly to counter 'dead time' during automatic recording for which there is no practical correction. When manual scanning was used, and a correction was made for dead time, Klug and Alexander verified that only three primary standards yielded an accurate straight line over the entire weight range in quartz/fluorite mixtures. The only way to obtain an accurate curve with automatic recording is to plot more points: fourteen standards were necessary for the curves shown in Figs. 1 and 2. Similar results in the detection of small percentages by weight and in the departure of the working curve from linearity have been reported by Carl[10], who used the same type and model of X-ray spectrometer with automatic recording on quartz/beryllium oxide mixtures.

Intensification of the Photographic Image

THE overall quantum yield for the production of developable silver in the silver halide grains of a fast photographic emulsion struck by light is of the order of 10^5. I have found that the catalytic effect of the exposed silver halide grain can be increased by a factor of one million by utilizing the amplification available in chain polymerizations.

Aromatic amines used as photographic developers pass through a semiquinone or free radical state in the course of their oxidation[1,2]. In some cases the free radical will initiate the polymerization of vinyl monomers. Thus, as each silver atom is produced, a semiquinone radical is formed which will initiate a chain reaction with a kinetic chain-length of as great as one million so that the overall quantum yield is 10^{11}. Not all aromatic amines will initiate polymerization when oxidized; in fact, the majority are polymerization inhibitors under alkaline conditions[3]. I have found, however, that polymerization of vinyl compounds is initiated when silver halide crystals struck by light are placed in contact with *p*-aminophenol at *p*H 8·0. The exposed crystals without developer will not initiate polymerization.

A suspension of silver bromide crystals (average size about one micron) was made up in water using a trace amount of glue as the stabilizer. The suspension was exposed to blue light and then divided into two parts. One part was developed with a 1/10 *M* solution of *p*-aminophenol hydrochloride buffered at *p*H 8·0 and the other was developed with the same solution but which also contained 20 per cent by weight of calcium acrylate. After 15 min. the sample which was treated with monomer turned an intense black and a large precipitate finally settled out. The sample without monomer turned into a murky brown stable suspension. Suspensions which had not been exposed to light remained unchanged whether or not the developer solution contained monomer. Apparently the polymer produced serves to bind the exposed and developed crystals; this thereby exhibits a very dense image, since light scattering per unit weight of developed silver is considerably decreased on aggregation of the grains[4].

A variation of the above experiment was carried out with a photographic plate containing silver bromide crystals in gelatin gel. The plate was exposed to feeble light just sufficient to produce an image which was barely perceptible when developed by conventional means. When developed with *p*-aminophenol and monomer, together with a short warming at 35° C. to allow for mobility of the grains, an intense black image was produced. This intensification of the image was produced at the sacrifice of some resolution, however.

The Clock Paradox in Relativity

As I have repeatedly pointed out, symmetrical ageing in this problem is an inevitable requirement of the postulate of relativity. I have given the argument in the simplest possible form[1] in order to facilitate refutation if it is indeed wrong. I therefore find it inexplicable that Sir Charles Darwin[2], while completely ignoring this argument (in which he is at one with all other critics), can write that "the accepted theory of relativity . . . quite definitely implies that a space-traveller will return from his journey younger than his stay-at-home twin brother". His reason for this assertion appears to be identical with that of Dr. J. H. Fremlin, on which I have already commented[3]. Since that comment appears to have been inadequate, I will consider the problem posed in more detail, in order to bring out what I believe to be the misconception underlying such arguments as that of Sir Charles Darwin.

The problem is this. S_0 and S_1 are originally together. S_1, by firing rockets, travels at uniform velocity V to and from a distant point. During their separation each sends out n light flashes per unit time by his clock, which the other receives. (In arguments, as distinct from illustrations, I prefer general symbols to numbers, to avoid accidental coincidences.) How many flashes does each send out and receive during the journey?

First let me state what is common ground. It is agreed that each observer receives 'slow' flashes at the rate $n\beta$, where $\beta = \sqrt{(c - V)/(c + V)}$ for a certain time, and then 'fast' flashes at the rate n/β until reunion. Apart from the conception of 'time-in-other-places' which is implicit in β, we agree not to introduce it further, so we let 0, t_0 and T_0 be the readings of S_0's clock at separation, at S_0's observation of the change from slow to fast flashes, and at reunion, respectively; while 0, t_1 and T_1 are the readings of S_1's clock at the corresponding times in his experience. It is then clear that S_0 will receive $n\beta t_0$ slow, and $(T_0 - t_0)n/\beta$ fast flashes, and will emit nT_0 flashes during the whole journey. There will be corresponding expressions for S_1's receipt and emission of flashes, and since every flash emitted by each observer is received by the other, we shall have the following equations:

$$\begin{aligned} n\beta t_0 + (T_0 - t_0)n/\beta &= nT_1 \\ n\beta t_1 + (T_1 - t_1)n/\beta &= nT_0 \end{aligned} \tag{1}$$

After this we part company. I proceed in this way. Since, according to relativity, there can be nothing observable that will distinguish the motion of S_0 with respect to S_1 from the motion of S_1 with respect to S_0, we must have $t_0 = t_1$; otherwise, by comparing notes at the end, they would be able to distinguish between these equivalent expressions of the relative motion. This yields, from (1),

$$T_0 = T_1 = t_0 + \beta t_0 = t_1 + \beta t_1 \tag{2}$$

that is, the two clocks read the same on reunion; each will receive slow flashes for a time t_0 and fast flashes for a time βt_0; and therefore each will receive $n\beta t_0$ slow and nt_0 fast flashes. The moment at which S_1 fires his rocket will be $T_1/2$ by his clock (we agree on this). Hence, since $\beta < 1$, it will be earlier than t_1; that is, S_1 will not observe S_0's flashes to change until after he has fired his rocket. This is a complete solution of the problem.

Darwin proceeds differently. He says first that t_1 is "certainly just half" T_1; that is, $t_1 = T_1/2$. Next, "the reversal" will occur at a time $T_0/2$ by S_0's clock, but at a distance $VT_0/2$ from him (time-in-other-places will keep breaking in), so he will observe it at a time $VT_0/2c$ after its occurrence; that is, $t_0 = \frac{1}{2}T_0(1 + V/c)$. Substituting these values of t_1 and t_0 in (1) we find:

$$T_1 = T_0\sqrt{(1 - V^2/c^2)} \tag{3}$$

which is the usual asymmetrical result.

It is not difficult to see that Darwin's postulates are equivalent to the introduction of a fixed ether against which velocities are measurable. S_1 sees "the reversal" immediately, but S_0 only after an interval. That means that "the reversal" must be located at S_1 uniquely. Furthermore, since the distance which the light has to travel to S_0 is S_0's estimate of it, S_0 must be at rest in this ether: if he were moving towards or away from "the reversal", he would observe it earlier or later. Hence not only is the reversal located at S_1, but also the whole motion, to and fro, belongs to him, since S_0 is at rest. There is nothing in Darwin's argument (except the value of β) that would not have been wholly acceptable in the nineteenth century.

The relativity view is quite different. The only motions admissible are those of one body with respect to another. Hence "the reversal" cannot be assigned to S_1 as though S_0 did not exist: it must be the reversal of S_1 with respect to S_0 or of S_0 with respect to S_1, for there are no other observable bodies in the problem. Furthermore, these expressions of it must be equivalent. Hence the reversal cannot be located at S_1 rather than at S_0. It is a relation between the two bodies, a change from recession to approach, and not a property of one of them.

All this, of course, is only an involved way of expressing the simple argument already cited, on which a strange silence is maintained. Critics would save themselves many headaches if they would find the flaw in that instead of devising new ways of bypassing it.

Corrugated Iron Pan

THE morphology of lateritic and ironstone concretions is generally attributed to soil texture[1], ground-water movements[2,3] and variations in the soil aggregates upon which deposition takes place[4,5].

That the mechanical properties of such deposits may also affect their ultimate structures is suggested by an iron pan found on a cutting at Pulau Bukom, an island four miles south-west of Singapore.

When first seen, the cutting lay at an angle of 70°, exposing a gravel to sandy loam soil derived from parental conglomerates. A subsequent visit about a year later showed that an iron pan had developed over the lower slopes of the cutting as a hard, dark-brown carapace, 1–4 in. thick (Fig. 1). The pan was homogeneous, unlayered and had no structures indicating rhythmic deposition. Its inner surface adhered to the underlying soil without ramifications but its outer surface was corrugated into numerous sub-parallel ridges ½–1 in. high, each of which was fissured along its crest to a similar depth.

These features suggest a rapid initial outflow of ground-water from the freely drained soils, which deposited a continuous plastic sheet, perhaps of limonitic composition, on the surface of the cutting. The high angle of the face and the weight of the

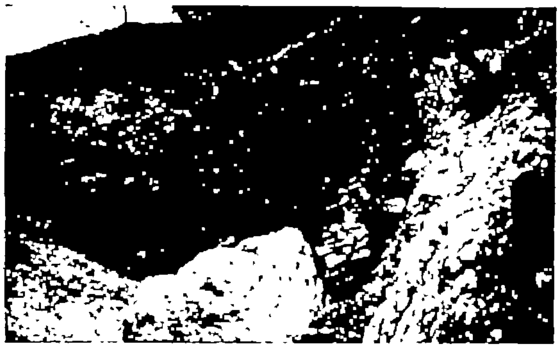

Fig 1

deposit initiated slumping and folding of the plastic sheet into its present form; the fissures correspond to tensional faults of anticlinal folds. Afterwards dehydration converted the original material into the existing rigid and impervious pan, thus inhibiting further development.

The evidence indicates that if rapidly accumulated, ferric oxide deposits may pass through a plastic phase before induration. The process may account for concretionary and vesicular structures of certain lateritic horizons, and is being investigated for a future report.

Dating of some Minor Intrusions of Ayrshire

AMONG the alkaline igneous rocks of Ayrshire are two groups of minor intrusions the age and genetic relations of which have aroused considerable interest in the past. The 'kylites' and 'crinanites' of Tyrrell[1] were originally classified together and were thought to be differentiates of the same magma, but later work by the Geological Survey (MacGregor[2]) has suggested that this may not be the case.

Kylites are olivine-rich theralites and essexites which frequently contain polysomatic clusters of purplish augite and only small quantities of analcite. The 'crinanites' are characterized by poikilophitic texture, an abundance of analcite, the presence of coarse, leucocratic segregation-veins (analcite–syenite of Tyrrell), and the frequent occurrence of accessory hornblende which is very rare in the kylites.

The Permian age of the kylites is fairly well established, as the majority of them are intruded into Coal Measures and two sills of the group are pierced by Permian volcanic necks. Fragments of kylitic rocks have been found in Permian necks, and the group closely resembles, both chemically and mineralogically, the Permian lavas of the Mauchline Basin.

Field evidence regarding the age of the 'crinanites' is not so conclusive, but similar intrusions on Arran are regarded as Tertiary. Mining evidence has suggested that a sill at Prestwick may be pierced by a small volcanic neck similar in type to the Permian necks around Dalmellington, but at Mauchline, a member of the group cuts sandstones above the Mauchline lavas. Crinanitic dykes trending north-west are thought to be connected with the Tertiary centres of Mull and Arran.

Since both the Permian and Tertiary directions of magnetization are well known in Britain (Creer *et al.*[3]), more than forty specimens, including typical representatives of both petrological groups, were collected, and a palæomagnetic study of the directions of permanent magnetism was made using a simple astatic magnetometer. The dual classification based on petrology was confirmed. The Permian age of the kylites was verified (the mean directions of magnetization calculated using Fisher's[4] statistics gave a declination of 181° and an inclination of + 7° compared with the Du Bois unpublished result of 180° and − 4° for the Mauchline lavas) and the 'crinanites' gave a direction of magnetization consistent with a Tertiary age. Evidence of reversals suggests intrusion at different times within the Tertiary, although the time interval may not be great.

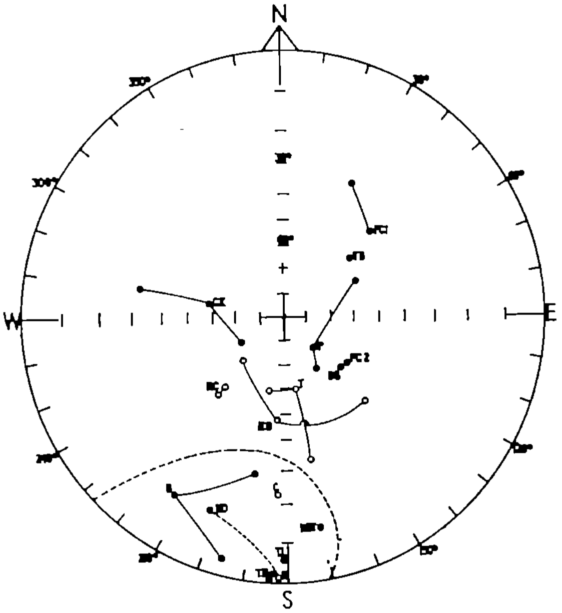

Fig. 1. Stereogram showing directions of magnetization of Ayrshire intrusions:
Specimen localities. *Kylitic group*: *B*, Benbeoch; *HD*, Hallyards Qy.; *H*, Hillhouse Qy.; *TH*, Tappet Hill; *C*, Crawfordjohn (essexite).
Crinanitic group: *FC*1 and *FC*2, Fisherton Cottage (dykes); *DB*, Dippol Burn; *TB*, Trabboch Burn; *KC*, King's Cross Point (Arran); *T*, Troon; *P*, Prestwick; *HB*, Howford Bridge. *Unclassified*: *TL*, Tarbolton Station (Mauchline lavas); *CK*, Carskeoch; *HBT*, Howford Bridge (tuff).
The dotted line encloses Permian points. ●, North-seeking pole pointing downwards; ○, north-seeking pole pointing upwards; +, theoretical dipole

Some of the samples were partially stable magnetically, particularly those from the Craigs of Kyle (kylitic group), which initially gave directions suggestive of a Tertiary age, but on partial demagnetization (which removed the isothermal remanent magnetization) gave directions consistent with a Permian age. Other specimens subjected to the same treatment were unaffected and therefore considered stable.

Thanks are due to Northumberland County Council for a grant towards research of which this work is a part, to the Physics and Geology Departments of this College for the use of apparatus, and to Dr. A. E. M. Nairn for making the majority of the measurements.

Intestinal Damage by Radiation and its Chemical Modification

The deoxyribonucleic acid content of the whole small intestine of mice and rats has been used as a measure of cell population in order to follow intestinal damage after X-irradiation, and has been found to be more reliable than simply measuring the intestinal weight. The method of Schmidt and Thannhauser[1] was used for separating the deoxyribonucleic acid and its concentration measured by Allen's method[2] of phosphorus determination and by ultra-violet spectrophotometry. At least three animals from different litters were used for each time interval after each radiation dose, and a control animal from each litter. The mean total deoxyribonucleic acid per small intestine from 43 control mice was found to be 0·72 mgm. The individual values were dependent on body-weight.

Consistent dose-response curves were obtained. The initial decrease in total deoxyribonucleic acid which became detectable 12 hr. after a dose of 200 r. was only slightly dependent on dose, and at 24 hr. after irradiation represented a reduction of approximately 30 per cent compared with controls. The time at which recovery began and the rate of recovery were markedly dependent on dose over the range 200–5,000 r.

Intraperitoneal injection into mice of β-mercaptoethylamine ('Becaptan') in doses of 150 mgm./kgm. 2–5 min. before X-irradiation significantly reduced the effect of 1,000 r. on intestinal deoxyribonucleic acid content 2, 3 and 4 days later to the same order as that of 750 r. (Table 1). Similar results, using 100 mgm. 'Becaptan'/kgm., were obtained in rats. The reduction of deoxyribonucleic acid content throughout the time 1–5 days after irradiation was greater than in mice, in agreement with the greater radiosensitivity of the rat intestine as judged by the clinical picture.

Mechanisms suggested for the action of 'Becaptan' are the promotion of regeneration without a concomitant reduction in the initial damage, or the reduction of initial damage without an effect on recovery[3]. When the time at which recovery begins and the rate of recovery are dependent upon dose, as in the intestine, bone marrow and lymph-nodes, the distinction may be easily confused, for a reduction in the degree of initial damage will show itself in an accelerated recovery, as illustrated in Table 1. A comparison on day 4 of the effects of 1,000 r. and 1,000 r. preceded by 'Becaptan' might suggest a marked enhancement of recovery by the drug. However, when account is taken of the time course of events after different doses it is clear that 'Becaptan' reduced the damaging effect of radiation by 25 per cent or a little more without intrinsically altering the course of recovery. This degree of effect is in quite good agreement with that given by Salerno[4] for the protective effect of 'Becaptan' on mortality in mice.

Table 1. TOTAL DEOXYRIBONUCLEIC ACID IN MOUSE SMALL INTESTINE

Mean values (mgm.) ± S.E. Figures in parentheses are numbers of animals used.

Days after X-ray	750 r.	'Becaptan' before 1,000 r.	1,000 r.	1,000 r. followed by 'Becaptan'
2	0·48 ± 0·02 (6)	0·48 ± 0·01 (4)	0·43 ± 0·02 (7)	0·40 ± 0·01 (4)
3	0·42 ± 0·02 (5)	0·47 ± 0·03 (3)	0·30 ± 0·01 (8)	0·27 ± 0·01 (3)
4	0·67 ± 0·02 (8)	0·76 ± 0·04 (4)	0·45 ± 0·05 (3)	
5	0·61 ± 0·06 (3)		0·56 ± 0·06 (3)	
6	-		0·61 ± 0·01 (4)	

After the recent report by Nerurkar and co-workers[5] the effect on deoxyribonucleic acid content of 1,000 r. with and without previous injections of methionine was determined, but neither in intestine, spleen, bone marrow nor liver could any protective effect be detected. The determination of total deoxyribonucleic acid in an organ or tissue provides a possible screening test for substances which might modify the effects of radiation. It has the advantages over the test commonly used with acute killing as the end-point of giving a result in less than a week, and of providing, with very few animals, a quantitative measure of any modification produced.

Isotopic Tracer Method for measurement of Iron lost into and re-absorbed from Gastro-intestinal Bleeding Lesions

It has been shown[1,2], with the help of rabbit and sheep erythrocytes labelled with iron-59, that appreciable amounts of iron from hæmoglobin were absorbed when these cells were administered orally to human beings. So far as we know, no information is available on the re-absorption of hæm-attached iron from intestinal bleeding lesions. A method for measuring such a re-absorption is here proposed.

Approximately 10 microcuries of iron-59 in the form of ferric ammonium citrate (from Abbott Laboratories, Oak Ridge) are injected intravenously. Blood radioactivity is determined on the subsequent days until a plateau is reached. A 20 c.c. aliquot of blood is then marked with 60 microcuries of chromium-51 and reintroduced in the patient's circulation[3]. Fæces are collected quantitatively in three 4-day periods, and blood obtained at the start of each period. Fæces are homogenized and prepared as previously described[4], and radioactivity from chromium-51 and iron-59 determined separately, with appropriate corrections[5], in a well-type scintillation counter (Nuclear-Chicago model 3037-*B*) with a pulse-height analyser (Radiation analyser, Chicago-Nuclear). Blood taken at the beginning of each fæcal collection period serves as a standard for that period. The amount of blood B_i (in ml./day) which is lost into the intestine can be readily calculated for each 4-day period :

$$B_i = \frac{R_f \times Q}{R_b \times 4} \qquad (1)$$

in which R_f is radioactivity from chromium-51 in the 4-day stool, in counts per mm. per gram of stool; R_b is radioactivity from chromium-51 in the blood obtained at the start of the 4-day stool collection, in counts per min. per ml. of blood; Q is quantity of stool in the 4-day period in gm.

The amount of iron lost into the intestine through the bleeding lesion Fe_i in mgm./day is then:

$$\mathrm{Fe}_i = \frac{\mathrm{Hb} \times B_i \times 3{\cdot}40}{100} \qquad (2)$$

in which Hb is blood hæmoglobin concentration, in mgm./100 c.c.; and 3·40 is mgm. of iron per gm. of hæmoglobin[6].

If in formula (1) we substitute for R_f the radioactivity in the stool due to iron-59, and for R_b the radioactivity in the blood due to iron-59, we obtain the value B_f, which is the quantity of blood, in c.c./day, which contains an amount of iron equivalent to that lost in the fæces. Substituting the value of B_f for B_i in formula (2), we obtain Fe_f, the amount of iron, in mgm. lost per day in the fæces. Then

$$\mathrm{Fe}_r = \mathrm{Fe}_i - \mathrm{Fe}_f$$

where Fe_r is the amount of iron re-absorbed in mgm./day.

It has been shown that chromium-51 attached to red blood cells is not significantly re-absorbed when it is placed in the gastro-intestinal tract of dogs and rats[7] and of humans[8].

Practically speaking, it may be said that comparison of radioactivity in stools and blood of patients with circulating erythrocytes marked with chromium-51 is a valid way of estimating the quantity of blood lost into the gastro-intestinal tract from a bleeding lesion.

Comparison of radioactivity from iron-59 in blood and stool gives us the quantity of iron lost in the stool. A minimal part of this iron, of the order of no more than 1 mgm./day[8], will represent the normal daily iron lost by the patient, and hence cannot be taken as coming from the bleeding lesion. The exact quantity could be calculated for each patient by measuring radioactivity in a stool before the erythrocytes are tagged with chromium-51. In any event, this cause of error would weight the balance on the side of apparently less iron re-absorbed than is correct.

The method has been tested thus far in four patients who harboured varying numbers of hookworms, since this represents a fairly constant daily source of bleeding[4]. The results may be seen in Table 1. In all these patients, the percentage of iron from hæmoglobin which is re-absorbed appears to be surprisingly high.

It will be of interest to study whether such a high degree of re-absorption is characteristic only of patients with hookworm, and to what extent intestinal re-absorption of hæm-bound iron is affected by the presence of anæmia and by the localization of the bleeding lesions in portions of the intestine other than the duodenum.

Table 1. IRON LOST INTO AND RE-ABSORBED FROM THE GASTRO-INTESTINAL TRACT IN PATIENTS WITH HOOKWORM INFECTION

Patient	No. of ova in stools (thousand/day)	Blood hæmoglobin (gm./100 c.c.)	Iron loss* Intestinal (mgm./day)	Fæcal (mgm./day)	Iron re-absorbed* (mgm./day)	(per cent)

Radioactivity of Blood Carbon Dioxide in Animals oxidizing Glucose labelled with Carbon-14 and Other Labelled Substances

THE rate of appearance of radioactive carbon dioxide in the expired air following the administration to an animal of a carbon-labelled oxidizable material has been widely used in making calculations of the rate of degradation of the particular material[1,2]. However, it is evident that, before isotopic carbon introduced into the body in this way can be excreted in the expired air, a number of physical processes must have intervened, quite apart from the chemical transformations which are involved. These physical processes include the passage of the original substance through the blood and tissue fluids, its mixing with unlabelled molecules of the same species and also the subsequent transport of the carbon dioxide produced at the sites of oxidative reactions to the alveoli of the lungs. The factors which determine the rate of elimination of radioactive carbon dioxide from the animal body have in particular received theoretical treatment[3].

In the experiments described here we have attempted to follow the catabolism of a labelled substance in different organs of the body by taking simultaneous samples of arterial and venous blood from those organs and examining the specific activity of the carbon dioxide entering and leaving the different vascular territories. We did not measure blood-flow, so that our results are in this sense qualitative; but they do reveal certain interesting differences between the various organs studied. Glucose was the substrate in the majority of our experiments, which were conducted on dogs and monkeys. In most cases the animals were under pentobarbitone anæsthesia, but some measurements have also been made under thiopentone, which is less suspect in terms of its effects on carbohydrate metabolism. Fig. 1 shows the results of comparing the specific activity of the carbon dioxide of arterial blood with that of blood taken from a number of sites in the venous system

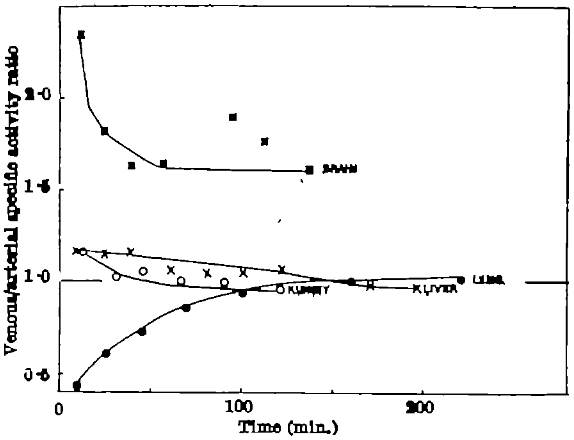

Fig. 1. Venous/arterial specific activity ratios of carbon dioxide for different organs after injection of ^{14}C-glucose. (The curves joining the observed points were drawn by eye solely as visual aids and no special importance attaches to their precise shape)

after injecting intravenously glucose labelled with carbon-14. Usually only one area of venous drainage was sampled in any one animal, but where simultaneous checks from more than one area were possible the results confirmed the accuracy of the composite picture built up from observations on separate animals. Moreover, the trends shown in Fig. 1 were all consistently present in a number of experiments. The lesser circulation has little effect on blood carbon dioxide specific activity; the specific activity curves of the carbon dioxide in systemic arterial blood, mixed venous (pulmonary arterial) blood and expired air have been found to be identical from the end of the third minute following ^{14}C-bicarbonate injection. This identity might reasonably be expected on the basis of data available from conventional studies of respiratory exchange[4]. The ratio of venous to arterial specific activity from blood circulating through the brain, liver and kidneys (Fig. 1) is also what might be expected from a *prima facie* consideration of the consequences of oxidation of a labelled substrate, that is, the venous carbon dioxide is more heavily labelled than the arterial. The general form of our curve for brain is in good agreement with a similar observation on human brain recently described by Sacks[5]. The curve (Fig. 1) of the changes in the venous/arterial specific activity ratio in the hind-limb, however, presents a totally different appearance from that of the other organs studied, since in the first 2¼ hr. after ^{14}C-glucose injection the venous carbon dioxide has a lower specific activity than the arterial. This effect cannot be attributed solely to the production of unlabelled carbon dioxide from other substrates, since the difference in total carbon dioxide content between venous and arterial blood (about 3 m.mol./l.) was insufficient to account quantitatively for the ratio. The reduction in specific activity of the venous as compared with the arterial carbon dioxide in the limb must, therefore, be explained by exchange with a large pool of unlabelled carbon dioxide which is held in the tissues of the limb and is in diffusional communication with the blood carbon dioxide. (The term 'carbon dioxide' is used in this context to include associated or dissociated carbonic acid.) We confirmed that such an exchange takes place by injection of $NaH^{14}CO_3$ into dogs, an example of the results from the limb in one such experiment being given in Fig. 2.

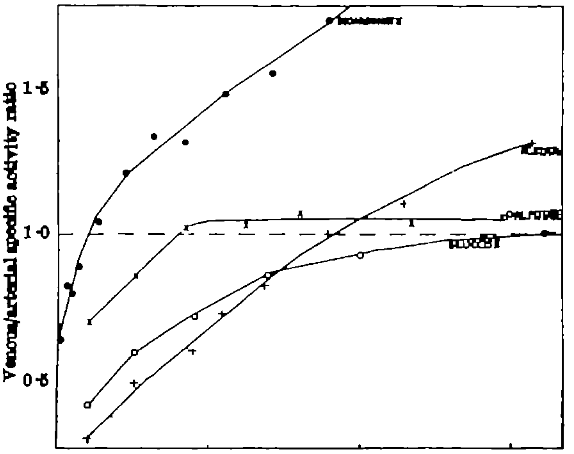

Fig. 2. Venous/arterial specific activity ratios of carbon dioxide in the dog's hind-limb following injection of various ^{14}C-labelled substrates. (Curves drawn by eye as in Fig. 1)

While the experiments with ^{14}C-bicarbonate provide a basis for understanding the reduction of the specific activity of the arterial blood as it passes through the limb in the absence of production of metabolic $^{14}CO_2$ they provide only a partial analogy with those in which the animal had been injected with ^{14}C-glucose. The fact that under these latter conditions the specific activity of the blood from the limb veins continues below that of arterial blood suggested that in the resting limb blood glucose does not undergo rapid oxidation. This conclusion would be in conformity with the findings of Andres, Cader and Zierler[6], who have demonstrated by non-isotopic methods that only some 7 per cent of the oxidative metabolism of the resting human forearm is based on glucose.

In an attempt to identify other possible substrates for the oxidative activity of the resting limb we injected 1-^{14}C-acetate and 1-^{14}C-palmitate. The changes in venous/arterial specific activity ratio in these experiments are indicated in Fig. 2. Although the ratio approached unity more rapidly than in the case of glucose it was still less than 1 for some 40 min. in the case of palmitate where the rise was most rapid. It thus appears that, whichever labelled substance is injected, in the early stages the specific activity of the blood carbon dioxide falls during the passage through the dog's hind limb because of the dominating influence here of the large tissue pool of unlabelled carbon dioxide. Drury, Wick and Almen[7] calculated that in rabbits 80 per cent of the (readily exchangeable) body carbon dioxide is present in muscle and skin and that after injection of ^{14}C-bicarbonate the carbon dioxide of these tissues reaches the same specific activity as that of the arterial blood less rapidly than does the carbon dioxide of liver. Our results suggest a similar distribution of exchangeable carbon dioxide in dogs. In the limb the diluting effect of the unlabelled carbon dioxide pool in the tissue (which includes bone) greatly outweighs the effect of newly produced metabolic carbon dioxide on the arterio-venous specific activity difference. This makes identification of the energy source difficult on carbon dioxide analyses alone.

The present results demonstrate rather forcibly that when the specific activity of carbon dioxide is measured in the expired air of an animal metabolizing carbon-labelled material the specific activity found will be considerably lower than that of the carbon dioxide leaving those organs where oxidation of the labelled substrate is most active.

It is hoped to publish a fuller account of these experiments in the near future.

Chromatography of Tobacco Mosaic Virus on a Cellulose Cation Exchange Adsorbent

Chromatographic procedures for tobacco mosaic virus using filter paper sheets[1,2] and starch columns[3] have been reported. Recently, cellulose ion-exchange adsorbents have been used for the chromatographic separation of serum proteins[4,5].

In the work reported here carboxymethylcellulose powder was prepared following the method of Peterson and Sober[4] and was used in experiments with extracts from tobacco-mosaic-infected Turkish tobacco plants. 30 gm. of infected Turkish tobacco leaves were frozen and ground in an 'Omni-Mixer' with 100 ml. of a mixture of 0·1 *M* acetic acid and 0·1 *M* sodium acetate having a *p*H value of 3·0. The *p*H of the blended mixture after grinding was 3·7. The liquid was separated from the fibrous constituents by pressing through cheese-cloth and was then centrifuged at 10,000*g* for 10 min. The sedimented material from this run was resuspended in 50 ml. of distilled water by grinding again in the 'Omni-Mixer'.

During this second grinding enough sodium phosphate salt was added to adjust the *p*H of the mixture to 7·0. This neutral mixture was centrifuged a second time at 10,000*g* for 10 min. This time the pellets were discarded and the supernatant liquid was saved and used as the sample material for chromatographic experiments. This liquid was opalescent and showed strong birefringence, typical of concentrated tobacco mosaic virus solutions, when viewed through crossed polarized filters.

A 2·5 cm. × 32·5 cm. chromatographic column was prepared and conditioned by the passage of 250 ml. of 0·005 *M* citric acid (*p*H 3) prior to the application of the sample. 4 ml. of sample was applied to the column. The column was then developed with 150 ml. of 0·005 *M* citric acid having a *p*H of 3·0. Next an elution schedule which gradually increased the *p*H and salt concentration was followed. The starting solution consisted of 200 ml. of 0·005 *M* citric acid in a constant-volume mixing flask. Mixing was achieved by a magnetic stirrer as solutions were added to the mixing flask in a dropwise manner with the rate of addition being controlled by the column elution rate.

A closed-system siphon was used for transferring liquid from the bottom of the mixing flask to the top of the column. The complete elution schedule was as follows:

In mixing flask	200 ml.	0·005 *M* citric acid (*p*H 3)
Solution I	150 ml.	0·005 *M* citric acid (*p*H 3)
Solution II	200 ml.	Mixture, 1 pt. 0·02 *M* citric acid : 1·45 pts. 0·02 *M* Na_2HPO_4 (*p*H 5)
Solution III	200 ml.	0·02 *M* Na_2HPO_4 (*p*H 9)
Solution IV	200 ml.	0·05 *M* Na_2HPO_4 (*p*H 9·05)
Solution V	200 ml.	0·05 *M* Na_2HPO_4 – 0·02 *M* NaCl (*p*H 9·05)
Solution VI	200 ml.	0·05 *M* Na_2HPO_4 – 0·05 *M* NaCl (*p*H 9·05)
Solution VII	400 ml.	0·05 *M* Na_2HPO_4 – 0·1 *M* NaCl (*p*H 9·05)

The effluent was collected in 8-ml. fractions by an automatic fraction collector. Infectivity of the fractions was estimated using pinto beans as the assay host. Each fraction was assayed on one leaf on each of five different bean plants. The bean plants were given a 10-sec. dip in 50° C. water, dried, dusted with 'Carborundum', and then inoculated with 0·1 ml. aliquots from the fractions. The hot-water dip increases the sensitivity of the bean leaves to the virus[6].

The hydrogen ion concentration, electrical conductivity, optical density at 2600 A., and infectivity of the fractions are shown in Fig. 1.

The light-absorption curve had two major peaks: one occurred quite early in the elution schedule while the other occurred much later. The infectivity curve is the best average curve that can be drawn from the

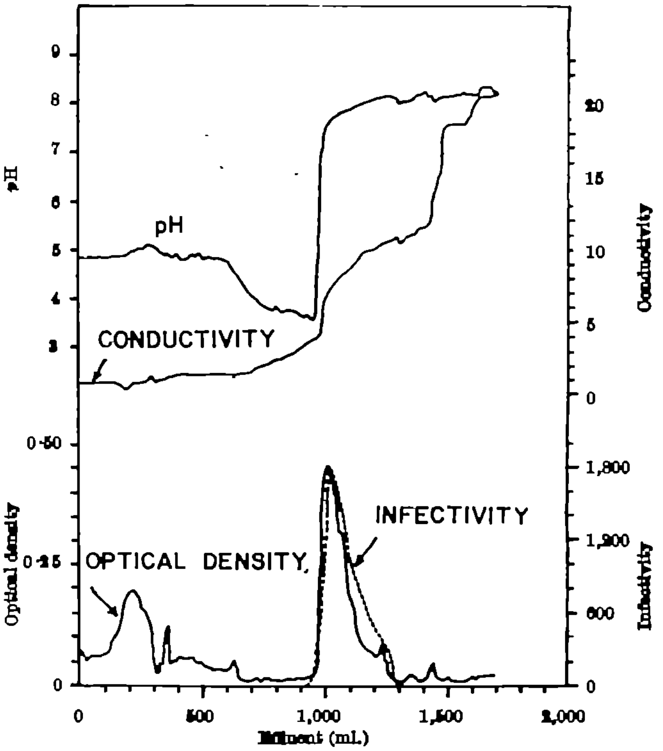

Fig. 1. Chromatography of a crude tobacco mosaic virus preparation on a carboxymethylcellulose column. Hydrogen ion concentration, electrical conductivity (millimhos/cm.[3] at 25° C.), optical density at 2600 A. and infectivity (average of lesion counts on five bean leaves) are all plotted against volume of effluent. Effluent was collected in 8 ml fractions

results of counting the lesions. As the curve of infectivity was almost coincident with the second light absorption peak, it was assumed that the absorption recorded in this portion of the elution schedule was principally that of tobacco mosaic virus. Ultra-violet absorption spectra of fractions in the major peak were typical of tobacco mosaic virus solutions. The nature of the absorbing components in the other peak has not been determined.

The *p*H of the effluent decreased gradually from a value of about 5 to 3·5 when the virus break-through occurred. This indicates that the lower part of the column had not reached an equlibrium with the *p*H 3 citric acid solution prior to the application of the sample. The *p*H of the effluent in the first virus-carrying fractions was 3·5. This *p*H value is assumed to be near the isoelectric point of the virus under the conditions existing on the adsorption column. It is believed that the virus can only be moved at *p*H values higher than its isoelectric point on a cation-exchanging adsorbent at the salt concentrations used.

It is significant to note that a marked break occurred in the *p*H curve at the point of virus elution. This break, amounting to four orders of magnitude, is probably a result of the buffering action of the virus protein.

There is also a significant break in the conductivity curve which lags slightly behind the break in the *p*H curve. This rapid change in conductivity cannot be accounted for in the gradual mixing of the salt-buffer developing solutions.

Because this rapid rise in conductivity is coincident with the rapid increase in ultra-violet absorption and the rapid increase in infectivity, it is concluded that this increased conductivity is caused by the presence of charged virus particles in the effluent. The amount of virus in the most concentrated fraction was calculated to be 0·014 per cent from the light-absorption results[7].

This same experiment was repeated using an identical column and elution schedule. The amount of sample applied was increased fourteen-fold. The elution results were quite similar. The virus was eluted at the same relative position in the elution schedule, with the width of the elution band only slightly greater than in the first experiment. An assay of comparable fractions from the two experiments showed that the virus was 10–15 times more concentrated in the fractions of the second experiment.

These experiments indicate that cellulose cation exchange adsorbents may be useful in virus isolation, particularly where *p*H, conductivity, optical density, and infectivity can all be studied in relation to the elution patterns.

Methionine Biosynthesis and Utilization in *Pseudomonas tabaci* and *Ps. angulata*

Pseudomonas tabaci, the wildfire bacterium of tobacco, produces an exotoxin, detectable by a bacteria-free, chlorotic halo surrounding the necrotic focus of infection in the leaf at the site of inoculation; *Ps. angulata*, the causative agent of angular leaf spot of tobacco, does not produce the chlorotic halo. These species are indistinguishable when *Ps. tabaci* is attenuated and no longer produces the exotoxin[1]. Since the exotoxin behaves as a methionine anti-metabolite for the host cells[2], the effect of a second methionine antimetabolite, methionine sulphoximine, on toxigenic strains of *Ps. tabaci* was determined. Furthermore, eighteen independently isolated, methionine-requiring mutants of this species were tested to establish the site of the block in the biosynthetic pathway for this amino-acid.

Two strains of *Ps. tabaci* (*R2* and *S3*) and one strain of *Ps. angulata* (62*B*), kindly supplied by Dr. H. E. Heggestad, U.S. Dept. of Agriculture, and Dr. A. C. Braun, Rockefeller Institute for Medical Research, respectively, were used. All strains were grown in a synthetic medium[3] which was solidified with Noble agar ('Difco') whenever a solid medium was required. Mutants of *Ps. tabaci* requiring methionine were isolated following ultra-violet irradiation and screening with penicillin[4].

None of the methionine-requiring mutants of *Ps. tabaci* responded to supplementation with the inorganic precursors (sulphur, sulphite, thiosulphate) or with the organic precursors (cysteine, homoserine, cystathionine, homocysteine) known to be involved in the biosynthesis of methionine in *Escherichia coli* and *Neurospora crassa*. One mutant was especially interesting, since it required both cysteine and methionine in a specific molar ratio. In the course of using crystals of the organic precursors of methionine as auxanographic supplements on the surface of plates seeded with the mutants it was noted that all mutants were strongly inhibited by cysteine and homoserine. The two parental strains of *Ps. tabaci* and the one strain of *Ps. angulata* were also inhibited by cysteine and homoserine.

Crystals of methionine sulphoximine were seeded on the centre of plates the surface of which had already been covered with cells of either *Ps. tabaci* or *Ps. angulata*. Both strains of the former species were resistant and one strain of the latter species was sensitive, displaying a large zone initially with no colonies in the region of the crystals. This response appears to be a second criterion for distinguishing these species.

During the investigation of the toxigenicity of the methionine-requiring mutants of *Ps. tabaci*, it was noted that almost all mutants were not toxigenic. When prototrophic reversions of these mutants, now able to grow in the absence of methionine in the synthetic medium, were inoculated into leaves, only the two tested reversions from one mutant did not regain toxigenicity[4]. These non-toxigenic reversions were sensitive to methionine sulphoximine. Six, independently isolated, methionine sulphoximine-resistant mutants of *Ps. angulata* did not produce a chlorotic halo in tobacco leaves. Although it has been possible to 'convert' *Ps. tabaci* to *Ps. angulata*, it has not yet been demonstrated that *Ps. angulata* can be 'converted' to *Ps. tabaci*. It should be mentioned in this connexion that resistance and sensitivity to methionine sulphoximine in *Chlamydomonas reinhardi* is controlled by a single gene difference[5].

These observations suggest that the biosynthesis and, perhaps, utilization of methionine in *Ps. tabaci* may not follow the familiar pattern found in *E. coli* and *Neurospora*, and that one of these species (*Ps. tabaci* and *Ps. angulata*) may be a variant of the other species.

This investigation was aided by a contract (*NR*135–267) between the Office of Naval Research, Department of the Navy, and the University of Chicago, and by a grant from the Dr. Wallace C. and Clara A. Abbott Memorial Fund of the University of Chicago.

Isolation of Intact Liver Cells

Liver cells have been isolated by various methods, such as by forcing the tissue through stainless steel sieves[1], by tryptic digestion[2] and by incubation in acid solutions[3]. Anderson[4] obtained a high yield of cells by perfusion of liver with calcium-free solutions containing chelating agents (such as ethylenediamine tetraacetate (versene) or citrate) and subsequent dispersion.

From investigation of these and other methods, a technique has been developed[5] which permits the isolation of cells in high yield in physiological solutions without use of enzymes, chelating agents or abnormal *p*H.

Under ether anaesthesia the inferior vena cava of a mouse is cut fairly low down and the vessel is clamped with a hæmostat just above the point of entry of the left renal vein. The hepatic artery is severed and the liver is perfused via the portal vein with 10–15 ml. of fluid (see below) at 37° C. using a hypodermic syringe (20 ml.) and a No. 25 needle. During perfusion the pressure is gradually increased until the blanched liver is fully distended. The initial stages of perfusion must be accomplished before the heart actually stops beating. The liver is quickly removed from the animal and transferred to a vessel containing the perfusion fluid at 37° C., cut into fairly large pieces with scissors and very gently dispersed in about 5 vol. of the perfusion fluid at 37° C. using a glass tube and a 'Polythene' pestle constructed as described by Kamphausen and Morton[6]. The clearance between the pestle and tube is about 0·002–0·004 in. The pestle is operated by hand and generally about 20–40 slow up and down strokes are sufficient to disperse the cells. The dispersion is filtered through bolting nylon of increasing mesh (for example, 5*N*, 9*N*, 12*N*, 17*N*, 21*N* and 25*N*) to remove strands of connective tissue and clumps of cells. Fig. 1 shows that the suspension contains very little cell debris or broken cells. For many purposes the cells may be used directly in this suspension or they may be sedimented by low-speed centrifuging and washed as desired.

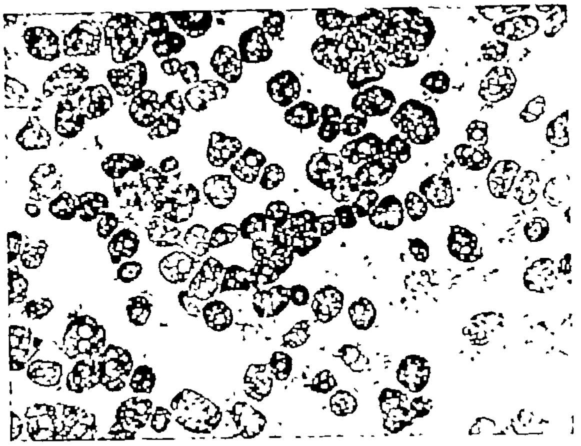

Fig. 1. Suspension of mouse liver cells isolated in calcium-free Locke's solution, as obtained directly after filtration. (× 140)

By this means cells have been consistently obtained with every perfusing fluid investigated, including 0·9 per cent (w/v) sodium chloride, calcium-free Locke's solution with and without versene, complete Locke's solution, 0·25–0·35 *M* sucrose solutions with or without 0·001 *M* magnesium chloride or 0·001 *M* calcium chloride, polyvinyl pyrrolidone–sucrose solution, and mouse serum. The most satisfactory preparations have been obtained from 7·3 per cent (w/v) polyvinyl pyrrolidone–0·25 *M* sucrose–0·001 *M* magnesium chloride at *p*H 7–7·4, a medium developed for isolation of intact mitochondria[7].

The ease of isolation of cells increases with increasing temperature of perfusion and dispersion up to 50° C.; but normally all work is carried out at 37° C.

This method enables conversion of almost the entire liver into isolated cells in a relatively short time after the death of the animal. With appropriate choice of hyperdermic syringe and needle, and with adjustment of the perfusion volume, cells may be isolated from livers of other animals, including the rat, the rabbit and the sheep.

Numerous studies have been carried out, and are continuing, with cells isolated in this manner to determine whether they may be regarded as being physiologically intact. Evidence has been sought by means of: (1) microscopic examination; (2) electron microscopy of thin sections; and (3) enzymic and respiratory studies. If unwashed, the isolated cells show a low but definite respiration without added substrates. This respiration-rate may be largely removed by preliminary cell washing, and restored to the washed cells by the addition of the supernatant in which they were originally prepared, after it has been made particle-free by centrifuging at 105,000*g* for 20 min. It seems that the higher respiration-rate of the unwashed cells is due to one or more factors which may be lost from the suspension by washing. These may include substrates, enzymic co-factors, or stimulating substances released from disrupted cells.

The same principle has been used successfully for isolation of intact cells from both kidney and tumour tissues. It is considered that suspensions of cells obtained as described here have many advantages over other types of preparations for studying biological reactions at the cellular level.

The details of these and related studies at present in progress will be described in further papers to be submitted for publication. The photograph (Fig. 1) was taken by Mr. E. Matthaei, to whom we wish to express our thanks.

Rapid Extraction with Ethyl Acetate of Free Fluorescein Derivatives from Fluorescein *iso*Cyanate-Globulin Conjugates

THE technique of staining tissues specifically with fluorescein-conjugated globulin has found wide application since it was introduced by Coons, Creech and Jones in 1942[1]. Though Coons and Kaplan[2] have recently introduced technical improvements the procedure remains in part tedious and time-consuming. Conjugation between fluorescein *iso*cyanate and protein is effected in a bicarbonate buffer (*p*H 9·0) in the presence of dioxan and acetone[2]; conjugation, however, is never quantitative and the presence of free dye in the protein solutions is inevitable. The free fluorescein derivatives must be eliminated since, when present in tissue sections being viewed with the fluorescence microscope, they impart a hazy appearance. At present the free fluorescein derivatives are removed from conjugates mainly by exhaustive dialysis and afterwards by adsorption with acetone-extracted or lyophilized mouse liver preparations. The dialysis is time-consuming, while in our experience prolonged adsorption with organ preparations removes specific conjugates as is shown by a fall in the antibody titre.

We have found that extraction of fluorescein-conjugated antisera with ethyl acetate at neutrality will remove from the reaction mixture both the free fluorescein derivatives and the acetone and dioxan. The following extraction procedure is used in this laboratory.

After the fluorescein *iso*cyanate and globulin have been allowed to react at *p*H 8–9 for 16 hr. at 0° C., the solution is extracted with 1 volume of ethyl acetate (A. R.) and the emulsion thus formed broken by low-speed centrifugation (1,000*g* for 5 min.). The supernatant acetate which contains the acetone and dioxan is discarded. The *p*H of the aqueous layer is then lowered to 7·0 (bromthymol blue) by the addition of *N* hydrochloric acid, and this solution extracted twice with 2 vol. of ethyl acetate. The supernatants are discarded and the dissolved acetate is removed from the aqueous phase *in vacuo* with a water pump.

During storage of either dialysed or acetate-extracted conjugated sera at – 10° C., there is a slow liberation of bound fluorescein derivatives which should be removed by a single acetate extraction before use.

Acetate extraction of serum globulin fractions did not affect the complement-fixing antibody titre of the rabbit and anti-rat-liver and anti-rat-kidney microsomal and mitochondrial sera which have been used in this laboratory.

While acetate extraction removes free fluorescein derivatives, it may be necessary, in addition, to adsorb the extracted serum with the appropriate heterologous antigen—often a dried acetone-extracted organ preparation[2] or a fresh particulate tissue fraction[3]—in order to yield a serum with the required specificity.

Clearing Action of Lysolecithin

G. R. WEBSTER has recently reported very interesting experiments on the clearing action of lysolecithin on brain homogenates[1]. Analogous findings with lysolecithin (and animal venoms) on brain brei suspended in physiological saline were published in 1942 by Grosse and Tauböck[2].

The solubilizing effect of lysolecithin may be observed also with suspensions of cholesterol, lecithin, oleic acid and particle preparations from liver[3] and on diluted egg yolk[4]. It may be connected with the high surface activity of lysolecithin[5].

Lysolecithin acts on enzyme systems, for example, of oxidative phosphorylation[5], succinoxidase system[6] and on tissue thromboplastin[6], possibly by disintegrating biological structures. Complete lysis of erythrocyte stroma[7] and changes of morphology of liver mitochondria[8] have been shown.

Lysolecithin has been sometimes thought to be involved not only in the normal or pathological turnover of blood cells (for review, see ref. 9) but also in pathological conditions of the central nervous system[10]. If lysolecithin, or the phospholipase *A* producing it, is present in the body, it may be very important for permeability and solubilizing processes of all kinds[3]. Knowledge of the presence of lysolecithin or phospholipase *A* in normal or pathological tissue, however, is very restricted.

Isolation of the Bound Form of Nicotinic Acid

Chaudhuri and Kodicek[1] have shown that almost the whole of the nicotinic acid in cereal bran was present in a bound form. They concentrated this 'precursor' of nicotinic acid from wheat bran considerably. Chaudhuri[2], starting from rice bran in this laboratory, concentrated this substance about seventy times, following the concentration by the usual colorimetric method using *p*-aminobenzoic acid as the coupling reagent[3]. It has now been possible to isolate the bound form of nicotinic acid from rice bran in a crystalline state. This work has been facilitated by the observation that the active substance, when subjected to paper chromatography using phenol–water (80 : 20) as the solvent system, gave two ninhydrin-sensitive spots, one of which moved with the solvent front and produced a blackish-violet colour with ninhydrin. It also gave an orange colour when sprayed with *p*-aminobenzoic acid after exposure to cyanogen bromide vapour according to the method of Kodicek and Reddi[4]. The orange colour has been shown to be produced by the bound form, and it is insoluble in amyl alcohol, which dissolves the colour produced by free nicotinic acid as observed by Swaminathan[5]. A method developed by Das and Ghosh[6] based on this observation has been used to follow the concentration of the bound form of nicotinic acid in the present work.

The method of isolation consists of: (1) the extraction of rice bran with 0·1 *N* hydrochloric acid; (2) precipitating inactive material from the extract with 3 volumes of acetone; (3) centrifuging and precipitating the active material from the centrifugate with 3 volumes of a mixture of acetone and ether (2 : 1); (4) extracting the precipitate with 65 per cent alcohol and precipitating the active material from the extract with 12 vol. of acetone–ether (2 : 1) and repeating this process; (5) drying the precipitate, dissolving it in the minimum quantity of water, fractionating it on a cellulose column by treating the column with phenol–water (80 : 20) when the active material forming the brown zone moves with the solvent front, and collecting the brown phenol–water fraction; (6) precipitating the active substance from the phenol–water solution with 45 vol. of acetone–ether (2 : 1) in the cold; (7) washing the precipitate with acetone–ether, drying, dissolving it in the minimum quantity of cold water, and allowing it to crystallize in a vacuum desiccator in the cold.

The substance crystallizes in shining russet rectangular plates (Fig. 1). Several preparations showed the same crystalline structure, composition and activity. The yield is 50–70 mgm. per 100 gm. of rice bran. It decomposes above 225° C. It gives a blue fluorescence in ultra-violet light, which changes to yellowish-green on treatment with alkali, as was observed with their wheat-bran concentrate by Chaudhuri and Kodicek[1]. Dissolved in 0·1 *N* hydrochloric acid, it gives an absorption maximum at 262 mμ. Analysis of the substance gives the following figures: C, 47·41; H, 6·93; N, 11·65; S, 0·85 per cent. Molecular weight, as determined by the diffusion technique using a sintered 'Pyrex' glass crucible fitted with a fritted disk (grade *G*-3), has been found to be of the order of 7,000, which agrees fairly well with the theoretical molecular weight (7,200) calculated on the assumption that there is one molecule of nicotinic acid per molecule of the substance. Preliminary experiments indicate that it is a peptide bound with a nicotinic acid moiety.

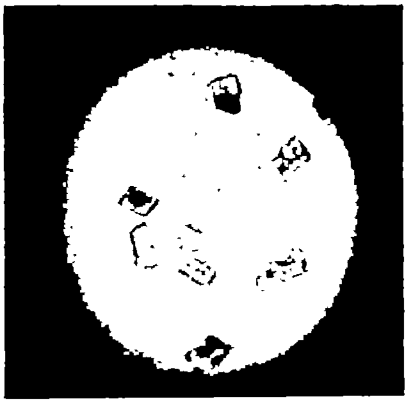

Fig. 1. Crystals of the bound form of nicotinic acid. (× 8)

In future communications this bound form of nicotinic acid, from which nicotinic acid is liberated by mild alkali treatment, will be referred to as 'niacinogen' for convenience.

We thank Dr. J. J. Ghosh, Dr. N. C. Ghosh and Dr. S. Ghosh for their kind assistance and also the Indian Council of Medical Research for financing this work.

Chromatographic Characterization of Soluble Deoxypolynucleotides released in Mouse Spleen by X-Irradiation

In connexion with a programme of studies concerning the biochemical effects of whole-body X-irradiation on the deoxyribonucleic acid–protein complex of radio-sensitive tissues of the mouse, we wished to explore the nature of the soluble deoxypolynucleotides released in the spleen after exposure to the irradiation.

Previously reported evidence[1] indicates that following whole-body X-irradiation of mice at the *LD*100 dose-level (810–850 r.) there occurs a significant rise in free deoxypolynucleotide values from a pre-exposure level of 20 μgm. per spleen to a maximum of 350 μgm. per spleen (average value) 4–6 hr. post-exposure. This maximum value occurs at the same post-exposure time when the spleen weight is decreasing and the deoxyribonucleic acid–nucleoprotein content of the spleen is falling precipitously. These deoxypolynucleotides were characterized by their solubility in 0·14 *M* sodium chloride solution (deoxyribonucleic acid–nucleoprotein is insoluble in 0·14 *M* saline), insolubility in cold 0·2 *M* perchloric acid, ultra-violet absorption characteristics, positive Dische diphenylamine reaction, and resistance to ribonuclease.

Main and Cole[2] have characterized calf thymus deoxyribonucleic acid by chromatography on calcium phosphate columns prepared by an earlier method of Tiselius[3] and used by him for the chromatography of proteins. We have shown that the short-term (30 min.) deoxyribonuclease-digestion products of deoxyribonucleic acid can be separated from the acid on such columns.

We now report results obtained by calcium phosphate column chromatography of the radiation-released deoxypolynucleotides. For the present studies, the calcium phosphate was prepared by a method[4] modified from the above. Dilute aqueous saline (0·14 *M* sodium chloride) extracts were prepared from spleens of young adult *LAf*$_1$ mice killed 6 hr. after whole-body X-irradiation, and also from non-irradiated mice as previously described[1]. A 100 per cent lethal X-ray dose was employed (810–850 r.).

In a typical experiment the spleens from six irradiated mice were homogenized in a few ml. of saline and then diluted to 16 ml. The resulting homogenate was centrifuged (5° C.) for 15 min. at 1,300 *g*. The absorbance at 260 mμ (A_{260}) of the resulting supernatant extract was 8·00. The A_{260} of a corresponding supernatant extract from four spleens of non-irradiated mice was 6·60. In an endeavour to equalize the amount of material absorbing at 260 mμ placed on each column, 4 ml. of the former were placed on one column, and 5 ml. of the latter were placed on another column.

Fig. 1*A* illustrates two elution histograms of the results derived from such spleen extracts after chromatography by continuous linear gradient elution with sodium phosphate buffer, *p*H 6·7. The peaks at the start of each chromatographic separation are of about equal magnitude and represent low molecular weight, that is, perchloric acid-soluble substances, presumably purine- and pyrimidine-containing compounds known to be present in these extracts[1]. Areas appearing between eluant phosphate concentrations of 0·08–0·100 *M* are of particular interest. A broad and characteristic elution band (between 0·07 and 0·10 *M*), with a sharp peak at 0·095 *M* is observed with the extract from irradiated mice. By contrast, no corresponding peak occurs with the spleen extract from non-irradiated mice, and furthermore the total 260 mμ-absorbance of substances eluted between 0·07 and 0·10 *M* is markedly lower.

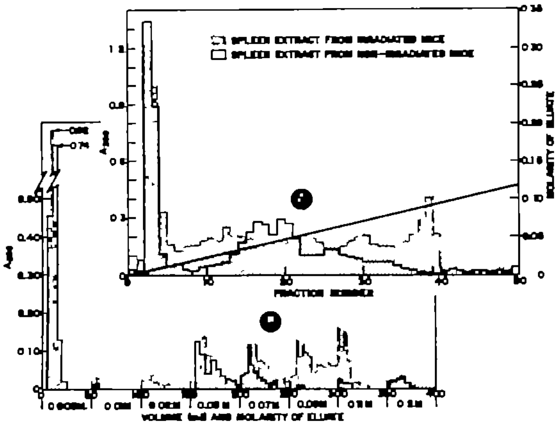

Fig. 1. Chromatograms of spleen extracts from X-irradiated mice and from non-irradiated mice eluted from calcium phosphate columns by sodium phosphate buffer, *p*H 6 7 in fractions of 4·5 ml. *A*, Chromatography by linear gradient elution; *B*, chromatography by discontinuous gradient elution

The results of discontinuous gradient elution chromatography of the spleen extracts (Fig. 1*B*) disclose the same general pattern as that obtained by continuous linear gradient elution. It is evident that the A_{260} of fractions eluted between 0·07 and 0·11 *M* phosphate buffer from X-irradiated mouse spleen extracts is considerably greater than that of corresponding eluate fractions from spleen extracts of non-irradiated mice. These eluate fractions from spleen extracts of X-irradiated mice give a positive test for deoxyribonucleic acid by Keck's method[5]. Further evidence that these 0·07–0·11 *M* phosphate eluants from irradiated spleens are macromolecular in nature comes from experiments[6] which show that calf thymus deoxyribonucleic acid exhibits similar chromatographic patterns on identical calcium phosphate columns. Macromolecular substances of lower molecular weight, for example, bovine serum albumin[6], as well as short-term deoxyribonuclease digests of deoxyribonucleic acid[2], were found to be eluted at lower phosphate concentrations, that is, 0·04–0·08 *M*. A typical monodeoxyribonucleotide (deoxyadenylic acid) was immediately and completely eluted from a column by 0·005 *M* phosphate buffer.

It will be of interest to determine the precise molecular weights of these polynucleotides released in the spleen following whole-body X-irradiation.

Liberation of Tyrosine Hydroxyl Groups in Urea Solutions of Bovine Serum Albumin and Ovalbumin

THE process of denaturation of proteins is being investigated in this laboratory by following changes in various properties which depend on the structure and the state of aggregation of the protein molecule[1]. In view of the possible importance of hydrogen-bonded tyrosine hydroxyl groups in maintaining the native configuration of the protein molecule[2] the liberation of tyrosine hydroxyl groups has been studied by examining the changes with time in the ultra-violet absorption spectra of bovine serum albumin and ovalbumin under different conditions of pH, both in the presence and absence of urea.

The spectrum (above 255 mμ) of aqueous solutions of bovine serum albumin was found to be essentially independent of pH over the range 4·4–8·0 in the absence of urea. However, when the pH was adjusted to less than 4·4, the absorption peak at 279 mμ shifted instantaneously to lower wave-lengths and the spectrum more closely resembled that of free tyrosine. At pH 3·2 the peak had shifted to 277 mμ. No further shift in the peak occurred on decreasing the pH below 3. Differential absorption spectra were obtained by comparing the spectrum of the protein at pH values below 4·3 with that of the protein in neutral solution. At any given pH below 4·3 the difference in optical density was found to be greatest at 287–288 mμ. The difference at 287 mμ reached a maximum near pH 2·6. No further change occurred on decreasing the pH below 2·6 until pH 1·0 was reached, when there was some decrease in this difference in optical density. These changes in the spectrum are almost entirely due to changes in the environment of the tyrosine hydroxyl groups[2,3]. The change in optical density at 287 mμ closely parallels the increase in viscosity of bovine serum albumin at low pH reported by Tanford *et al.*[4].

On exposure of native bovine serum albumin to urea at concentrations above 2 *M*, over the pH range 4–9, an instantaneous shift of the absorption maximum towards 277 mμ occurred. The spectrum then resembled that of the protein in acid solutions below pH 3. Likewise differential spectra obtained by comparing the spectrum of the protein in urea solution with that of the native protein at neutral pH showed a maximum difference at 287–288 mμ.

Unlike bovine serum albumin, ovalbumin showed no change in the 280 mμ band over the pH-range 2·0–9·0 in the absence of urea. On exposure of ovalbumin to urea at concentrations greater than 4 *M*, a hypsochromic effect was observed. The extent of this effect varied with the pH, urea concentration and time of exposure to urea. The greatest shift observed was obtained by exposing the protein to 9 *M* urea at pH 3·1. The absorption peak under these conditions was shifted from 280 mμ for the native protein to 277 mμ for the denatured protein. Examination of differential spectra showed that the maximum difference in optical density occurred at 288 mμ. These spectral changes were very strongly dependent on the urea concentration.

The rate of liberation of the tyrosine hydroxyl groups in urea solutions of ovalbumin at pH 5·8 and 7·8 was studied by examining the rate of change of optical density at 288 mμ. At both pH values the rate has apparent first-order dependence. This observation may be compared with Harrington's studies[5] on the acid-base titration curve of ovalbumin in the presence of guanidine hydrochloride.

The rate of liberation of tyrosine hydroxyl groups in urea solutions of ovalbumin was a minimum near pH 8. This observation agrees with the finding of Simpson and Kauzmann[6] that ovalbumin has its maximum stability towards urea denaturation in the pH-range 7–9.

A comparison has also been made of the rate of liberation of tyrosine hydroxyl groups with the rate of change of other properties such as optical rotation. This and the present work will be published in detail elsewhere.

Determination of Chlorogenic Acid

SLOTTA AND NEISSER[1] found that *o*-dihydroxyphenolic compounds such as chlorogenic acid and caffeic acid could be oxidized quantitatively with an alkaline hypoiodate solution, and used this method for the determination of these acids in coffee. They found that for every mole of chlorogenic or caffeic acid, 10 gm.-atoms of iodine were required for complete oxidation and that the oxidation involved the aromatic ring only without affecting the side chain, This method has recently been used by Wilkinson. Phillips and Bacot[2] for the determination of chlorogenic acid in flue-cured tobacco. In their method the polyphenols were precipitated from an aqueous extract of tobacco with neutral lead acetate solution. The precipitate of lead salts was then washed with water to remove sugars, suspended in water and decomposed with hydrogen sulphide. Caffeic acid was removed by extraction with ether and chlorogenic acid estimated in the resulting solution by the above method[1]. This solution may, however, contain other substances which possess *o*-dihydroxyphenolic groups, such as rutin[3,4], *iso*quercitrin[5,6] and quercetin[6]. Wilkinson *et al.*[2] state without any proof that rutin did not interfere to any appreciable extent. Since these authors used their results for drawing conclusions about the quality of flue-cured tobacco, it was decided to investigate the action of alkaline hypoiodate on pure polyphenols which contained *o*-dihydroxyphenolic groups.

Chlorogenic and caffeic acids were recrystallized twice from water containing a trace of hydrochloric acid[7], and rutin, quercitrin and quercetin crystallized three times from aqueous ethanol (charcoal). After recrystallization the polyphenols were dried at 100° C./15 mm. for 6 hr.

Solutions containing 0·2 gm. of the appropriate polyphenol in 100 ml. of water were prepared. (In the case of the flavonols 1 ml. of a ·2 *N* sodium hydroxide solution was added.) 5 ml. of the polyphenol solution, 10 ml. of 0·05 *N* iodine solution and 10 drops of 2 *N* sodium hydroxide solution were placed in a flask and the solutions well mixed. The flask was then stoppered and the reaction mixture allowed to stand in the dark for one hour. After acidification with 2 *N* sulphuric acid the liberated iodine was titrated with 0·05 *N* sodium thiosulphate solution using starch as indicator. Duplicate determinations and blanks were carried out at the same

Table 1

Polyphenol	Atoms of iodine/mol. of polyphenol
Chlorogenic acid (3-caffeoyl quinic acid)	9·94
Caffeic acid	10·06
Rutin (quercetin-3-rhamnoglucoside)	14·95
Quercitrin (quercetin-3-rhamnoside)	14·13
Quercetin	14·33

time and the amount of iodine consumed in the reaction found. No further increase in the amount of iodine consumed was found on allowing the reaction mixture to stand for two or three hours. The results are given in Table 1.

These results show that rutin and related compounds will interfere with the alkaline hypoiodate determination of chlorogenic acid. Not much work has been carried out on the estimation of flavonols in tobacco, but Turner[8] obtained a value of about 1 per cent for the amount of rutin in flue-cured tobacco. The amount of rutin present will vary from sample to sample, but taking this as an average value the error introduced in the chlorogenic acid content due to rutin alone is considerable. It would appear that a method for the determination of chlorogenic acid in tobacco would have to be based on the quantitative removal of other polyphenols, probably by paper chromatography and along the lines suggested by Paech and Ruckenbrod[9].

It is hoped to report other related work on this problem more comprehensively at a later date. Thanks are due to the Directors of the Imperial Tobacco Company (of Great Britain and Ireland), Ltd., for permission to publish this communication.

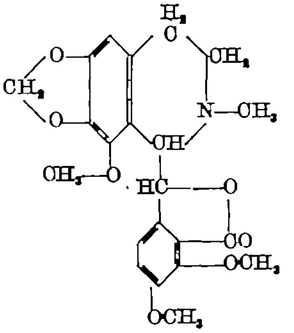
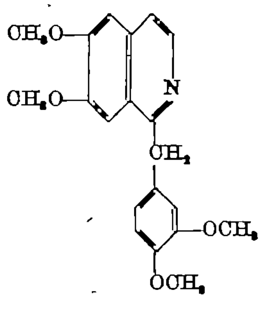
Determination of Papaverine and Narcotine by using Ammonium Reineckate

Methods of analysis of opium[1] and major opium alkaloids are required in determining the place of origin in those areas of the world where illicit traffic in opium arises. The Economic and Social Council of the United Nations in 1949 authorized research into devising chemical methods of identifying opium and invited member governments to participate in such a programme. Under this International Narcotics Research programme, Canada offered to train scientists from governments of other countries. This note is a publication of research results obtained by a U.N.T.A.A. fellow (L. K. T.) under this programme[2] and reports a new method of separating papaverine and narcotine.

Anneler[3] proposed the only satisfactory quantitative method of analysis of papaverine and narcotine, which are well known for their chemical similarities. The extractability of papaverine and narcotine from aqueous buffer solution of acetate was found to be similar which indicates the futility of attempting to separate this pair of alkaloids by ordinary countercurrent methods. Narcotine contains a lactone ring as shown in formula *A* compared with papaverine in formula *B*.



A



B

Anneler's method is based on the splitting of the lactone ring by strong alcoholic potash followed by extraction of papaverine with chloroform from this alkaline solution. The narcotine is then recovered after ring closure using strong hydrochloric acid and subsequent extraction with benzene from an alkaline solution. Fulton[4] has employed this method in a unified analysis of opium for morphine, codeine, thebaine, papaverine and narcotine. In a recent study of this method low recoveries varying from 80 to 85 per cent were obtained from experiments on opium and on pure narcotine and on mixtures of narcotine and papaverine.

It had been observed, in our search for a general method for the determination of organic bases, that narcotine in the presence of chloroform and aqueous acid solution of ammonium reineckate does not give a precipitate, whereas papaverine does. It was observed that the chloroform layer in that mixture was red-coloured. Subsequent quantitative determinations of mixtures of pure papaverine and narcotine, and opium showed quantitative recoveries of these alkaloids. The recoveries of pure drugs from mixtures are shown in Table 1, and from opium in Table 2. Procedure: A chloroform solution of

Table 1. Recoveries of Narcotine and Papaverine from Mixtures

Narcotine and papaverine used		Narcotine and papaverine recovered

Table 2. Recoveries of Narcotine and Papaverine from Opium

	Anneler's method	New method
Narcotine	58·3 mgm.	63·5 mgm.
Papaverine	23·7 mgm.	29·8 mgm.

papaverine and narcotine was shaken with $N/10$ hydrochloric acid and ammonium reineckate solution (2 per cent) for about ½ hr., using a mechanical shaker. Filtration through a fritted glass filter (medium porosity) yields papaverine reineckate on the filter pad, which is afterwards determined colorimetrically at 525 mμ, and a filtrate containing the narcotine. The red-coloured chloroform from the filtrate is separated from the aqueous layer and shaken with aqueous silver nitrate (1 per cent). The clear chloroform layer is separated and evaporated, yielding colourless crystals of narcotine (even from opium) which are determined by non-aqueous titration using perchloric acid in acetic acid and crystal violet as an indicator.

Large Periods in Polyethylene: the Origin of Low-Angle X-ray Scattering

Most crystalline polymers exhibit discontinuous X-ray diffraction effects at small angles indicative of a structural discontinuity of about 100 A., which appears to be a basic feature of these materials[1]. In spite of much research in this field, there is no fully satisfactory explanation of this phenomenon. In our present work an unexpected possibility of interpretation has presented itself.

The linear polyethylene 'Marlex 50' was crystallized by cooling a hot solution in xylene. Plate-like crystals were obtained with habits varying between that of regular lozenges and dendrites[2,3]. The thinnest parts were about 100 A. thick, thickening taking place by a stepwise accretion of new layers of the same thickness resulting in spiral pyramids[3]. The c-axes (molecular chains) were found to be perpendicular to the surface of the plates. It was concluded in ref. 2 that the molecules must fold sharply back on themselves to be accommodated in the layers. Accordingly, the thickness of the first layer and that of successive steps would correspond to the distance between successive folds along the molecule. A regular stacking of such layers is expected to give a diffraction effect at small angles. This assumption was tested.

At first a 1 per cent solution of 'Marlex' was crystallized at 68° C. By filtering, a crumbling porous tablet was obtained. The wide-angle X-ray pattern revealed that this material was randomly oriented and fully (or at least very nearly) crystalline. At low angles the pattern consisted of at least four rings which were identified as the first four orders produced by a periodicity of 120 A. These results show: (*a*) We have real Bragg reflexions, a point often debated in the past because of the absence of higher orders in earlier experiments. (*b*) The effect is not produced by an alternation of amorphous and crystalline regions as usually envisaged. (*c*) The magnitude of the periodicity corresponds to that of the thickness of the layers and steps visible under the electron microscope[3].

In another preparation the same polymer was crystallized from a 0·01 per cent solution at 68° C. The crystals were plate-like, similar to Fig. 4 in ref. 2. On slow filtering they formed a compact film. Wide-angle X-ray patterns showed that the film as a whole was oriented, with the c-axes perpendicular to the plane of the film. Thus the plane of the crystal plates must be parallel to the film surface. This evidently results from the crystals sedimenting horizontally. The low-angle pattern again revealed a periodicity of 120 A. Once again four orders were distinguishable. These reflexions were in arcs, corresponding to planes parallel to the surface of the film. (This is in close analogy with paraffins.)

In view of this agreement both in magnitude and orientation it can be stated that the discontinuous low-angle scattering effects are produced by the layer structure within the single crystals. The latter is interpreted by us as resulting from the regularity of chain folding[2], and accordingly the low-angle diffraction would record the periodicity of the folding. This implies that the unit cell as usually defined by the chemical repeat period is only a subcell, the real unit cell extending over the full length of the fold.

Strong continuous diffraction was also present within the first discontinuous maximum. In the second type of specimen this had the same direction of orientation as the discontinuous diffraction, but with a still more sharply defined orientation than the latter. This continuous scatter is likely to be due to the individual crystals themselves, the whole stack of layers scattering incoherently. The better orientation is possibly due to the fact that the crystals themselves always lie flat while the top layers within them can be rolled up[3].

Experiments were also carried out on two types of samples which reflect the orientation within the spherulites. One of these was extruded polythylene possessing the 'row structure'[4], the other was nylon 6,6 solidified while flowing out from an extruder[5]. In the first sample the direction perpendicular to the extrusion corresponds to that along the radius of a spherulite[4]; in the nylon sample it is the direction along the extrusion which corresponds to the spherulite radius[5]. In both cases the usual, but strong, discrete low-angle scatter was equatorial with respect to the spherulite radius as identified above. (This same conclusion was reached by Point[6] with another type of specimen.) Thus when single crystals aggregate into spherulites the original layering must become parallel to the radius of the spherulite. This is consistent with the picture of the fibrillar units responsible for spherulite formation being built of curled-up single crystals[3].

In its present form our explanation does not directly account for the discontinuous low-angle X-ray scattering in drawn polymers. As the corresponding spacings are of the same magnitude as in the undrawn samples one would expect the same structural feature to be responsible for it. It is possible that a small proportion of the original crystals turn with their c-axes in the draw direction without an unfolding of the chains. (This appears to be supported by the big reduction in the scattering intensity on drawing; unpublished experiments.) Another possibility is that the location of the fold is preserved when the molecules are drawn out in a way which cannot be specified at the moment.

Our thanks are due to Prof. F. C. Frank for many helpful discussions.

Membrane Currents in Clamped Vertebrate Nerve

Placing nerve membrane in the feed-back arm of an operational amplifier allows one to see what current is needed to make the membrane follow a change in voltage across it. Such a measure, termed 'voltage clamp', has been used for the giant axon of the squid by Hodgkin and Huxley[1]. Their exhaustive study showed several specific non-linear ionic conductances the behaviour of which accounted for the properties of the excited membrane. Whether all irritable tissues show qualitatively the same pattern and use the same ions is yet unknown, since Hodgkin and Huxley's essay has been unique. We have now succeeded in devising voltage clamps for both the node of Ranvier and the cell body.

The first experiments were done with single, isolated motor-nerve fibres of *Rana pipiens* in springtime and at room temperature. These fibres were dissected from sciatic–gastrocnemius preparations following the method described by Tasaki[2] and Stämpfli[3]. The isolated node was laid across a window cut in a 1-mm. (outside diameter) polyethylene tube through which flowed Ringer solution. The tube was separated by air gaps from glass slips on which lay the two adjacent nodes, N_1 and N_3, bathed in artificial intracellular fluid and even cut open to reduce the impedance of the path to the interior of the middle node N_2. External shunts along the internodes were minimized by first bathing the preparation in isotonic sucrose and then playing a gentle air jet on the internodes after the gaps were made. A block diagram of both the mechanical and electrical systems is shown in Fig. 1. Our amplifiers were direct-coupled to the preparation through head stages emitting a current of less than 10^{-14} amp. and showing an impedance to earth better than 10^{14} ohms for direct current, and dropping to 10^{8} ohms at 10 kc./s.

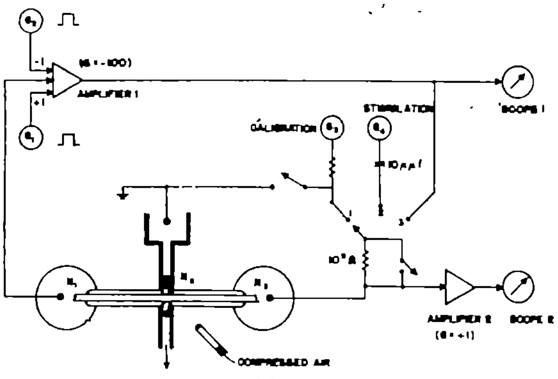

Fig. 1

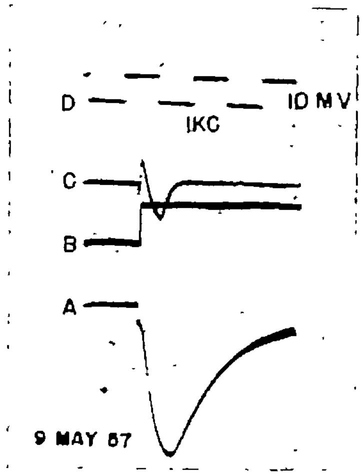

Fig. 2

It seems that the monophasic action potentials which can be recorded from isolated nodes are of two sorts, one showing a smooth fall-away from the peak, the other a marked downward inflexion somewhere in the falling phase. This inflexion can occur sufficiently late to give a trapezoidal appearance to the spike, very like that seen in records from heart muscle. At present, we feel that these two shapes are connected with two different patterns of current flow under the voltage clamp. In the first case (Fig. 2) there is a spike, 2*A*, characterized by a smooth and nearly exponential fall of potential away from the peak. With a sudden depolarization of the magnitude shown in 2*B* (inverted during clamping by the feed-back) we see the current transient, 2*C*. This appears to be a pulse of active inward flow of current which is turned off fairly sharply. The rapid decay of this inward current is to the base-line, indicating that little if any flow is required thereafter to keep the membrane at the new potential. There is not the slightest sign of an active outward current corresponding to the active potassium ion flow in the squid. Such behaviour, true for all levels of depolarization in this

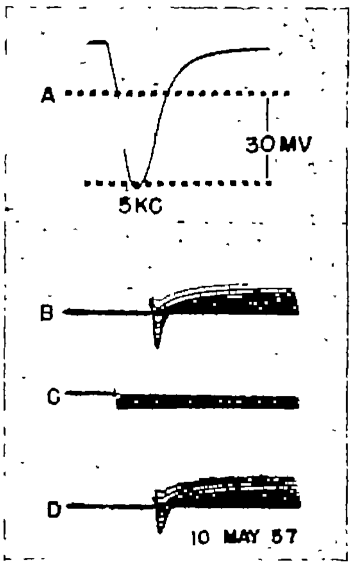

Fig. 3

possibly injured node, holds also for depolarization up to 20 mV. in nodes of the following sort.

In the second case (Fig. 3) the spike, 3*A*, shows a clear doubly inflected decline from the peak. The membrane was clamped to a family of voltage steps, cathodal in 3*B*, anodal in 3*C* and cathodal again in 3*D*. The maximum steps were the same for both polarities. Here, during cathodal clamps at increasing levels of depolarization, all superimposed to show the trend rather than specific quantitative relations, an active initial inward current changes rapidly into an active outward current, and the whole configuration resembles grossly that recorded from the squid axon save for the time-scale. Inward current reversals occur during large enough voltage steps, as is shown in the top record of 3*B*.

These results have been submitted prior to a longer study not only to show the feasibility of a voltage clamp on nodes but also to indicate at least two sorts of behaviour in isolated nodes.

Paramyosin Elements in Lamellibranch Muscles

In a recent communication[1] it was reported that the ribbon-shaped filaments of paramyosin, isolated from the smooth-muscle fibres of molluscs, closely resemble in their submicroscopic structure the 'crystals' of a tropomyosin which is present in these muscles in very large amounts[2-4]. This implies that paramyosin ribbons contain tropomyosin, that their fine structure is due to their content of this protein, and that 'paramyosin', which until now has been defined only in structural terms[5,6], may in fact be identical with tropomyosin.

These suggestions raise several important questions, one of which concerns the function of the tropomyosins which occur not only in smooth molluscan muscles but also in all the other main types of muscles. In the molluscan muscles, however, one of the tropomyosins is present in exceptionally large quantities. As it happens, very little is known about these muscles. For example, the location of the paramyosin ribbons and the general structure of the muscle fibres have not yet been described; nor is it known where the actomyosin[7] is situated. Clearly such information is needed before one can consider a possible mechanism of contraction. As a beginning we give here a preliminary account of studies on (*a*) the structure of the muscle fibres and (*b*) the location of the water-insoluble tropomyosin. We have used the white parts of the adductor muscles of the following lamellibranch molluscs: ***Mytilus edulis***, ***Ostrea edulis***, ***Gryphaea angulata***, ***Pinna nobilis*** and ***Mercenaria mercenaria***.

Mechanical disintegration of the muscles releases paramyosin elements in the shape of long flat ribbons[5], and at first sight it is difficult to see how these fit into the intact fibre, for it is known[6] that in a transverse section through a muscle all the filaments are approximately circular in shape. But further work on sectioned fibres has now shown that all their filaments have a complex and variable banded structure which can be related to that of the isolated paramyosin ribbons, and that the muscles contain no other elements from which paramyosin ribbons might be derived. Moreover, in accurate transverse sections many of the filaments show a series of regularly spaced parallel lines, and this suggests that they are made up of ribbon-shaped 'sub-filaments' stacked with their surfaces apposed. We conclude that in the intact muscle paramyosin is located in filaments in the fibres, and that all the filaments contain paramyosin.

Between the filaments in the sectioned fibres there is only a relatively small quantity of material, and this does not seem to be arranged in any organized manner. The material has the appearance of irregularly shaped strands which lie approximately parallel to the fibre axis. Existing methods for extracting structural proteins from these muscles remove both actomyosin and tropomyosin[3,7]. Therefore it is not feasible to study the location of either protein by examining extracted muscle fibres. The quantities of these proteins are not accurately known either, but there appears to be more tropomyosin than actomyosin[7]. Thus it is quite possible that actomyosin is located between, rather than within, the filaments. This point cannot be clarified by examination of actomyosin precipitates as these are amorphous[7].

The structural similarity between isolated paramyosin ribbons and 'crystals' of water-insoluble tropomyosin naturally suggests that this protein is located in the filaments; and its quantity[3,7] is too great for all or most of it to lie outside them. Therefore it was surprising to observe in two different types of experiments that isolated paramyosin filaments do not dissolve in hypertonic potassium chloride solutions at neutral *p*H, that is, in solutions which efficiently extract tropomyosin from the muscle[3,7]. The isolated filaments, which are visible in a phase-contrast microscope, do not appear to dissolve when the preparation under the microscope is irrigated with potassium chloride solutions (of any concentration) at *p*H 7·0 or 7·4 (phosphate buffer). Similarly, filaments are still visible in their usual abundance in the residue of a muscle brei which has been extracted several times, or even left overnight in a hypertonic potassium chloride solution. In the electron microscope, banded ribbons with an axial period of 145 A. can still be found. In many of these experiments it was confirmed that normal quantities of protein had been extracted from the brei and that typical tropomyosin 'crystals' were precipitated from the extract.

These experiments did not exclude the possibility that material is removed from the paramyosin ribbons; the results demonstrate only that the ribbons are not destroyed during the usual procedure for the extraction of tropomyosin.

In other experiments it was found that an alkaline (or acid) potassium chloride solution, for example, Weber's solution (μ 0·7, pH 9·1), rapidly and completely dissolves the paramyosin ribbons. After tropomyosin had been extracted thoroughly from the muscle brei at neutral pH, a further protein fraction was removed with Weber's solution, and this second fraction was found to be precipitated at about μ 0·15 in the form of needle-shaped 'crystals'. Dr. H. E. Huxley examined these 'crystals' and found that they have the same structure as those of water-insoluble tropomyosin.

All these experiments indicate that some tropomyosin can be left behind in the paramyosin ribbons when the muscle is extracted with neutral hypertonic potassium chloride solutions. The results therefore strengthen our original suggestion that water insoluble tropomyosin is located in the paramyosin ribbons of lamellibranch smooth muscles. Structural evidence indicates that the ribbons are sub-units of the filaments in the intact fibre. It now remains to be shown if these filaments also contain actomyosin, and if tropomyosin is involved in the contractile mechanism. A full account of the structure of these muscles will be published elsewhere.

One of us (J. L.) acknowledges the financial support of the Nuffield Foundation. We are very grateful to Dr. K. Bailey and Dr. H. E. Huxley for many useful discussions. Dr. Huxley has also helped with electron microscope techniques, and he, together with one of us (J. H.), first observed the fine structure of the filaments in sections of *Mercenaria*.

An Unsuspected Factor which influences Consumption of Alcohol by Rats

A few years ago a study was made in this Department of the role of alcohol in the production of fatty livers and cirrhosis[1] in rats. The conclusion was drawn that the hepatotoxic effect of long-continued consumption of non-intoxicating amounts of ethanol was negligible under the experimental conditions. Several repetitions and extensions of the work, which we hope to report elsewhere in the near future, have confirmed the conclusion. In the course of attempts to overcome a technical weakness in the earlier study, namely, some uncertainty as to the exact amount of dilute alcohol consumed daily by the rats, a device was developed by one of us that permits accurate measurements of the liquid drunk by the animals. This so-called 'Gillespie drinking fountain', which has now been in use in our rat-colony for about five years, catches any spillage and reduces losses by evaporation to a small known amount (about 300 mgm. or less per day).

Recently, as part of the study, an experiment dealing with self-selection of drinking fluids was undertaken. Measurements were made of the daily consumption of water and dilute alcohol (15 per cent v/v) by 25 rats when offered a choice. Most of the rats drank water almost exclusively. A few, however, seemed to show a marked preference for alcohol. A few rats drank some from each fountain. These observations seemed of interest in view of the nutritional or genotype explanations for alcoholism proposed by Mardones *et al.*[2-4] and by Williams and his colleagues[5,6]. Deficiencies in the ration appeared unlikely to be the cause of the 'alcoholism' of these rats since the diet was as 'complete' as we could make it. Hence a genotype defect, or 'inborn error of metabolism', seemed a possible explanation.

Suddenly, most of the 'alcoholic' rats became 'teetotallers' and some of the others began to consume considerable alcohol. This result was so surprising that it was at first considered probably to be due to an error in recording. When it was repeatedly observed, however, and its reality proved by analysis of the liquids in the fountains, another explanation had to be sought. The mystery was solved when it was noticed that the relative positions of the food-dish, water-fountain and alcohol-fountain controlled, to an astonishing degree, the drinking pattern of some of the rats. The positions of the dispensers were therefore varied deliberately over an 82-day period and the consumption of food, water, alcohol and total calories was noted daily. Only five rats were uninfluenced by the arrangement of the fountains. Thus in the case of 20 rats out of the 25, position of the fountains seemed to affect and in a few cases to control the 'preference'. Two of the rats actually did appear to like alcohol; they drank moderate amounts of it regardless of the arrangement of the fountains. Nine animals seemed rather definitely to prefer water.

The amount of dilute alcohol consumed per day never exceeded 21 ml. and for any one rat did not average more than 7·5 ml. per day. However, with one arrangement an average value as high as 16·7 ml. was attained. The same rat with other arrangements averaged 13·5, 1·7 and 0·6 ml./day, respectively. The amount of energy supplied by alcohol never on any day exceeded 28 per cent of the total calorie intake and usually was less than 20 per cent. The rats never appeared stuporous. The average daily intake of total calories tended to remain relatively constant. When alcohol was consumed the food intake usually fell.

We cannot present a fully satisfactory explanation for the influence of the position of the fountain on the intake of alcohol; but we have noticed two facts that may be significant. Most of the rats lift the automatic-closing lids of the fountains with one paw and use it to hold the lid up while drinking. Many rats also show a preference for the drinking fountain that is in an uncrowded location.

Possibly our colleagues interested in animal psychology and behaviour might suggest that these observations raise the question of right- or left-pawed preference in rats. Perhaps many of the animals prefer to drink in comfort. The fact remains that neither dietary deficiency nor 'genotype' was concerned in most of the cases of 'alcoholism' observed in the twenty-five rats given a choice of dilute alcohol or tap-water to drink, since the 'disease' was 'cured' by changing the positions of the fountains.

This communication is to provide a warning that the size and shape of cage and the arrangement of self-selection dispensers may exert a strong influence on the apparent 'preference' of rats. Details of the work will be published shortly.

The Quadratic Relation in Differential Growth

IT was shown[1] that the growth in width of the abdomen of the female pea crab, *Pinnotheres pisum*, did not show simple allometry[2], but a continuously variable allometric relation, relative to carapace width. For purely empirical purposes a general polynomial relation was fitted to the two measurements[1], but the quadratic proved a very good 'fit' and it was later pointed out (Reeve, E. C. R., personal communication) that no appreciable improvement was effected by fitting higher powers of the polynomial. It is possible, therefore, that the relation between abdomen-width (y) and carapace-width (x) may be defined, not only adequately but also significantly, by the simple equation $y = a + bx + cx^2$, where a, b, c are constants for any particular abdominal segment, and are parameters for the abdomen as a whole[3].

It seems worth considering possible implications of this relation, should it prove to have more than empirical significance. The second differential of y with respect to x is a constant: $d^2y/dx^2 = 2c$, which implies a constant-differential acceleration of growth between the two measurements. At first glance this might seem to have little biological meaning, but supposing that the rate of protein synthesis, and therefore of growth, should be related to the amount of a critical growth-promotor or catalyst present in the cell, for example, possibly pentose nucleic acid[4], then the acceleration of growth should be related to the rate (velocity) of synthesis of this promotor, and therefore a constant differential acceleration of the two measurements could be due to a constant differential pattern of synthesis of pentose nucleic acid in the body. This would apply equally if the two accelerations are negative, as in fact they usually are, in Metazoa; here a constant differential pattern of depletion of pentose nucleic acid, by dilution, exhaustion, etc., is visualized.

Polynomial relations have already been advocated from time to time. A logical merit of such a relation in differential growth is that it could be valid both for y and for the constituent parts of y, unlike the simple allometry relation and many others. Also, the second differential implies that reciprocally it would be equally valid to express x as a quadratic in y. It has been shown further[3,5] that a simple quadratic is technically useful, permitting various integrative algebraical exercises, aimed at defining shape and form as continuous functions of space and time. Other potentialities of the relation need not be considered here. Other examples of continuously variable allometry have been recorded and both these and other examples of differential growth might usefully be tested for a quadratic relation. Where two compared measurements are of different orders of dimension, a more complex relation would be expected and it is important to reduce them to the same dimensional order before testing for the quadratic (or any other) relation.

The limitations and dangers of the mathematical approach to growth are appreciated, but on the other hand no possibly fruitful relation can be neglected. Mathematical approaches have never failed to stimulate interest and further work.

Production of Sclerotic Granules by *Streptomyces* sp.

THIRUMALACHAR[1] has proposed a new genus *Chainia* of the order Actinomycetales in honour of Prof. E. B. Chain, of the Istituto Superiore Sanità, Rome. The chief distinguishing character of the genus is the formation of sclerotic granules, 16–75μ in diameter, on glucose peptone medium. *C. antibiotica*, the only species described by him, has a branching non-septate mycelium without true aerial mycelium and spores.

Sclerotic granules were observed in a strain of *Streptomyces griseus* isolated from soil at Lethbridge, Alberta, Canada, during my investigations on an anti-fungal antibiotic produced by this organism. These granules developed abundantly on trypticase soy agar (Baltimore Biological Laboratory, Baltimore, Maryland) when the organism was streaked on the plates and incubated at 25° and 37° C. for 36 hr. On this medium no aerial mycelium and spores are produced. In granule formation a hypha thickens and other hyphae start surrounding it, resulting in the development of a brownish-green mass of sclerotic tissue which eventually becomes black. In the early stages a hyaline circular sheath can be distinguished around the sclerotic granule but eventually the sheath ruptures and it appears as if the sclerotic mass is surrounded by a sheath of black radiating hyphæ. Some of these sclerotic granules coalesce in pairs, and sometimes in threes, producing a big granule up to 75μ in diameter. The small isolated granules range in diameter from 12 to 45μ.

Sclerotic granules were also produced on trypticase soy agar plates streaked with *S. griseus* strain A.T.C.C. No. 10137 and incubated for 72 hr. at 25° C. The granules in this case were morphologically different from those of the strain isolated from Lethbridge soil as they were more or less circular. No sclerotic granules were produced by *S. antibioticus* A.T.C.C. 8663, *S. lavendulae* A.T.C.C. No. 8664, *S. scabies* St. Catharines No. VI–3a–3 obtained from the Bacteriology Division, Science Service, Canada Department of Agriculture, Ottawa, Ontario, and *S. venezuelae* obtained from the Prairie Regional Laboratory, Saskatoon, Saskatchewan. Aerial mycelium with spores but without sclerotic granules was produced when the *S. griseus* strain isolated from Lethbridge soil was grown on glucose peptone medium, potato dextrose agar, 'Bacto Tryptone' glucose agar and 'Bacto Sabouraud' maltose agar. On 'Bacto Endo' agar and 'Bacto' nutritive caseinate agar neither aerial mycelium with spores nor sclerotic granules were produced.

When the sclerotic granule-producing strains of *S. griseus* A.T.C.C. No. 10137 and the one isolated from Lethbridge soil were streaked on media containing trypticase and phyton (components of trypticase soy agar) separately no granules were produced. This indicates that, at least with these two strains, both the constituents should be present in the same medium for the production of sclerotic granules.

In the light of these investigations it will be seen that the production of sclerotic granules can occur in strains of *Streptomyces griseus* and that there is no justification for creating the new genus *Chainia* on the basis of the production of these structures.

Sarcocystis sp. in the Red-legged Partridge, *Alectoris rufa*, and the Pheasant, *Phasianus colchicus*

A RED-LEGGED partridge, *Alectoris rufa*, was sent to this laboratory from Norfolk for post-mortem examination. It was an old cock which had died of a heavy infestation of *Syngamus trachea*, but it was also parasitized with a species of *Sarcocystis*.

The main sites of infection were the superficial pectoral muscles, which were obviously streaky, dehydrated and aerated. The structure of the individual muscle fibres had broken down, and many cysts could be seen under low magnification. They were oval and measured 100–165μ × 60–110μ, with a laminated wall, and contained large numbers of crescent-shaped spores, some of which were degenerating.

Erickson[1] records species of *Sarcocystis* (Sporozoa ; Sarcosporidia) from eight orders of birds. The only gallinaceous host is the domestic fowl, from which v. Ratz (1908) recorded *S. horvathi* in Hungary, and Krause and Goronoff (1933) recorded *S. gallinarum* in Bulgaria. Other records from fowls are Kuhn, 1865, and Haines (quoted in Stiles), 1894. Only the first article is available to me here.

A similar infection with cysts of the same size and appearance was seen five years ago in a wild pheasant, also from Norfolk. Once again, the superficial pectoral muscles were affected.

Occasional cases of mallard, infected with *S. rileyi* have been seen, but this would seem to be the first time *A. rufa* and *P. colchicus* have been recorded as hosts.

Effect of Benzimidazole on Detached Wheat Leaves

DETACHED wheat leaves when floated on water retain their green colour for a few days only and are usually chlorotic within a week. During a study of the effects of analogues of nucleic acid components on detached wheat leaves we noticed that those that floated on 30–100 p.p.m. of benzimidazole retained their green colour and their capacity to support growth of leaf and stem rusts of wheat for periods up to at least one month. Other compounds reported to be analogues of essential purines and pyrimidines (barbituric acid, 2-amino-4-methyl pyrimidine, 2,6-diamino purine sulphate, thiouracil, 2-chloro-4-methyl benzoic acid at 1–1,000 p.p.m. or azaguanine and azaadenine at 50–100 p.p.m.) did not give this effect. Similarly, there was no effect with the purines, adenine and guanine, and the pyrimidines, thymine, cytosine and uracil at 50–200 p.p.m.

The action of benzimidazole in preventing the destruction of chlorophyll was further investigated. Leaves of *Triticum compactum* (var. Little Club) were detached and floated on 50 p.p.m. benzimidazole and on water. The detached leaves were kept in 6-hr. light periods of 800 foot-candles alternated with 18-hr. dark periods. The temperature was maintained at 20° C. in the light and 13° C. in the dark. Under these conditions microbial development was minimal. Respiration-rates, water-soluble nitrogen and alcohol-insoluble nitrogen were determined at intervals up to 13 days after detachment.

When the colour-value of normal leaves was rated at five and that of leaves devoid of green at zero, the colour of leaves on the benzimidazole solution remained at five for the thirteen days. The colour of the leaves floated on water was estimated at four on the fourth, two to three on the eighth, and one to two on the thirteenth day. The respiration-rate was lower on treated leaves than on those floated on water

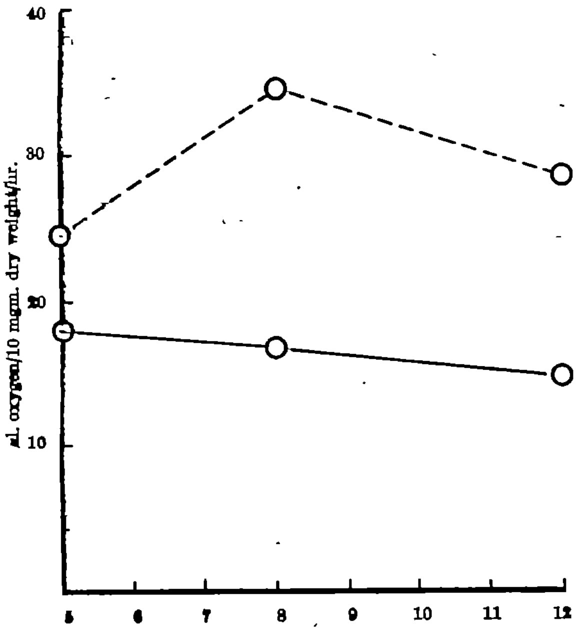

Fig. 1. Oxygen uptake of detached leaves floated on water (broken lines) and on benzimidazole (solid lines)

(Fig. 1). It is seen that the respiratory increase, which normally follows detachment[1], does not occur on benzimidazole. A similar stability in nitrogen metabolism was also observed. Fig. 2 shows that there was little change in the levels of soluble and insoluble nitrogen in the leaves on benzimidazole whereas marked changes occurred in those floated on water. The action of benzimidazole in conserving protein was also indicated by analyses with paper chromatography of the water-soluble extracts used for the nitrogen determinations. Amino-acids, and particularly the amides, were present in much smaller amounts in treated leaves than in leaves floated on water.

While benzimidazole has been shown to act as an antipurine when used on micro-organisms[2,3], there is some evidence that it may also act on other systems, particularly in higher plants[4,5]. Attempts to reverse the effect of benzimidazole on colour retention by adding normally occurring purine and pyrimidine bases, singly and in combination, were unsuccessful. Chloramphenicol, known to inhibit protein formation in phage-infected bacteria[6], neither reproduced the benzimidazole effect when used alone nor reversed the effect when used in combination with benzimidazole.

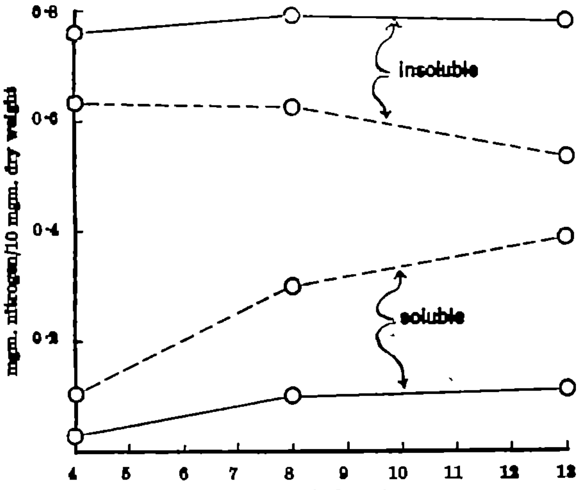

Fig. 2. Changes in soluble and insoluble nitrogen in detached leaves floated on water (broken lines) and on benzimidazole (solid lines)

In a study of protein metabolism in runner-bean leaves Chibnall[7] found that protein breakdown, normally rapid in detached leaves, was arrested following the development of adventitious roots from the cut petioles; and during the course of this study, Richmond[8] reported that kinetin (6-furfuryl-amino purine) reduced protein loss in detached leaves of *Xanthium*. We have floated detached wheat leaves on 5 p.p.m. of kinetin and found that the effect is similar to that of benzimidazole.

Since so little is known about protein metabolism in detached leaves, it is not possible to state why protein breakdown is arrested by the development of adventitious roots or by the application of these chemicals.

Variability in Retention of Marine Phytoplankton by Membrane Filters

DURING a series of experiments designed to determine the relative sizes of tropical pelagic phytoplankton labelled with carbon-14, it was noted that the retentive capacity of '*AA* Millipore' membrane filters varied considerably in three experiments as shown by retention of passed material on a fine filter (Table 1). It seemed surprising that a membrane filter with a pore size of 0·8µ would pass significant amounts of carbon-14 activity, bound in phytoplankton.

Three experiments were performed in the laboratory to determine the retention of *Dunaliella euchlora*, a phytoflagellate grown in sea-water medium, by using membrane filters of different porosities. In each experiment a 40-ml. culture was inoculated with about 10 µc. (0·9 ml.) of $NaH^{14}CO_3$, *p*H 9·7. This was incubated at 22° C. over fluorescent bulbs of 545 foot-candles. The $NaH^{14}CO_3$ was prepared according to the method of Steemann Nielsen[1]. The initial experiment (*A*) was performed with a 25-day-old culture inoculated with carbon-14 twenty-two days before filtration, which may have become bacterized. A 10-ml. aliquot of the algal suspension was removed and filtered through an '*AA* Millipore' filter (pore size, 0·8 ± 0·05µ). (Porosity figures are those supplied by the manufacturers, Millipore Filter Corporation, Watertown, Mass., and Membranfilter, Göttingen.) The filtrate was then drawn through an *HA* (pore size, 0·45 ± 0·02µ) and a *PH* filter (pore size, 0·3 ± 0·02µ). All filter membranes were finally

* c./m. = counts per minute; † *MF*, 'Membranfilter'

washed with approximately 75 ml. of *HA*-filtered sea water before drying by suction. The water thus filtered was combined with the original filtrate. The final filtrate was acidified with phosphoric acid to remove uncombined carbon-14, and an aliquot was air-dried for counting on a steel planchet. Each 'Millipore' filter was also air-dried. The activity of the filters and planchets was counted with a Nuclear Measurements Corporation proportional counter (Model *PC*–1). The results are presented in Table 1.

Experiment *B* (Table 2) differed in two respects from experiment *A*. (1) A four-day-old, bacteria-free culture was inoculated with carbon-14 five days before filtration; (2) a 3-ml. aliquot of the radioactive algal suspension was filtered through each of the filters. The filtrates from the *PH* filters were analysed for activity. In experiment *C* (Table 2) an 18-day-old, bacteria-free culture was used and carbon-14 was added two days before filtration of the 3 ml. aliquots. Dry 'Membranfilters' (Göttingen) were also tested to compare their retention of *Dunaliella*. These are rated by the manufacturer as coarse (pore size, 3·0–0·75μ), medium (pore size, 0·75–0·5μ), dense (pore size, 0·5–0·2μ), and very dense (pore size, less than 0·2μ). Filtrates from a dense filter and a *PH* filter were tested for activity.

In Table 1, it can be seen that there may be considerable variability in retention by '*AA* Millipore' filters when used in the field. (Steemann Nielsen[1] found in two experiments that virtually all activity was retained by membrane filters with a pore size slightly in excess of 1μ.) In experiments *A* and *B*, a similar variability in retention of activity exists which seems to be associated with the age of the culture. We believe that this difference in retained activity is largely due to the fragility of the labelled cells. This seems to be borne out by the independent observation of Dr. W. Rohde (personal communication) who, by visual microscopy, noticed that many naked flagellates are destroyed beyond recognition on the surface of membrane filters after filtration. Presumably this is a result of mechanical destruction resulting from filtration. The loss of activity noted with dense and very dense filters may be due to prolonged filtration periods. Such a loss was not found by Steemann Nielsen[1].

Except in the last experiment, a significant portion of the algal-bound activity passed through the *AA* filters. In the case of the *Dunaliella* experiments, the cell-size ranged from 6 to 8μ and there was no evidence of cell debris in the culture medium prior to filtration. From these experiments it is concluded that it is advisable to employ filters with a porosity of at least 0·45μ and with relatively rapid flow characteristics, when sampling phytoplankton labelled with carbon-14.

Two Species of *Trachelomonas* (Euglenineae) without Chlorophyll

In 1883 Klebs[1] published a paper of fundamental importance describing a great number of flagellates, particularly Euglenineae, and their relationships. Among these organisms there were members of the genus *Trachelomonas* which is characterized by a *Euglena*-like cell-body in an envelope encrusted with iron and manganese compounds[2]. Two of the species Klebs observed are of special interest because, in contrast with the multitude of species of this genus, they were devoid of chromatophores, have consequently no photosynthetical pigments and must have been heterotrophic.

Colourless forms are not rare in the Euglenineae[2,4]; but members of *Trachelomonas* have not generally a tendency to utilize organic nutrients. Chlorophyll-free species appear therefore to have a kind of nutrition different from the majority, and it is difficult to imagine how they can have survived the loss of their chromatophores.

Although Klebs found at least one of the colourless species of *Trachelomonas* to be not at all rare in infusions of algae, these species have scarcely been observed since. Deflandre[5] in his monograph records only one instance of the occurrence of permanently colourless trachelomonads.

I have recently found in mud gathered from a road puddle two chlorophyll-free species of *Trachelomonas* which are identical with, or very near, those observed by Klebs. One that was seen soon after the material had been brought in disappeared after a few days. Three weeks later, however, when the putrefaction caused by a boiled pea I had added to supply organic substances had diminished, and green Euglenaceae had appeared, the two colourless species of *Trachelomonas* were found in considerable numbers, first one and then the other.

These heterotrophic forms have evidently narrow ecological ranges. After a few days they disappeared again. Both are very motile, possess eye-spots and are negatively phototactic. That which appeared first has an envelope like that of the green species *T. volvocina*. It may be identical with Klebs's *T. volvocina* var. *hyalina*. The other one is no doubt Klebs's *T. reticulata* and has an ovoid reddish-brown envelope characterized by neat delicate ornamentation.

The peculiarities of the habitat in which these organisms live are difficult to define; only by growing them under controlled conditions would it be possible to understand them better; but such cultures have not been accomplished. Obviously a certain degree of putrefaction is relevant, but the two species are now identical in their ecological requirements. It is nevertheless remarkable that the only two colourless trachelomonads known were found in the same place, and together with several species of green Euglenaceae. These thrive where organic substances are broken down by bacteria, and the availability of iron and manganese reduced to the lower oxidation state and kept in solution by complex formation is probably the main factor, along with a high carbon dioxide content. This appears to be similar in the colourless forms for which, however, organic nutrients play a greater part. In no case have the conditions as yet been established in which iron- and manganese-deposits are formed by 'iron organisms', neither with flagellates[6] nor with bacteria[7]. In the case of the colourless species of *Trachelomonas* this would be of special interest.

Fractionation of Isolated Lucerne and other Triterpenoidal Saponins

THE constituent saponins of bulk triterpenoidal saponins of lucerne and certain other plant materials did not separate satisfactorily on paper chromatograms with various solvents used for other saponins[1]. It has been found that modified solvent systems or multiple development give the most promising results[2]. Ascending paper chromatography was more convenient; long running times with descending paper chromatography produced streaking with many saponins. Horizontal paper electrophoresis with weak borate buffer was also used successfully.

Ascending paper chromatography using *n*-butanol/ethanol/*p*H 9 borate buffer (1/1/1), ethyl acetate/glacial acetic acid/water[3] (11/2/2) and ethyl acetate/glacial acetic acid/water (13/3/3) were employed. Whatman No. 4 paper was impregnated with *p*H 9 borate buffer for the first solvent and *M*/5 potassium hydrogen phosphate solution for the second solvent and the papers dried in air before use. With ethyl acetate solvents multiple development was employed (five times).

Lucerne (*Medicago sativa* L.) bulk saponin, isolated by the cholesterol method[4], appears to consist of four constituents separable by paper electrophoresis using borate buffer (sodium tetraborate 9·54 gm./l.), probably seven separable by paper chromatography using *n*-butanol/ethanol/*p*H 9 borate buffer solvent and seven by paper chromatography using ethyl acetate/glacial acetic acid/water solvent. Various lucerne saponin fractions prepared by the recommended[4] ethanol–ether precipitation procedure were examined before and after deionization with 'Zeo-Karb 225' and 'De-Acidite E'. There was no apparent difference in saponin constituents between these fractions and the bulk saponin. It would thus seem that these precipitation procedures fail to bring about any fractionation.

Bulk triterpenoidal wood saponins from *Castanospermum australe* R. Br. (wood), *Emmenospermum alphitonioides* F. Muell. (wood), and *Sideroxylon pohlmanianum* F. Muell. (bark); mora (*Mora excelsa*), morabukea (*M. gonggripii*) and makoré (*Mimusops heckelii*); commercial saponin (B.D.H., Ltd.) from bark (*Quillaja saponaria* Molina) and commercial saponin white (B.D.H., Ltd.); Mexican cactus bulk saponins (triterpenoidal) from *Lemairocereus beneckei* Ehrenberg, *L. longispinus* sp. nov., *L. stellatus* Pfeiffer and *L. thurberi* Engelmann, as well as pure echinocystic acid glycoside, were examined. All bulk saponins examined proved to be mixtures of closely related substances; some were of appreciable complexity. Echinocystic acid glycoside behaved as a single substance.

Some bulk saponins behaved as single substances during paper electrophoresis, but proved to be inhomogeneous when examined by paper chromatography using the ethyl acetate/glacial acetic acid/water solvent (for example, mora group saponins). Another, when examined by paper electrophoresis, proved to be a mixture, although paper chromatography with the ethyl acetate/glacial acetic acid/water solvent failed to resolve this mixture (*Castanospermum* bulk saponin). One explanation could be that paper electrophoresis with aqueous borate buffer may indicate the number of different oligosaccharide species attached to the sapogenin, while separation achieved by paper chromatography with non-borate containing organic solvents may be due more to the differences in the sapogenin portion than in the oligosaccharide.

The nutritional effects of triterpenoidal bulk saponins[3], and especially the pronounced physiological effects that can be produced in the ruminant by bulk lucerne saponin[5], stress the need for the isolation of purified constituent saponins from lucerne, and other herbage plants, to facilitate further studies of these effects and, in particular, their role in bloat, since bloat causes considerable losses in animal production in the Commonwealth and elsewhere[6].

I wish to thank Prof. C. Djerassi, and Drs. R. Laidlaw, J. H. Simes and C. R. Thompson for generous gifts of saponins as well as Dr. L. Belič for a pure sample of echinocystic acid glycoside. I am grateful to the Agricultural Research Council for support.

Antitumour Effect of Culture Media from Tumour-Immune Spleens

The antigenic activity of tumours has been indicated by several authors using immunological or other *in vitro* methods, and also passive transfer of antitumour agents by serum injections from animals with regressed tumours[1–4].

In the experiments reported here, fragments of spleens of rats (black Walker-resistant strain, eleventh generation of brother–sister mating) were cultivated in roller tubes on glass, one whole spleen in ten 16 mm. × 160 mm. tubes with 4 ml. 50 per cent horse serum–Tyrode medium in each. Abundant outgrowth of amoeboid, giant and fibroblast-like cells was noted. The medium was collected three times a week during three weeks. Spleens were taken either from normal rats, or from rats hyperimmunized by repeated implantations of the Walker 256 tumour; this regresses in resistant rats at first implantation and does not take at further implants.

The medium was collected and thoroughly centrifuged to remove any cells released from the cultures, and then injected without storage on the days of collection in ten doses of about 5 ml. intraperitoneally. The recipients were Wistar rats implanted intramuscularly on the day of the first culture medium injection with Walker 256 tumour-cell suspension. The suspension was prepared overnight by means of an electromagnetic stirrer from tumour fragments at 4° C. in phosphate-buffered saline. In each experimental set every rat was implanted with an equal dose of live tumour cells (estimated by the method of unstained cells count[5]). The doses were about 6 million cells per rat in the first experiment, 1 million in the second, and 8 million in the third.

Table 1

Treatment: culture medium from		No. of rats with tumours	Deaths up to 42 days after tumour implantation		Range of survival (days)	No. of regressions after treatment
				(Per cent)		
I	Normal spleens	5	5/5	100	19–36	0
	Immune spleens	7	4/7	57	28–46	0
II	Normal spleens	8	6/8	75	24–75	0
	Immune spleens	7	2/7	29	37–73	2
III	Normal spleens	9	8/9	89	19–46	0
	Immune spleens	9	4/9	44	25–47	3
Total	Normal spleens	22	19/22	86	19–75	0
	Immune spleens	23	10/23	43	25–73	5

The results of three independent experiments are summarized in Table 1.

Our experience has shown that, as a rule, six weeks is the life-span of susceptible rats implanted with the tumour used. For this reason the number of deaths up to the 42nd day was chosen as a standard for the influence of the treatment. The rats used in these experiments are commercial Wistar, not inbred for the susceptibility to Walker 256 tumour; some individuals from this source can live with the implanted tumour considerably longer without any treatment. Even typically resistant individuals can be selected from this strain, the immune serum of which inhibits the growth of the tumour if injected to tumour-bearing rats (unpublished results). We conclude that the animals in our experiments, which are capable of relatively high spontaneous defence, are those which were cured by the addition of active principle from immune spleens cultivated *in vitro*.

The production of antibodies against bacterial and protein antigens in cultures of immune spleens has been repeatedly demonstrated[6,7]. This was not done, within our knowledge, with tumour antigens, though an inhibition of tumour explants grown together with immune spleen was observed[8].

These results show that passively transmissible antitumour factors are present in a culture medium of tumour-immune spleens. It is not decided here whether the active substance(s) are produced in the cultures as a continuation of the process initiated *in vivo*, or simply extracted from the cultivated spleen fragments. Elucidation of this, the isolation of the active principle, and a trial of active immunization of spleen cells *in vitro* against tumour antigens are being investigated.

Development of Multiple Cysts and of Hæmorrhagic Affections of Internal Organs in Albino Rats treated during the Embryonic or New-born Period with Rous Sarcoma Virus

In contrast to other malignant animal tumours, such as the Ehrlich adenocarcinoma of mice, the Croker mice sarcoma or the Brown–Pierce rabbit epithelioma, which could be transplanted to the embryos of white rats in serial passages[1], the tissue of the Rous chick sarcoma could only exceptionally be grown under such conditions. However, in many rats grown from embryos inoculated with minced tissue of the Rous sarcoma we have detected[2] multiple cysts. The observations recorded here reveal that white rats are highly susceptible to the Rous sarcoma virus administered both during embryonic life and the first two days of postnatal life.

A thoroughly minced dense suspension (about 50 per cent) of the Rous sarcoma of a young chick was injected under the skin of the back of each embryo of a laparatomized pregnant white rat, 5–1 day prior to birth in a dose of 0·1–0·25 ml.

6–45 days after inoculation, and eventually at a later date, multiple cysts develop in rats originating from the inoculated embryos, in the cervical region and/or in the region of the groin and axillary lymphatic nodes, eventually in other places as well. Usually the cysts appear in 2–3 week old rats. Such multiple cysts have developed in 74 out of 123 rats originating from embryos inoculated with the Rous sarcoma, that is to say in more than 50 per cent[3] (Figs. 1, *A*, *B* and *C*).

These are thin-walled cysts filled with a fluid which contains about 20,000,000 lymphocytes and about 4,000,000 macrophages per ml. At more advanced stages of development the erythrocyte number in the fluid is appreciably increased. The cysts grow in size more or less rapidly, eventually up to 7–10 or even 20 ml. capacity, resulting in death of the rats. The total nitrogen content of the cell-free cyst fluid averaged 450 mgm. per cent and protein nitrogen 320 mgm. per cent. The wall of the cyst consists of rat fibroblasts and of a small amount of collagen fibres. It is infiltrated somewhat with lymphocytes while eventually large numbers of mast cells may appear. Horse serum protein administered to the cyst-affected rats is readily revealed in the cyst fluid through precipitation with the anti-horse rabbit serum.

Susceptibility of the rat embryos to the virus of the Rous sarcoma decreases with age. The administration of the suspension of the Rous sarcoma to newborn rats either subcutaneously or intraperitoneally, within the first 48 hr. of life, likewise results in the development of multiple cysts, but they appear late and in a smaller percentage of cases than after administration to the embryos.

In some rats inoculated with Rous sarcoma both during the embryonic and new-born period there develop, at various periods following inoculation (sometimes late), vesicular-hæmorrhagic affections of the lungs with a hæmorrhagic exudate in the pleural cavity, and eventually hepatic affections with a pronounced jaundice. These affections are less frequent than the cysts. Sometimes they are combined with the latter and eventually appear in rats with no cysts at all.

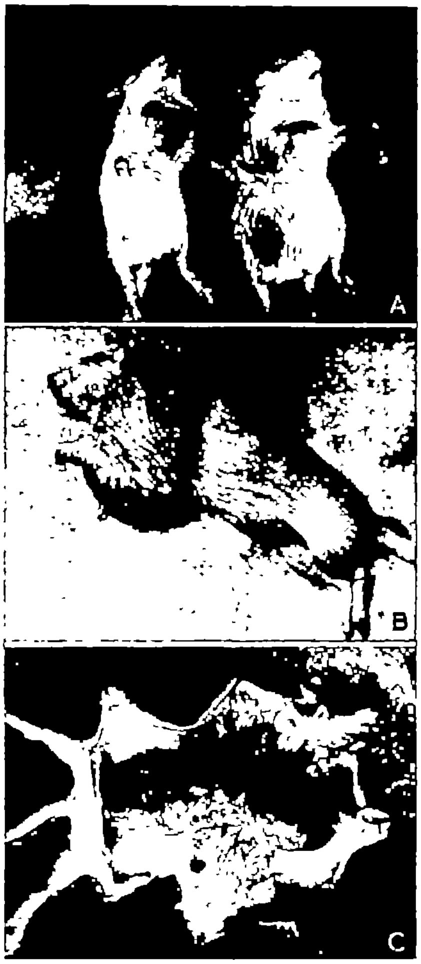

Fig. 1. *A*, Multiple cysts in the cervical region and in the region of the groin and axillary lymphatic nodes in 21-day old rats, inoculated during the embryonic life. *B*, Large cysts of the cervical and axillary region of a 30-day old rat. The cyst appeared on the fifteenth day of life. *C*, A dissection of the cyst of the cervical region

The virus of the Rous sarcoma is present in the cyst membrane: inoculation of the minced membrane of the cyst to chicks resulted in development of a typical Rous sarcoma 31–40 days after the inoculation.

No cysts develop at the site of injection of the suspension of the Rous sarcoma to embryos or newborn rats. Moreover, in those single cases where they do develop at the site of injection heterotransplants of the chick Rous sarcoma multiple cysts appear after resorption of the transplant.

In no case did we note any cysts or affection of the internal organs after injection of rat embryos with suspensions of normal tissues of the chick, rabbit or man, nor of other malignant tumours (Crocker's sarcoma, Ehrlich's adenocarcinoma or Brown–Pierce epithelioma). All the experiments were carried out on rats of the same batch free of spontaneous neoplasms.

All these facts show that the pathological processes at issue are caused by the virus of the Rous sarcoma.

Cyst formation in rats as caused by the above virus changes suggests a comparatively restricted specialization and peculiarity of pathogenic action of these tumour-inciting viruses.

The foregoing results might presumably be related to the hæmorrhagic disease as caused by the Rous sarcoma in chick embryos[3] being associated with vascular affections.

It is likewise possible that the mechanism of cyst formation approaches to a certain extent normal morphogenetic processes in animals. The morphogenetic correlations of the terminating period of embryonic development may keep under a certain control the cells reproducing under the influence of the virus of the Rous sarcoma, and this may be one of the causes of cyst development. The question is thus raised as to the possible role of viruses in the genesis of some kinds of cysts in humans.

Treatment of Cancer in Dogs by Intravenous Methylene Blue

THE appearance of a report by Holman[1] on the apparently destructive effect of orally administered hydrogen peroxide on rat tumours has prompted me to set on record my own experiences.

Since 1941 numerous cases of neoplasia in dogs have been brought to my small-animal clinic, often in advanced stages of the disease. Generally, biopsies were performed and the nature of the tumour established histologically. Standard treatment involved the intravenous administration of a 2 per cent aqueous solution of methylene blue in doses of 2–10 c.c., repeated on alternate days or at weekly intervals. When practicable, the whole or greater part of the primary growth was removed surgically.

Methylene blue treatment appeared to be without effect on the slowly growing tumours and on carcinomas, but gave encouraging results in the rapidly growing sarcomas, particularly where most of the primary growth could be removed. In such cases the use of the dye was followed by necrosis and sloughing of remaining tumour tissue and complete healing of the wound. A number of cases are in good health and have survived without apparent recurrence of the tumour for up to five years, although at the time of treatment the growth was doubling itself in size every fortnight. Thus, there is evidence that early metastatic conditions may be successfully treated, but where internal organs are extensively affected, dye administration is prone to produce an acute toxæmic state.

There seems to be no doubt that the intravenous use of methylene blue can be a most valuable adjunct to surgery in the destruction of primary sarcomatous growths, and perhaps also of early secondary growths, but the mechanism of its action can only be surmised. In the light of Holman's observations it seems possible that methylene blue, which can function as a hydrogen acceptor, may interfere with the catalase–hydrogen peroxide system and that tumour cells are more sensitive to this kind of metabolic disturbance than normal tissue cells. I do not, of course, claim that methylene blue is necessarily the most effective agent for achieving this effect, but hope that my experience may have helped to identify a weak link in the metabolic processes of the tumour cell and may arouse the interest of investigators better equipped to attack this problem.

Attempted Control of Ectromelia in a Mouse-breeding Colony

A REVIEW of intercurrent ectromelia infection in mouse colonies in Great Britain has been made by Tuffery[1]. During April 1955 a virulent form of the disease became manifest among all three main strains, *R III*, *A* and *CBA*, bred in this laboratory. The establishment and growth of transplantable tumours *in vivo* and *in vitro* concurrently deteriorated, and a connexion with the outbreak of the disease was suspected. In consequence, a programme of vaccination with calf lymph was instituted, as suggested by Lane-Petter[2]. This communication records the results of this procedure carried out over a period of two years.

A satisfactory technique was scarification of a small region on the dorsal surface of the tail with a sterile scalpel dipped in calf-lymph vaccine—diluted five times with McIlvaine's citric acid phosphate buffer at pH 7·0 at a concentration of one part to forty-six of distilled water. The vaccinated mice were checked after six days for the typical scab and swelling denoting a positive reactor to the vaccinia virus.

Initially all mice in the colony were vaccinated, but owing to the demands of experimental programmes it was not possible to cull all negative reactors. Breeding mice were replaced as soon as possible by positive reactors and all negative reactors were culled when a sufficient number of positive reactors became available for experimental purposes. All five-week-old mice have now been vaccinated for a period of two years. Fig. 1 illustrates the average monthly

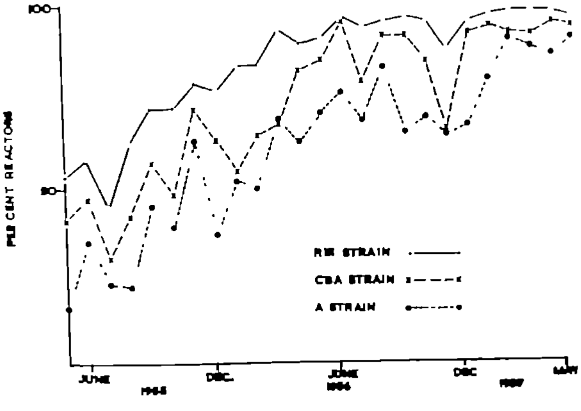

Fig. 1

proportions of reactors in the three strains over this period. The numbers vaccinated weekly were 200–350 in the *R III* strain and 30–60 in the *CBA* and *A* strains. The incidence of the disease prior to vaccination showed a correlation with the initial proportions of reactors in the three strains. The establishment and growth, *in vivo* and *in vitro*, of the transplantable tumours maintained in these strains improved considerably soon after the commencement of vaccination.

The results of this extended programme of vaccination suggest that the control of ectromelia can be accomplished in a breeding colony by this technique. It is suggested that once the proportions of reactors approximate 100 per cent, vaccination of breeders only should be necessary to maintain a high degree of control.

A Technique for obtaining Clone Cultures of Soil Amœbæ in Sterile Liquid Medium

On previous occasions free-living and parasitic amœbæ have been obtained free from their associated bacteria by sterilization of the cysts either by washing in bactericidal chemicals[1,2] or in antibiotics[3,4]. The technique I have used for isolating clones of soil amœbæ and growing them in sterile peptone solution involves the treatment of the trophozoite stage with antibiotics, making use of the fact that the amœbæ are more tolerant to many antibiotics than are certain bacteria.

The complete isolation procedure was as follows: A soil sample taken from 1–2 in. below the surface was mixed with distilled water and, after allowing the larger debris to settle out for 2–3 min., the supernatant was poured in a thin film on to a nutrient agar plate. Nutrient agar for this and subsequent platings was made up of 1·5 per cent agar and 0·5 per cent peptone in distilled water. After incubating the soil-washing plate for 10–12 days at 27° C. many cysts of 10–20μ in diameter could be seen together with bacteria, fungal hyphæ and debris.

The contents of this plate were then washed into a centrifuge tube and the cysts largely freed from bacteria and hyphæ by repeated centrifugation and resuspension in sterile distilled water.

A drop of water containing cysts was placed on a slide and single cysts selected and removed with the aid of a Zeiss micromanipulator. A ×10 eyepiece and a ×10 objective were found to be the most convenient for the manipulator microscope. Each cyst was transferred to the centre of an *Aerobacter aerogenes* streak on a nutrient agar plate. *Aerobacter* was selected because it is non-motile and is a good food source for soil amœbæ[3]. Thirty such transfers were made and after incubating them at 27° C. for 10–15 days twenty-one of them had formed large colonies of amœbæ.

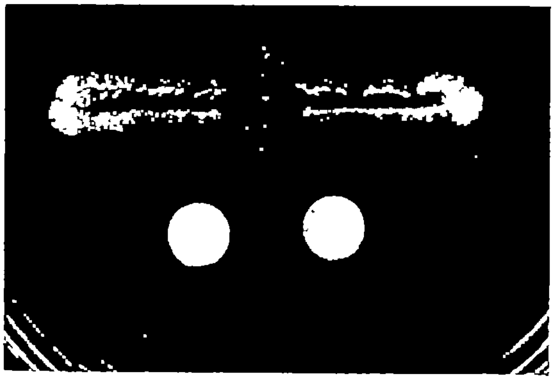

Fig. 1

Upon examining these cultures it could be seen that many trophozoites had migrated out on to the agar and many of these were found to carry a small clump of bacteria at their 'posterior' end. It appeared that any bacteria from the original cyst washing which were transferred in the pipette along with a cyst had been diluted out and suppressed by the *Aerobacter*. Accordingly, antibiotics having the maximum effect on *Aerobacter* were selected. Streptomycin, terramycin and erythromycin gave satisfactory results.

A sterile wire loop was then used for transferring some of the amœbæ from the outlying area on to a second *Aerobacter* streak prepared as before. This plate was incubated at 27° C. until the amœbæ had begun to move on to the surrounding agar, usually after 2–3 days, at which point filter-paper disks ¼ in. in diameter and containing 10 μgm. of an antibiotic were placed approximately ¼ in. apart and ¼ in. from the streak (Fig. 1). Two disks containing different antibiotics were placed on each plate.

After incubation of these plates for a further 24 hr. a ring of amœbæ could be seen around and at a little distance from the disk at what was presumably the region of the antibiotic gradient corresponding to their maximum tolerance. Two days later the amœbæ could be seen close to the disks.

A small piece of agar from the region between the disks was then cut out with a sterile wire loop and transferred to a McCartney bottle containing sterile 4 per cent peptone solution. After incubation for 20 days, eleven out of the twenty bottles used were found to contain dense cultures of amœbæ. Various kinds of peptone have been used in liquid media, of which the most satisfactory was 'Oxoid' mycological peptone at a 4 per cent concentration in distilled water. Although the addition of autoclaved *Aerobacter* to the peptone solution increased the growth-rate appreciably it was not essential for growth in any of the clones isolated. It was also found unnecessary to add antibiotics to the medium. Growth was considerably inhibited when penicillin (200 units per ml.) and streptomycin (1,000 units per ml.) were added.

The most convenient vessels for maintaining cultures are wide-mouthed McCartney bottles, which, with 10 ml. of solution, will support a culture density of 4–8 × 10^5 amœbæ per ml.

Standard sterility tests have been carried out and the results indicate a truly axenic culture. The procedure has been repeated on subsequent occasions with similar results.

A preliminary investigation has indicated that most of the clones belong to the genus *Hartmanella*[5], and a fuller inquiry, together with the isolation of clones from different habitats, is being carried out.

I wish to thank Dr. J. C. Gould, of the Bacteriology Department, University of Edinburgh, for his advice concerning antibiotics, and Prof. M. M. Swann and Mrs. K. M. G. Adam for their help and discussion.

Ultra-thin Serial Sectioning with Rocking Microtomes

A well-known difficulty in using rocking microtomes for ultra-thin sectioning is the tendency for the cut section to be picked up on the return stroke. A number of mechanical devices have been described[1] which attempt to overcome this. The device described here is a non-mechanical and exceedingly simple but effective aid to serial sectioning.

A No. 1 hypodermic needle is cut off a quarter of an inch or so from the hilt and bent to hook over and into the trough attached to the cutting knife. The hilt is provided with a rubber teat and reconnected to the hook with a suitable 'Polythene' or other tube. The whole is then filled with the liquid normally used in the trough, say, 10 per cent acetone, and the hook suspended on the trough edge, the tip inside. The trough is then filled with liquid to just below the knife edge, a level normally inadequate for sectioning. The level can now be brought to the optimum for section cutting by pressing on the teat for the cutting stroke of the microtome, while by releasing the teat the liquid level can be reduced to prevent the section being picked up on the upward stroke.

Incidental points in the construction are the *S*-bend made in the 'Polythene' tube to improve its accommodation to the various positions of the knife, which would be unnecessary if a more flexible rubber tube were used, and a clamp attached to the knife-holder to keep the tube in position.

Uniform serial sections, showing the silver or gold interference colours associated with the thinnest sections, can be cut without great difficulty from blocks with the relatively large surface area of 1 mm. × 0·5 mm., while smaller blocks can be cut serially *ad lib.* and with ease.

Response of the Ceric–Cerous System at High Dose-Levels of Cobalt-60 γ-Rays

The radiation yield value of cerous ion in the irradiation of ceric solutions has recently been given as 2·45 ± 0·08 for cobalt-60 γ-rays[1]. This is somewhat lower than figures which have formerly been accepted. In a recent determination of the value of $G(\mathrm{Ce}^{3+})$ at high dose-levels, I have obtained a result which confirms the lower value. This value of $G(\mathrm{Ce}^{3+}) = 2{\cdot}36 \pm 0{\cdot}12$ molecules/100 eV. was obtained by working in the dose-range 0·1–1 megarads at a dose-rate of $1{\cdot}4 \times 10^5$ rads/hr.

The ceric ammonium sulphate solution used was made up in triply distilled water to a strength of 4,000 μmoles/l. in cerium, the solution being made 0·8 *N* in sulphuric acid ('Analar'). The water used was distilled twice over alkaline potassium permanganate. The ceric ammonium sulphate was used without further purification, and as supplied by G. F. Smith Chemical Co., Columbus, Ohio.

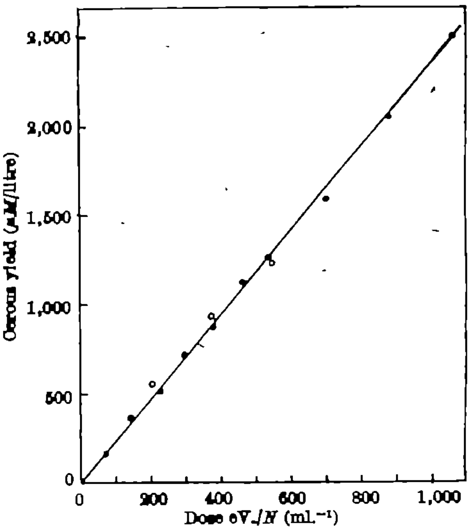

Fig. 1

The solution was irradiated in a four-kilocurie cobalt-60 source in 15-ml. bottles placed in standardized positions. Dose-rates were measured in the standard positions by filling the same bottles with ferrous sulphate solution, and measuring spectrophotometrically the concentration of ferric ion produced. A $G(\mathrm{Fe}^{3+})$ value of 15·6 was assumed. In this way, errors due to attenuation in the 15-ml. bottles were avoided. Analysis was carried out by potentiometric titration with ferrous ammonium sulphate solution in 0·8 *N* sulphuric acid. 5-ml. samples were titrated using a Willard–Baldyreff electrode system[2], each titration being duplicated.

The graph shows that within the limits of error the response of the ceric/cerous system is linear up to one megarad eV./*N* (ml.⁻¹).

FORTHCOMING EVENTS

(*Meetings marked with an asterisk * are open to the public*)

Monday, December 9

Institution of Electrical Engineers (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Where Should Research End and Development Start?" opened by Dr. K. J. R. Wilkinson.

Society of Chemical Industry, Plastics and Polymer Group (at 15 Belgrave Square, London, S.W.1), at 6.30 p.m.—Prof. H. Batzer: "Experiments on, and Theory of, Formation of Fibres".

Tuesday, December 10

Institution of Civil Engineers (at Great George Street, London, S.W.1), at 5.30 p.m.—Mr. K. H. Clare, Mr. M. J. Tomlinson, Mr. I. K. Nixon and Mr. B. O. Skipp: Symposium on "Airfield Construction on Overseas Soils".

Institution of Mechanical Engineers, Automobile Division (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6.45 p.m.—Discussion on "Air or Water Cooling?"

Wednesday, December 11

University of London (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 2 p.m.—Dr. H. Harris: "Biochemical Genetics".*

Physical Society, Colour Group (in the Physics Theatre, Imperial College of Science and Technology, Imperial Institute Road, London, S.W.7), at 3.30 p.m.—Mr. L. C. Jesty: "Report on the Meeting on Colour Television, Paris, 1957"; Dr. W. S. Stiles, F.R.S.: "Report on the Symposium on Visual Problems of Colour, Teddington, 1957"; Prof. W. D. Wright: "Report on the C.I.E. Working Party on Colorimetry, Teddington, 1957".

Geological Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. W. B. Harland: "The Caledonian Sequence in Ny Friesland, Spitsbergen".

Buckland Foundation (at the Sir John Cass College, Jewry Street, Aldgate, London, E.C.3), at 5.30 p.m.—Dr. A. P. Orr: "The Fertile Sea—From Plankton to Fish".

Eugenics Society (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Dr. J. S. Weiner: "The Settlement of Europeans in Extreme Climates".*

Institution of Electrical Engineers, Radio and Telecommunication Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. H. E. Holman, Mr. G. C. Newton and Mr. S. F. Quinn: "A Flying-Spot Film Scanner for Television".

British Glaciological Society (at Bedford College, Regent's Park, London, N.W.1), at 6 p.m.—Annual General Meeting. Mr. G. Manley: "Snow, Glaciers and Climate".

Institute of Physics, London and Home Counties Branch (at 47 Belgrave Square, London, S.W.1), at 6 p.m.—Dr. B. H. Briggs: "Irregularities and Movements in the Ionosphere".

Society of Chemical Industry, Food Group—Nutrition Panel (at 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Second Meeting on "Some Nutritional and Allied Problems Confronting the Food Manufacturer". Dr. C. H. Lea: "Technological Aspects of Antioxidants"; Mr. R. J. Ward: "Biochemical and Pharmacological Aspects of Antioxidants".

Institution of Mechanical Engineers, Lubrication Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6.45 p.m.—Discussion on "Reclamation of Lubricants".

Institute of Metals, London Local Section (joint meeting with the London Branch of the Institute of British Foundrymen, at the Constitutional Club, Northumberland Avenue, London, W.C.2), at 7.30 p.m.—Mr. F. Hudson: "Properties of Castings".

Radar Association (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 7.30 p.m.—Mr. L. D. Bedford: "Some Aspects of Guided Missiles".

Wednesday, December 11—Thursday, December 12

Iron and Steel Institute, Iron and Steel Engineers Group (at Church House, Westminster, London, S.W.1)—Meeting on "Water Pollution in the Iron and Steel Industry".

Thursday, December 12

Royal Institution, Library Circle (at 21 Albemarle Street, London, W.1), at 5.30 p.m.—Mr. K. D. C. Vernon: "The Re-organization of the R.I. Library".

Royal Institute of Chemistry, London Section (at the Northern Polytechnic, St. John Street, London, E.C.1), at 7 p.m.—Mr. A. R. Powell, F.R.S.: "Recent Advances in the Chemistry and Technology of the Rare Earth Metals".

Chemical Society (at Burlington House, Piccadilly, London, W.1), at 7.30 p.m.—Scientific Papers.

Royal Society of Tropical Medicine and Hygiene (at Manson House, 26 Portland Place, London, W.1), at 7.30 p.m.—Dr. J. F. B. Edeson: "The Experimental Transmission of *Wuchereria malayi* from Man to Various Animals in Malaya".

Friday, December 13

Biochemical Society (at the Institute of Basic Medical Sciences, Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C.2), at 11.30 a.m.—Scientific Papers.

Institution of Electrical Engineers, Education Discussion Circle (at Savoy Place, London, W.C.2), at 6 p.m.—Discussion on "Basic Experiments on Servo Mechanisms", opened by Mr. W. Chellingsworth.

Institution of Mechanical Engineers (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Dr. Ing. Hans Thoma: "High Pressure Hydraulic Transmission" (James Clayton Lecture).

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. King: "A Debt to Defects".

Friday, December 13—Saturday, December 14

British Psychological Society (at University College, Gower Street, London, W.C.1)—Conference.

Saturday, December 14

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Mr. Douglas Botting: "Socotra: The Island of Dragon's Blood".*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Head (graduate of a British university with appropriate teaching, industrial and research experience) of the Department of Science and Metallurgy, Constantine Technical College, Middlesbrough—The Director of Education, Woodlands Road, Middlesbrough (December 14).

Lecturer to teach Science Subjects, including Applied Science and Nutrition—The Principal, College of Bakery, Catering, Domestic Science and Associated Studies, Bridge Street, Birmingham 1 (December 14).

Reader (with high academic qualifications and special experience of analytical techniques) in Analytical Chemistry—The Clerk to the Governors, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (December 14).

Scientist (graduate with a biochemical background), for work mainly on amino-acid tolerance tests—The Secretary, Institute of Neurology, Queen Square, London, W.C.1 (December 14).

Teacher, Grade B (with an honours degree and able to take the subject to degree standard), in Mathematics—The Director of Education, The Polytechnic, 309 Regent Street, London, W.1 (December 16).

University Demonstrator (with an honours degree or post-graduate qualification in an appropriate subject, and preferably some teaching experience) in Agricultural Entomology—The Secretary, School of Agriculture, The University, Downing Street, Cambridge (December 20).

Assistant in the Department of Zoology—The Secretary, The University, Edinburgh (December 28).

Senior Lecturer (with a good honours degree, teaching experience, and wide industrial experience related to instrument engineering and/or electronics) in Physics—The Registrar, Flintshire Technical College, Connah's Quay, near Chester (December 31).

Lecturer (with a special interest in mycology and plant pathology) in Botany at the University College of Ghana—The Secretary, University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (January 3).

Professor of Animal Husbandry; and a Lecturer in Veterinary Medicine at the Veterinary College, Dublin—The Secretary, Civil Service Commission, 45 Upper O'Connell Street, Dublin (January 7).

Chair of Zoology—The Registrar, The University, Sheffield (January 11).

Research Chemist (with a university honours degree in science with chemistry or biochemistry as a major subject, or equivalent qualifications, and preferably research experience in physical chemistry) at the Irrigation Research Station (C.S.I.R.O.), Merbein, Victoria, Australia, to carry out investigations into the dipping, drying and processing of vine fruits with special reference to problems of diffusion kinetics in the transfer of water through organic membranes such as the waxy coating of the grape—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 490/62 (January 11).

Chair of Social Anthropology in the Department of Anthropology, University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, January 18).

Assistant Lecturer (with a degree or diploma in horticulture) in Horticulture—The Registrar, Massey Agricultural College, Palmerston North, New Zealand (January 31).

Lecturer (with experience of research in organic, inorganic or physical chemistry, or in an appropriate branch of physics) in Colouring Matters—The Registrar, The University, Leeds 2 (February 22).

Assistant Physicist (with good academic qualifications in physics and mathematics) in the Unit of Clinical Investigation, Royal North Shore Hospital, Sydney, Australia—Dr. C. W. Wilson, Physics Department, Westminster Hospital Medical School, London, S.W.1.

Biochemist, Senior or Basic grade (with a B.Sc. degree with honours in chemistry or biochemistry or equivalent qualification)—The Group Secretary, Royal Hospital, Wolverhampton.

Electron Microscopist in the Biological Laboratories, Harvard University, to collaborate in research with members of the department—The Chairman, Electron Microscope Committee, Biological Laboratories, Harvard University, Cambridge, Mass., U.S.A.

Entomologist (with a natural science degree from a British university and preferably a knowledge of tsetse, particularly *Glossina morsitans*) in the Veterinary Department of Northern Rhodesia, for duties involving tsetse surveys and identification of species; field observation on seasonal distribution and habits of tsetse flies, particularly *Glossina morsitans*; and duties in connexion with the control of the species—The Director of Recruitment, Colonial Office, London. S.W.1, quoting BCD.67/408/015.

HEAD (with high academic qualifications in mathematics, with teaching and research or industrial experience, and preferably specialized in statistics and/or numerical analysis) OF THE DEPARTMENT OF MATHEMATICS—The Principal, Technical College, Queen Street South, Huddersfield

JUNIOR TECHNICIAN/TECHNICIAN (preferably with an interest in biochemistry) IN THE CLINICAL PATHOLOGICAL LABORATORY—The Secretary, The National Hospitals for Nervous Diseases, Queen Square, London, W.C.1.

LECTURER (with teaching and research experience, preferably in applied entomology or soil zoology) IN AGRICULTURAL ZOOLOGY—The Registrar, The University, Nottingham.

MATHEMATICAL PHYSICIST or MATHEMATICIAN (capable of carrying out independent research without supervision) to join a research team engaged in studying point defects in metals with special reference to radiation damage—Prof. J. G. Ball, Metallurgy Department, Imperial College, London, S.W.7.

MICROBIOLOGIST and a CHEMIST (with a good honours degree in an appropriate branch of natural science, and preferably with at least two years suitable postgraduate experience or training) IN THE DEPARTMENT OF AGRICULTURE, Federation of Nigeria, to carry out team research into the improvement of soil and crops under high rainfall conditions—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.63/14/046.

PHYSICIST, Senior grade (with an honours degree and appropriate previous experience in hospital physics), IN THE RADIOTHERAPY DEPARTMENT, which includes an Isotope Laboratory—The Group Secretary, Oldchurch Hospital, Romford, Essex.

RESEARCH ASSISTANT (preferably with some biochemical knowledge), to work on experimental pathology problems—The House Governor, The London Hospital, Whitechapel, London, E.1.

SENIOR BIOLOGY MASTER—The Headmaster, King's College, Taunton.

SENIOR LECTURER IN THE CHEMISTRY DEPARTMENT—The Bursar, Royal Agricultural College, Cirencester

SENIOR SCIENTIFIC/SCIENTIFIC OFFICER (with a first or second-class honours degree in physics or metallurgy and some research experience), to carry out basic research on the alloying behaviour of radioactive metals—The Senior Recruitment Officer, Atomic Weapons Research Establishment, Aldermaston, Berkshire, quoting Ref. A/1421/34.

STATISTICIAN (with a good honours degree in mathematics or statistics), for biometrical research and consultation in the Section of Statistics—The Secretary, National Institute for Research in Dairying, Shinfield, Reading, quoting Ref. 57/9

NEW STATISTICAL BOOKS

THE MATHEMATICAL THEORY OF EPIDEMICS

NORMAN T. J. BAILEY, M.A.
Reader in Biometry, University of Oxford.

A valuable survey with main emphasis on the biometrical and epidemiological rather than the purely mathematical. Relevant to many of the problems encountered by Public Health Authorities, medical officers, biologists, and research workers. Just out 36s. net

"GRIFFIN'S STATISTICAL MONOGRAPHS & COURSES"

Edited by M. G. KENDALL, Sc.D.
Professor of Statistics in the University of London.

A new series of moderately priced books on subjects of special interest. Further important titles in the press.

No. 1 ANALYSIS OF MULTIPLE TIME-SERIES
M. H. QUENOUILLE Just out 24s. net

No. 2 A COURSE IN MULTI-VARIATE ANALYSIS
M. G. KENDALL Just out 22s. net

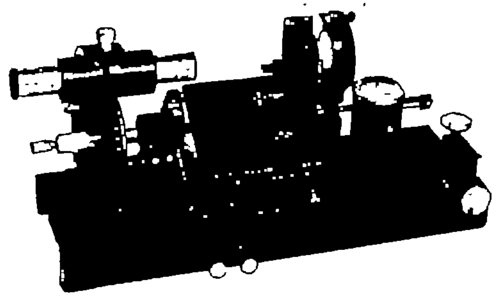
PRECISION INSTRUMENTS

Fabry-Perot Interferometer



Although of very simple design, this instrument is suitable for much of the work usually carried out by more elaborate and costly apparatus, and reads directly to 1/250 mm. It can be supplied with an attachment to convert to a Michelson Interferometer, thus giving a dual purpose instrument.

Price Complete	£190 0s.
Attachment for converting instrument into Michelson Interferometer, extra	£45 0s.
Polished wooden case, extra	£9 10s.

ANGLO-AMERICAN RELATIONS IN THE NUCLEAR AGE

MORE than five years ago, Dr. J. B. Conant, in the Stevenson Lecture for 1952, discussed frankly the broad question of Anglo-American co-operation in the modern world. The successful launching by the U.S.S.R. of two Earth satellites is only one of a series of developments that has since convinced the United States as well as Britain that the security of the free world is not to be found in the achievements of individual countries, but rather in a more effective co-operation which avoids duplication of effort and waste of precious resources of trained man-power and materials. The case of J. R. Oppenheimer three years ago brought to the front a new conception of national security, and raised questions regarding the co-operation of scientists with government and the organization of security to which clear answers are still being sought. Later that year, indeed, in one of his Reith Lectures, Sir Oliver Franks discussed some of these problems. The Supreme Court's judgment in three cases on civil liberties last June dealt a blow to McCarthyism which should at least facilitate closer Anglo-American co-operation and understanding, just as in Britain the Government statement on January 29 and the earlier statement of March 1956 on the findings of the Conference of Privy Councillors on Security should help to establish confidence in both countries in the effectiveness of the British security system, and in the care taken to reconcile the needs of public security and the claims of the individual.

Moreover, there has been during these years an able exposition in the United States of the dynamic conception of security by such men as H. S. Commager, R. M. MacIver, R. M. Hutchins and others, and the Geneva Conference on the Peaceful Uses of Nuclear Energy resulted in a marked advance in the release of information in a field where secrecy has hitherto hampered scientific advance as well as technical development. The opening of the world's first nuclear power station at Calder Hall in October 1956 showed that in technological development, as well as at the frontiers of science, Britain has much to contribute. Even in the field of defence, there has been a substantial exchange of information between Britain and the United States in such fields as guided missiles. In July 1954, Mr. Duncan Sandys, then Minister of Supply, assured Parliament that the arrangements made for co-operation should enable both countries to make the most productive use of their available scientific and technical resources in this field and help to accelerate the development and introduction of the missiles urgently needed for common defence. After visiting Washington early this year, now as Minister of Defence, he told Parliament on February 6 that, after reviewing the arrangements previously made for collaboration in military research and development, with particular reference to guided rockets, it had been decided to extend still further the common work.

It is against this background that the statement which the Prime Minister made in Parliament on October 29 regarding his visit to the United States and Canada with the Foreign Secretary, and the Declaration of Common Purpose issued by Mr. Macmillan and the President of the United States at the end of their talks in Washington, must be considered. The main purpose of the Declaration was to establish the principle of interdependence of the countries of the free world, and the Declaration affirms that only in genuine partnership, by combining their resources and sharing tasks in many fields, can progress and safety be found. "For our part, we have agreed that our two countries will henceforth act in accordance with this principle."

The Declaration affirms that the two countries regard their possession of nuclear-weapon power as a trust for the defence of the free world, and that they plan to discuss their ideas as to collective security with all their partners and to reinforce such efforts by co-operative economic effort. The plans for developing a European Free Trade Area in association with the European Common Market are welcomed. It is also recognized that, especially in the less-developed countries, there should be a steady and significant increase in standards of living and economic development.

In his statement in the House of Commons, Mr. Macmillan said that the two Governments would seek to secure the participation of all their allies, and the support of other free nations, in a common partnership. The Canadian Government had expressed itself as ready to subscribe to the principle of interdependence and to join in the common effort to make it effective. Neither the Prime Minister, even when specifically questioned by the leader of the Opposition, nor the Declaration, as circulated in *Hansard*, referred to the announcement in Washington on October 24 that two study groups had already been set up by the President and the Prime Minister. To the Strauss–Plowden Group was assigned the responsibilities of making recommendations in the field of nuclear relationship and co-operation. The Powell–Quarles group was asked to make recommendations in the field of military defence, particularly those problems dealing with missiles and rockets.

Replying to Mr. Gaitskell, who, with reason, seized on the exchange of scientific information and the provision of much closer collaboration as the most valuable feature of these talks, Mr. Macmillan pointed out that full interchange of information between Britain and the United States already existed on the peaceful uses of nuclear energy, but he hoped that the Declaration would extend such co-operation and bring all our friends and allies, especially in the North Atlantic Treaty Organization, into full partnership. Whether a complete exchange of scientific information in the latter Organization is to become possible depends on the willingness of Congress to meet the President's wishes.

The Joint Parliamentary Under-Secretary of State for Foreign Affairs, Lord Gosforth, replying for the Government in the debate on the Queen's Speech in the House of Lords on November 7, could give no detailed information about the exchanges in progress. He realized the difficulties inherent in the Atomic Energy Act, 1954, but Britain has been assured that the Declaration is one of substance. Lord Stansgate, who asked the question, had pointed out that the Atomic Energy Act, 1954, was a very lively party political issue in the United States, and it was by no means certain that the President would receive the support he desired.

The debate in the House of Commons added little to the Declaration and the Prime Minister's accompanying remarks. Speaking on November 5, Mr. Macmillan commented that the American people are no longer confident that even their great country could do everything itself without allies to secure its own survival, still less the survival of the ideals for which they stood. The days of national self-sufficiency have gone, and we have in the Declaration the first common agreement that the free world can no longer afford to waste its resources in skill and money, but must make its joint effort truly co-operative.

The implications of the Declaration have still to be worked out, as the Prime Minister in fact recognized, and they were to some extent indicated by Mr. Duncan Sandys on November 7. Mr. Sandys pointed out that, although there has already been a good deal of collaboration between the two countries, it has been limited largely to the exchange of information and has not prevented wasteful duplication of effort, both in research and production. Moreover, we have reached the point where in practice the Atomic Energy Act, 1954, tends to frustrate agreements to collaborate in almost any field, because practically every modern weapon of importance now carries a nuclear warhead. Even unrestricted exchange of information is not enough. To make full use of our resources of brain, skill, experience and experimental facilities, we must go so far as practicable in planning and executing a common, rationalized programme of research and development, within which each country must undertake tasks and responsibilities in accordance with its capacity, and each must assist the other to the utmost in carrying them through.

Before considering what is involved in the formulation, let alone the execution, of such a programme, even in its scientific and technical aspects, it is as well to recall the fundamentals which Dr. Conant and Sir Oliver Franks stressed. Although McCarthyism has lost some of its force, secrecy is still an important issue, and the modification of the Atomic Energy Act, 1954, may well depend on whether the U.S. Senate is satisfied that the American secrets will be safe with her partners. Now, as Dr. Conant observed, if we are to help the United States in this matter, especially towards the adoption of that positive conception of security which her own leaders have formulated so ably, we must try to understand conditions in the United States, and counsel rather than scold. Co-operation will be the smoother the more scientists, academic men and government officials are able to operate in a framework which is similar in both countries. Furthermore, the conditions most favourable to creative work and scientific advance do not vary as national frontiers are crossed.

Sir Oliver Franks, in his Reith Lectures, gave much the same counsel, pointing out further that, even on major issues, there would have to be give and take between the partners, that Britain must be more articulate about her policies, and also be careful to demonstrate her ability to perform. We cannot be content to rest on the Calder Hall achievement since those lectures were delivered, and it is as well to examine more closely some of the consequences for our whole economy, as well as for our scientific and technological effort, if the hopes of the Declaration are to be realized.

First, it should be noted that this matter affects the whole of Britain's scientific and technical man-power ; it concerns the universities and technical colleges as well as Government establishments and industry. Mr. Chuter Ede sought to make a party political point, but he and Mr. Callaghan were quite right to remind the House of Commons that the question of Anglo-American co-operation in science and in defence is inseparably related to education. Resources of scientific and technical man-power are determined, both qualitatively and quantitatively, by the character of the educational system and the manner in which it is geared to a country's needs and traditions.

This needs to be remembered in considering how far the structure of the scientific and technological institutions and the organization of research in Britain are appropriate to the needs of to-day. What needs particularly to be stressed at this juncture is that educational systems are not usually exportable ; differences in organization and emphasis are inevitable between those of Great Britain and the United States, if each is to give the best service to its own community. But there is no virtue in difference for difference's sake, and care might well be taken to make the British outlook and ideals readily understandable in the United States. How important this can be is readily seen in the storm that arose earlier this year over security checks in so far as they involved university teachers. In discussing the personal inquiries which have been made of university tutors, among others, regarding candidates for Government posts involving access to classified material bearing on the security of the State, the Council of the Association of University Teachers scarcely gave sufficient weight to the very real security problem.

Such an unrealistic attitude is unhelpful and at the present time could easily hinder the establishment of that confidence in the security practices and policy of Britain which is an essential preliminary to the modification of the Atomic Energy Act, 1954. The point is one which is not easily over-stressed, and scientists and technologists as well as other professional men should take particular care to see that security issues are not raised or discussed in a manner calculated to raise doubts as to British good faith or efficiency in so vital a matter. Further, by the consistent exposition of the positive conception of security to which the National Science Foundation gave admirable expression in its last annual report, they could contribute also to the formation of a climate of opinion calculated both to encourage the smooth operation of the unofficial checks and balances which are usually more effective than official action, and the vision, sense and vigilance which are the ultimate safeguard. It might well be worth while exploring Dr. Conant's suggestion of a Joint Anglo-American Commission to examine the security issue, if indeed that could not be better done by the academic alliance he also suggested.

ANNUAL REVIEW OF BIOCHEMISTRY—A PERENNIAL PROBLEM

Annual Review of Biochemistry

Edited by J. Murray Luck, in association with Frank W. Allen and Gordon Mackinney. Pp. x+768. (Palo Alto, Calif.: Annual Reviews, Inc., 1957.) 7 dollars.

THE twenty-sixth volume of the "Annual Review of Biochemistry" shows several changes. The number of chapters is reduced from twenty-three to twenty, the sections on lipid chemistry, cancer, immunochemistry, viruses, cellular particles, drugs and fungi being omitted and replaced by sections on X-ray studies of compounds of biological interest, biochemistry in the U.S.S.R., biochemistry of muscle, and clinical applications of biochemistry. In part, these changes reflect the established practice of not reviewing annually certain aspects of biochemistry. However, in this issue, the editors have announced their intention of transferring to sister volumes topics which seem more appropriate to microbiology or to plant or animal physiology. It is to be hoped that this does not mean that certain topics of interest to biochemists are to be permanently removed from this book. One pleasing feature of the "Annual Review of Biochemistry" is that it is a book for biochemists to browse in, in addition to providing an annual refresher course; it is to be hoped that this feature can be retained.

In so far as individual chapters are concerned, the editors claim to insist that reviews shall be critical appraisals and not summaries. Nevertheless, it is clear from reading this book that the style of the individual chapter is more often dictated by the state of the subject than by editorial policy. Thus, Steinberg and Mihalyi in their chapter on the chemistry of proteins have, in the space of thirty-four pages, welded together 340 references into an unusually lucid, critical and well-balanced review. The chapter is, in a sense, a tribute to those who have contributed to methods of determining protein structure, since a new approach to the vexed problem of protein purity, by considering proteins of known chemical structure, is now possible, and sections on genetic determination of protein structure, and relation of structure to function have an atmosphere of reality not previously possible. Dorfman, on the other hand, in a chapter on the biochemistry of steroid hormones has been content, for the most part, to list the many steroids formed by animals and their tissues without indicating how they are formed. Indeed, one gets the impression from this chapter that with steroids the end rather than the means to the end is the important consideration, and a thorough briefing in steroid biochemistry would appear to be an essential prerequisite in attempting to read this section.

Many authors have complained in their prefatory remarks of the vast extent of literature to be reviewed. One effect of this seems to be that critical considerations have to be so brief that they perhaps lose their value. This type of difficulty was evident in the section on carbohydrate metabolism by de Duve and Hers. This would perhaps suggest that the summary may, after all, be the best way of dealing with much of the new knowledge in those topics reviewed annually. In cases where a notable change in the subject has occurred during the year, more space could then be devoted to a comprehensive and critical account. In this connexion, in the present volume, the revision of ΔF° for hydrolysis of the pyrophosphate bond in adenosine triphosphate from 12 down to 7 kcal./mole is considered only briefly by Mahler and by Weber. One would have thought that a re-evaluation of this magnitude of one of the most important thermodynamic considerations in biochemistry would have received more than passing mention. It would be interesting to know, for example, why previous estimates have been so much in error, and how thermodynamic balance sheets such as that for the triosephosphate dehydrogenase reaction have passed the auditors in the past.

In the case of those topics which do not merit annual review, the present policy of publishing a critical type of review from time to time would seem to be admirable. In this volume, the chapters by Kendrew and Perutz on X-ray studies of compounds of biological interest and by Rimington on hæm pigments and porphyrins are excellent illustrations of what can be achieved in this connexion.

The chapter by Jakob A. Stekol on biochemistry in the U.S.S.R. seems to raise a further problem in relation to future policy. An attempt is made here to review the whole of research in animal biochemistry by Soviet biochemists in recent years. The author must be congratulated for attempting this impossible task. It was difficult not to conclude after reading this chapter that many of the papers must have suffered in translation, for several of the abstracted comments are scarcely intelligible. This was particularly true of the somewhat ideological discussion on the last page. It is to be hoped that in future volumes of the "Annual Review of Biochemistry" it will be unnecessary to review Russian biochemistry in a separate chapter, but that it will be possible to record the contributions of Soviet biochemists in the ordinary chapters of this book.

The prefatory chapter this year is by Sir Rudolph Peters and is entitled "Forty-five Years of Biochemistry". Written in a most persuasive and charming manner, it not only records Sir Rudolph Peters's recollections of personalities and landmarks in the history of the subject, but also his conclusions as to the future of the subject and the training of biochemists. The editors are to be especially congratulated on their choice of author for this particular chapter this year. PHILIP J. RANDLE

STRATTON'S *FESTSCHRIFT*

Vistas in Astronomy
Edited by Dr. Arthur Beer
Vol. 1: Co-operation and Organization, History and Philosophy, Dynamics, Theoretical Astrophysics, Instruments, Radio Astronomy, Solar Physics. (Special Supplement No. 3 to the *Journal of Atmospheric and Terrestrial Physics*.) Pp. xvi + 776. 9 guineas net.
Vol. 2: Solar–Terrestrial Relations; Geophysics; Planetary System; Stellar Astronomy; Photometry; Spectroscopy; Spectral Peculiarities and Novae; Galaxies; Cosmogony and Cosmology. (Special Supplement to the *Journal of Atmospheric and Terrestrial Physics*.) Pp. x + 777–1770. 15 guineas net.
(London and New York: Pergamon Press, Ltd., 1955 and 1956.)

THE two volumes entitled "Vistas in Astronomy" are dedicated to F. J. M. Stratton, professor emeritus of astrophysics in the University of Cambridge, "by his friends and admirers everywhere". The idea of this tribute originated with Dr. Arthur Beer, and he wrote in 1952 to a number of astronomers and geophysicists. He received in reply 192 contributions by 215 authors belonging to twenty-six different countries; the printed text occupies 1,732 pages. As its editor had hoped, the work surpasses the ordinary dimensions of a *Festschrift*: it constitutes "a generous and thorough cross-section through the whole of contemporary astronomy and the allied sciences". It imposed an enormous task upon Dr. Beer, but he has been recompensed by a well-merited success.

None is more worthy of this universal tribute than Prof. Stratton, who is one of the best-known figures of contemporary astronomy. His scientific career opened in 1906 with the publication of a paper "On Planetary Inversion". This paper was followed by many others, some of which have become the bedside companions of numerous specialists. His monographs on novæ (Nova Geminorum, 1912; Nova Herculis, 1935) remain models of their kind, and indispensable guides. They inspired in Sergei Gaposchkin, of Harvard College Observatory, a poem printed on p. 1506 of "Vistas in Astronomy", where one may read the lines:

> "And you will occupy
> In the Science of Heavens
> A perpetual niche".

Prof. Stratton is also one of the great instigators of international co-operation in science. In 1919 he participated in the meeting at Brussels when it was decided to form the International Astronomical Union, of which he was to become general-secretary during 1925–35. He has not missed a single General Assembly of the Union, and those which he organized at Leyden in 1927, at Cambridge (Massachusetts) in 1932 and at Paris in 1935 were very successful. They brought him those innumerable friendships of which he is justifiably proud and that popularity to which "Vistas in Astronomy" bears witness. It is to him that the Union owes its robust constitution and the cohesion which is its strength. With perfect tact and a profound knowledge of the behaviour of men and of nations, Prof. Stratton knows how to create about him an atmosphere of friendship and conciliation in which the spirit of co-operation blossoms naturally. He has the art of persuasion, which he exercises at a distance, adhering faithfully to the old custom of using longhand for all his correspondence: a written letter establishes far better than a typewritten one a community of thought between writer and correspondent.

When the International Union decided to create a Commission for the Exchange of Astronomers, Prof. Stratton was naturally made chairman. Thus he acquired new rights to the respect and gratitude of astronomers the world over. Nor must one forget the distinguished services which he rendered to the International Council of Scientific Unions, of which he was secretary-general during 1937–52.

Dr. Beer's plan was beautifully simple: "the purpose of the book was to present original articles and reviews, reflecting fully and critically the present situation and recent advances in astronomy and related fields . . . while the concluding paragraphs were to be devoted to a survey of unsolved questions and possible 'vistas' of future research". The length of each contribution was fixed at about 2,500 words. Naturally, some authors have followed these recommendations to the letter, whereas others have taken greater or smaller liberties with them. In fact, the length of the articles varies considerably; on average they are twice as long as the editor suggested. Since it is unlikely that anyone will read without pause, page by page, through these two large volumes, a certain variety in the form and extent of the articles presents no inconvenience to the reader; but if the foreseeable delays in publication were largely exceeded in the event, the reason lies in the unforeseen importance of the book.

The subjects treated are divided into sixteen sections: (1) co-operation and organization; (2) history and philosophy; (3) dynamics; (4) theoretical astrophysics; (5) instruments; (6) radio astronomy; (7) solar physics; (8) solar–terrestrial relations; (9) geophysics; (10) planetary system; (11) stellar astronomy; (12) photometry; (13) spectroscopy; (14) spectral peculiarities and novæ; (15) galaxies; (16) cosmogony and cosmology. It is out of the question to give an analysis here, however brief, of the contents of the different chapters, but the importance and wealth of information contained in them should be stressed. Each of the authors of the 192 monographs has discussed, according to his inclinations and temperament, a subject in which he is a leading authority. He has indicated its place in contemporary astronomy as well as its hopes for the future. Some articles are concerned with particular points, others with wider fields. It might be asked whether it would not have been advantageous to place a general article at the beginning of each section; this question presented itself to the reviewer in running through sections 12 and 13, which contain excellent studies confined, however, to specialized subjects. On reflexion it is by no means certain that the book would have gained in interest from the inclusion of such introductory articles. A third volume would have been necessary, and such heavy didactic apparatus would, perhaps, serve only to diminish in the reader the exciting impression of being launched straight away *in medias res*. Opening "Vistas in Astronomy" at random, he immediately finds there information both abundant and precise, and often hitherto unpublished; problems neatly posed; and finally, projects for research. He has thus the feeling of participating in the very life of astronomy and feeling its rhythm. Such was the stimulating effect desired by Dr. Beer, which makes the work so much more than a 'Handbuch'.

It was inevitable that a collective work, with each author freely choosing his own subject, should present some gaps. Some are undoubtedly fortuitous, but others are due to progress in certain branches of astronomy made between the preparation and publication of the articles. Dr. Beer should not regard this as a criticism but rather an invitation to produce a sequel at some future time.

The care with which the book has been printed and the skill with which the figures have been reproduced are in the best British tradition. This fine presentation is not the least attraction of "Vistas in Astronomy". ANDRÉ DANJON

PHYSIOLOGY OF INVERTEBRATES

Recent Advances in Invertebrate Physiology

A Symposium sponsored by the National Science Foundation; the Tektronix Foundation; and the University of Oregon. Edited by Bradley T. Scheer. Pp. vi+304. (Eugene, Oregon: University of Oregon Publications, 1957.) 5.50 dollars.

THIS volume contains sixteen papers that formed part of a symposium held in the University of Oregon in September 1955. It gives a well-balanced survey of selected topics which have been notably developed in recent years and most of the contributions are well written and readable.

The mechanism of the nerve axon does not come in for consideration, but the neuromuscular mechanism is discussed from different angles by several authors. The review by C. A. G. Wiersma, which ranges over the main invertebrate phyla, brings out very clearly the great differences in the observable reactions to stimuli that result from slight changes in the characteristics of neuromuscular transmission, and such differences do not fall neatly into phyla. The same lesson is to be got from the account of the nervous control of insect muscles by G. Hoyle. Here there is no evidence of the inhibitory nerves familiar in Crustacea. The conception of 'fast' axons responsible for twitch-like contractions produced by single impulses, and 'slow' axons which produce a mechanical response only when a chain of impulses passes along them, is well established. These two sorts of fibres share the same end-plates, and a single axon always supplies numerous end-plates in one fibre. It is this distributed end-plate supply which enables the insect muscle to function in the extraordinary mineral environment of the insect body fluid in which the propagated action potential of vertebrates would be paralysed.

Studies on the physiology of flight muscles in insects, described by J. W. S. Pringle, have led to a satisfying picture of the possible evolution of insect flight. A large insect develops thoracic expansions, used for gliding. They can be inclined by muscular action and later folded. More powerful muscles give them a slow flapping movement to aid flight, each contraction being evoked by a nerve impulse of conventional type. Then a 'click' mechanism develops in the thorax (it is described in full in the article by E. G. Boettiger) and this leads to a sudden release of tension in the contracting muscle, causing instant relaxation, while the antagonist that is suddenly stretched instantly contracts. It is this mechanism, evolved many times independently, which makes possible the intensely rapid wing movements of the higher insects.

It is nice to have a clear account in English by H. Mittelstaedt of the 'feed-back' mechanism which ensures the accurate capture of flies by praying mantids. This makes an interesting companion piece to the review by L. M. Passano on the recognition of prey and predators by coelenterates the co-ordinated responses of which occur in the absence of a central nervous system. 'Neurohormones' as defined by J. H. Welsh embrace both the 'neurohumors' responsible for immediate and often local reactions, and the products of neurosecretory cells which often have a prolonged hormonal action. Since the two classes of material merge into one another this is perhaps the most logical treatment.

There are many other contributions of much interest and value. For the general reader one might commend the final review by F. A. Brown, which describes the fascinating advances made by his group in recent years in defining the properties of the 'physiological clocks' by which so many living organisms regulate their lives.

V. B. WIGGLESWORTH

ELECTRO-TECHNOLOGY

Electro-Technology for National Certificate Courses

By Dr. H. Buckingham and E. M. Price. Vol. 2. (Technical College Series.) Pp. 298. (London: English Universities Press, 1956.) 12s. 6d. net.

THIS is the second volume in a series of books on electro-technology intended mainly for those students who attend the part-time National Certificate courses in electrical engineering. The general arrangement follows the same plan so that the text of each chapter not only comprises a number of fully worked examples where this is desirable, but is also supported by a set of appropriate problems to be solved by the reader. In all there are 142 well-selected problems, with answers to these in an appendix at the end of the book. The authors have included in the text a description of fifteen important laboratory experiments.

There are, however, two new features. In the first place, it is wisely based on the MKSμ_0 system of units, and secondly it contains more material than would be, or could be, covered in the *S*.2 year.

The ten chapters deal successively with units, magnetization, self-induction, mutual induction, electrostatics, generators and motors, alternating currents, resistors, reactors and capacitors, measuring instruments and illumination. There is also an appendix containing nine tables of data. The text is well illustrated with 183 figures and diagrams, with some of the illustrations depicting essential details of equipment and apparatus: a very good feature.

It is evident that this is a well-thought-out textbook based on a thoroughgoing treatment within the limitations imposed by the nature of the student for whom it is intended. Although almost all the symbols, units and abbreviations are those now generally accepted, there are still anomalies. An example of this is that although illumination is based on the candela, the foot-and-candle disease still persists, with the foot-candle as a unit of light intensity.

Few will quarrel with the quality of the contents, but many will undoubtedly consider that the authors should not have included so much material that is more appropriate to the *S*.3 year. In this way a fuller treatment and coverage could have been given to the rest.

There is a great need for text-books having a specific purpose, and in this case there is fairly general agreement as to the material appropriate for inclusion in an *S*.2 course in electrical engineering. Such text-books would have a beneficial effect on the standard of lecturing as they should eliminate or reduce the use of the chalkboard and the corresponding copying of notes by students.

In any revision of the text the author might usefully consider whether the mathematical approach is always essential as it is possible that with this type of student this may disguise or confuse the physical principles. There is some doubt whether the academic standard is not above the average reader for whom the book is intended. In particular, the approach to alternating currents could well be based entirely on the use of the rotating vector, thus leaving the trigonometrical method an applied exercise for the mathematics course.

The book is well printed on good quality paper with an attractive format and good binding. It is distinctly readable and is strongly recommended.

P. F. SOPER

VOLTAGE STABILIZATION

Voltage Stabilized Supplies

Basic Principles, Characteristics and Applications. By Dr. F. A. Benson. Pp. 370. (London: Macdonald and Co. (Publishers), Ltd., 1957.) 50*s*. net.

THIS book, as stated by the author in his preface, is based on a monograph published in 1950 and most of the material of this monograph (including ninety-three figures) is reproduced with little alteration. Additional material has, of course, been added. Like the monograph the book does not deal with electromechanical devices or with the control of generators.

A large proportion (one-third) is devoted to glow-discharge tubes and their circuits. This is to be expected in view of the author's work on this subject. It would have been helpful to include manufacturers' data on the many tubes considered and one tends to be confused by the use of *CV*-numbers for valves and tubes in one section and civilian numbers in other sections. A large number of figures and graphs are given on discharge tubes but it is difficult to come to conclusions. Explanations of the practical importance of these results and suggestions for suitable tubes for various purposes would have been helpful. A most useful chapter is included on corona discharge tubes.

The two chapters dealing with thermionic valve stabilizers would be improved by the inclusion of more design data on 250–500 V. stabilizers and by the use of modern valves and tubes in the circuits and performance calculations. It should be noted (p. 169) that a shunt stabilizer valve is available for 20 kV.

A most useful chapter is devoted to battery reference sources but the work on bridges in Chapter 10 might also have been included, with advantage, in this chapter. The next chapter deals adequately with magnetic stabilizers.

The final chapter (85 pages) deals with bridge circuits, saturated diodes and miscellaneous circuits. Fig. 205 appears to be so nearly identical with Fig. 202 as to be scarcely worth including. The chapter covers an extensive range of circuits but sections tend to read as a list of published works.

Heading of the right-hand page with the title of the chapter or subject of the page would be a great improvement.

More than a thousand references are included from numerous sources and this forms a most valuable portion of the book.

Dr. Benson has been most successful in producing a well-written, clearly illustrated and valuable book for the engineer and research worker, but not quite so successful in producing a book suitable for the student.

G. N. PATCHETT

THE SCYTHIANS

The Scythians

By Tamara Talbot Rice. (Ancient Peoples and Places.) Pp. 255+62 plates. (London: Thames and Hudson, Ltd., 1957.) 21*s*. net.

LITTLE has been written in English about the Scythians since the late Sir Ellis Minns's great works, the second of which was published in 1942. Yet these people, who appeared suddenly as nomadic folk in the plains to the north of the Black Sea and who vanished just as suddenly as a result of the incursions of the Sarmatians, extended their influence during the period of their dominance (c. 700 B.C. to c. A.D. 50) well beyond the area of their homelands, and the characteristic art they developed still remains a joy to all art lovers to-day. It is not certain where they were cradled, the most popular suggestion being the Altai steppes, but they first appear before us as horse-breeding nomads, only now and then developing a village life. They seem to have erected no temples and we know little about their religious ideas. But they attached enormous importance to the burial of the dead and their tombs are filled with the richest of funeral furniture. Naturally, for nomad peoples wandering over vast plains, the horse was of supreme importance and value, and nearly always horses were slaughtered and buried with the dead man. There is one case where no less than 400 were so destroyed. Some of these animals were not without blemish—one could scarcely expect the living to give up all their best horses for this purpose. However, they frequently did.

Mrs. Talbot Rice has written a volume on the Scythians in a new series, "Ancient Peoples and Places", which is under the editorship of Dr. Glyn Daniel. It is an exceedingly good and readable book and is exceptionally well illustrated, both with line blocks in the text and with no less than thirty-two full pages of illustrations at the end of the work. Naturally the illustrations are concerned with the art, but one or two of the line drawings are devoted to such subjects as the plan of the Kostromskaya burial and a section at the same site. The book will fill a gap, and such a work is overdue. Doubtless the specialist in the prehistory of those regions will regret many details which the size of the volume has made it necessary to omit. But the general archæologist and the interested reader will welcome Mrs. Talbot Rice's book.

M. C. BURKITT

SCIENTISTS IN SOCIETY TO-DAY*

By the RIGHT HON. THE VISCOUNT HAILSHAM, Q.C.

Lord President of the Council

I AM very glad to be the Minister of the Crown selected this year to propose the toast of the Royal Society. For the toast accords full well with all three Departments which it has fallen to my duty to administer in the past twelve months. Apart from its general scientific interests, the Admiralty is responsible by a strange historical chain of circumstances for the Greenwich Observatory, now established in the parish of Herstmonceux, a village known to me personally very well, but before the advent of the Astronomer Royal, possessing as it did in the Domesday Book "a priest and a wood for six Hoggs". The Ministry of Education, too, engaged as it is on its vast new programmes of teaching and awards in science and technology, would have formed a good jumping-off ground for proposing the toast of the Royal Society. Best of all, perhaps, is my present office, responsible for the Councils of Medical and Agricultural Research, the Department of Scientific and Industrial Research, and the Advisory Council on Scientific Policy. All these departments have their intimate connexions with science and their own reasons for wishing health and prosperity to the Royal Society, upon the talent of whose members they so very largely draw.

But quite apart from official interest, this toast accords also well with my own inclinations, and, as I see them, the needs of the moment. I have conned the speeches of my predecessors, and I find it has been their custom to stress the limitations of their humanism in a society of scientists, of which I, too, am a poor example.

But I would stress a point of contact rather than a point of difference. And I hope that in doing so I may be taken quite seriously even though my remarks may be couched in jocular and even facetious language. Both in Britain and the United States it is popular fashion to ridicule and condemn what the Americans call the 'egg-head', the man who from boyhood up deliberately and consciously pursues intellectual pursuits, whether humanistic or scientific (or, better still, both), with whole-hearted zest—an unbalanced fellow, they would say, a dreamy unpractical other-worldly sort of chap, unfit for the society of successful politicians, hard-headed men of business, simple soldiers, silent sailors or working journalists and all the other kind of folk who make such a botch of this practical world by refusing to think about the theoretical problems involved in the art of living.

To-night I can be as bold as brass. Although not a scientist, I am at least an 'egghead' by conviction and, I hope, by practice, and I am addressing a society of scientists who are also, always by achievement and almost by definition, 'eggheads'. It is time we got together. 'Eggheads' of the world, unite! We have nothing to lose but our brains. A country neglects its 'eggheads' at its peril. For it is the 'egghead' who is the greatest realist. It is the 'egghead' who invents the *Sputnik*, not the captain of football, nor the winner of the sword of honour, nor the president of the Junior Common Room. It is the 'egghead' who discovers penicillin, who splits the atom, who thinks of the printed circuit, the electronic brain, the guided missile in the world of science, and it is the 'egghead' on the other side of the academic fence who studies and produces the political and philosophical ideas which shake thrones, destroy empires or inspire millions of humble citizens to heights of self-sacrifice and devotion. It is the ordinary man who is the unpractical sentimentalist who dreams away three-quarters of his life in wish-fulfilment, phantasies, and leaves no trace on his generation but a nasty smell of peardrops. Therefore, I say let us be proud of our 'eggheadedness'. And let us join in a united protest to Downing Street and the White House demanding higher recognition. It is a formidable indictment of Western civilization and democracy that 'eggheadedness' is not valued at its proper worth.

When our protest is made and our just claims are allowed, as with a Government as good as this is clearly inevitable, let us remember to stress a further point of union. Let us resolve to bury for ever the divorce, almost the schizophrenia, which divides our present society (or at least our present society of 'eggheads') into two hostile and mutually uncomprehending camps—the classical humanism deriving its origin in the last resort from the culture of Greece and Rome, and the scientic world of Cavendish, Harwell and Imperial College. For the truth is that neither is complete without the other. No humanist is complete without an intimate understanding of the characteristics, the working and the potentialities of the techniques of our current scientific civilization. And I would say that no scientist was capable of giving his best unless he used the added perception he has acquired from his scientific studies to form a part of a cultured and humanized approach to life. If I may quote from a recent notable speech by H.R.H. Prince Philip, the Duke of Edinburgh: "The educated man can be a specialist or need not be a specialist, but the important thing is that his specialization, whatever it may be, should in no way prevent him from being, behaving, and thinking, as an educated man". If I may venture an example: your president, with whose name this toast is coupled, is not merely a distinguished professional chemist, but also a connoisseur of Chinese porcelain and a linguist who has addressed gatherings in Rome, Moscow and Paris in their own tongues.

Part of the trouble at least has lain in the fact that there are in the civilization of the West, of which we are members, not merely the classical lore of Greece and Rome, not merely the scientific culture of our own forebears and contemporaries, but also the living tradition of justice, integrity, compassion, love and service which we have inherited from another source, and some would say a source of divine origin. Neither classicism nor scientific brilliance, though the one may produce beauty, and the other uncover truth, is a substitute for virtue; nor can the divorce between the two be reconciled until both stand humbled at the shrine of love.

---

* Substance of the speech made in proposing the toast of the Royal Society at the 295th Anniversary Dinner on November 30.

But there is one more thing which we may say together in all sincerity.

In the ideological war the scientific discipline is not merely the indispensable condition of survival; it stands four square with humanism and morality on the side of freedom.

For science, to which the work of the Royal Society is dedicated, is not primarily a subject, or a series of subjects, but an attitude of mind, and specifically the attitude of mind actuating those who seek the truth for its own sake by experiment and experience without philosophical, political or even religious preconceptions, other than the belief that the truth is there to be known, and that it can be recorded and related logically to the general body of other truths similar ascertained. Science does not give a man the faculty of knowing, or the desire for freedom, the qualities of compassion or love, or the experience of God. These are part of his eternal inheritance. But the scientist is driven by his very terms of reference to seek and publish the truth with all the single-heartedness of Galahad pursuing the Grail. Though the scientist remains as vulnerable as his neighbour to political and moral error, he is yet unlikely to accept indefinitely or corporately the political or moral indoctrination of a tyrannical system of government tied authoritatively to a body of *a priori* beliefs. Whoever retains the scientist in the employment of his society or seeks to breed a race of scientists in his schools and universities, though they may for a time neglect the humanities or despise the ordered teaching of morality and virtue, will in the end create and harbour a race of men and women rebellious against the nonsensical assumptions of a political creed unbased on human experience, and unwilling to accept as part of its natural machinery the self-adjusting mechanism of rational discussion and argument. It is this which causes me to proclaim my faith and hope in the scientist. No nation dare neglect him save at great peril; for this reason the scientist can penetrate barriers which exclude the moralist and the democratic politician. He can penetrate those barriers without political motives or even while himself suffering from political delusions, but he carries the virus of freedom in the very constitution of his being, and he cannot fail to pass it on to his new neighbours.

But here in Britain the scientist is at home, though he is, in my opinion, like other intellectuals accorded too little honour in his own country. He has been at home in Britain since Charles II formed the Royal Society not quite three centuries ago. He is at home in Britain to-day and the symbol and centre of his influence is found in your Society.

In proposing the toast of the Royal Society, coupled with the name of its president, I am thus consciously proposing the toast of a great historical institution, with its roots deep in the past, but dedicated in the present to the cultivation of a living and contemporary spirit, the spirit which is at once the especial mark and glory of our current civilization as it is to some extent the occasion of some of our deadliest perils.

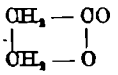
PROGRESS OF CANCER RESEARCH

The thirty-fourth annual report of the British Empire Cancer Campaign (11 Grosvenor Crescent, S.W.1) is a sizeable volume of nearly six hundred pages. The Campaign spent about £500,000 in 1956 supporting research at some thirty centres, in addition to financing more than sixty individual investigators.

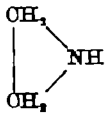
The work described in the report can be classed conveniently in three main branches. First, studies of human tumours and clinical investigation (including diagnosis, prognosis, and the evaluation of therapeutic measures); secondly, radiology, which includes physics of radiations, radio-therapy and radio-biology (namely, action of radiations on tissues, cells, macromolecules and other substances of biological interest); and finally, the largest class, which embraces: (1) Carcinogenesis and carcinogens. (2) Environmental cancer, in particular the relation between smoking and lung cancer, which is the most interesting topic in cancer research at the present time. Some experts are convinced that environmental research, which uses demography as its principal theme, is to-day the most hopeful way of attacking the cancer problem. It does not yet occupy a very prominent position in the studies catalogued in the report because very few, if any, of the young scientists qualified to take part in, say, work on nucleoproteins have any interest in, quite apart from training or capacity for, research on environmental, demographic and statistical lines. (3) Carcinogenic viruses. (4) Biochemistry of tumours; including the application of tracer compounds to the study of tumour and tissue metabolism, and the factors which affect tumour growth. (5) Enzymes. (6) Hormones. (7) Nucleic acids. (8) Cytology and cytochemistry. (9) Steroids. (10) Immunology. (11) Chemotherapy. (12) Tissue culture. (13) Genetics.

Some passages are highly technical and could perhaps be described in Baedeker's terms as "for adepts only, with steady heads". Parts of the report might be regarded as inflated with unnecessary detail, while other sections dismiss in a few lines what has in fact demanded several years of disciplined study and laboratory technique: this helps to explain why the task of the reviewer, in deciding what to put in and what to leave out, has a subjective element.

With regard to carcinogens, the latest advances seem to be that certain comparatively small molecules, and quite well-known compounds, have been revealed as possessing carcinogenic activity or able to 'initiate' carcinogenesis (stage 1 on the Berenblum theory) or 'promote' it (stage 2) once the first step has been overcome by an initiator. The standard carcinogens, benzpyrene, etc., can accomplish both stages. β-Propiolactone (I), ethyleneimine (II) and cholesterol have been shown to be carcinogens; urethane induces carcinogenic changes when it is given by mouth to mice, for not only do lung cancers develop but cancers of the dorsal skin are initiated—tumours appearing in this area after painting with croton oil. Phenol has been found to have strong 'promoting' activity and weak total carcinogenic potency. An important feature of the assay for tumour-inducing activity is the variation of response due to differences in susceptibility in the experimental animals. For example, Rusch (United States) is quoted (p. 193) as reporting that "almost as many tumours were produced when croton oil, phenol, iodoacetic acid, or allylisothiocyanate, were applied alone, as after treatment with DMBA. However, croton oil applied alone to mice of another strain produced no tumours".



(I)



(II)

Salaman and colleagues find that croton oil is a powerful promoter, but a weak complete carcinogen and only for sensitive strains of mice. These workers have bred strains of mice varying widely in response when treated by one application of dimethylbenzanthracene followed by painting with croton oil ("Strain 101—high and homogeneous susceptibility; strain *AKR*—moderate, variable susceptibility; strains C_3H, $C_{57}Br$ and *A*—no tumours produced.") Such differences of sensitivity could explain the discrepancies between the results of tests for potency when different laboratories are working with carcinogenic agents of low intensity; of course if mouse tissues are treated with an excess of powerful carcinogen, susceptibility differences become obliterated. These facts should still the storm-in-the-teacup raised by the failure of workers in Britain to confirm the positive results of Wynder (United States) on the tumour-inducing activity of tobacco tar on mouse skin. It might perhaps be pointed out that the lack of carcinogenic response of some mouse skin to tobacco tar does not *prove* that it must therefore be inactive on human lung tissue (pure benzpyrene, for example, is highly carcinogenic for mouse skin but far less so for rat skin or for rabbit skin).

The report includes an interesting account of a visit to Wynder's laboratory and to other important centres of cancer research in the United States.

A large number of experiments are still being devoted to the nucleoproteins of tumours and normal tissues, chiefly with the aid of tracers; details of more than thirty such studies are included in the report. Investigation of nucleoproteins is fundamental to the biochemistry of living matter but no great advance in cancer research has yet been made from that angle, and it might perhaps be questioned whether the attack from this basic level is not too academic an approach.

The immunological aspect of neoplasia, which has always attracted great interest from the earliest days of cancer research, has received an increasing volume of study in the past few years. Some of this work has lately been expressed in very difficult terminology, theories being offered without adequate observations in support. One such exponent is now beginning to take up a rather more critical point of view; he writes (p. 292): "However, as with all reported cancer differences, the difficulty of isolating an exactly comparable control normal tissue makes firm interpretation difficult. Moreover, it is always possible to object that antigenic simplification, if found, is an expression of the immaturity of the cancer cell and not primarily of the malignant state. The most convincing evidence would be to discover new facts predicted by the theory".

Research on the sex hormones and related steroids has encountered something of a setback, temporarily no doubt; one of the leading authorities (after an extended account of a "Symposium of Oestrogen Methodology" and a very competent study of "The Excretion of Steroids in relation to Neoplastic Disease") concludes that (p. 501): "The excretion pattern of the remaining twenty cancer patients, all of whom had large neoplastic growths, did not differ significantly from normal and it cannot be assumed that the abnormal pattern, when it occurs, is primarily a result of the neoplastic growth. The results do not support the idea of a specific urinary steroid excretion pattern associated with neoplastic disease".

Chemotherapy received slightly less emphasis this year: the efforts put into this line of work have in the past been nothing less than heroic. The American laboratories have by no means given up hope: on the contrary, it is said that they are embarking on an immense-scheme of screening tests for cancer chemotherapy, involving something of the order of a million mice.

Tissue culture seems to be moving up in the hierarchy; a dozen studies are outlined in the report and it is good news that tissue culturists are at last becoming aware of the possibilities of Earle's discovery, about 1943, that normal mouse fibroblasts growing *in vitro* can become transformed spontaneously to malignant cells in the absence of carcinogens; this discovery is re-stated in two places in the report.

The work being carried out in the various medical physics laboratories mentioned in the report indicates that the age of automation is coming closer in research as in industry. In view of the widespread shortage of trained physicists it seems profitable for those who are working in this field to produce methods and instruments designed to reduce the time spent in routine calculations; and in the study of the distribution of radiation within patients being treated either by X-irradiation or with radioactive isotopes. In one centre the possibility of the application of electronic computing to routine problems of treatment is being considered, and in another generalized distribution charts regardless of the contours of the individual patients have been produced. Automatic scanners are also being designed for the localization of radioactive sources in patients or on chromatograms and also in the form of scanning X-ray tubes. X-ray tubes in their turn may be superseded by radiography with radioactive sources and a detailed study is being made of xenon-133 for this purpose. This isotope can be produced as a fission product or by direct irradiation of xenon gas. Determination of the physical factors of xenon-133 is complicated by the presence of other isotopes of xenon. In practice, good radiographs of fractures of the wrist and ankle can be obtained with exposures of only a few seconds using sources of high activity. In the treatment of malignancy, more and more emphasis is being placed on the use of cobalt-60 and cæsium-137 units containing kilocurie amounts and on the use of the linear accelerator. As a consequence of this an immense amount of work is being done on their dosage distributions and on the properties of the radiations produced. This in turn requires the design and production of dosimeters suitable for the accurate measurement of beams of this quality. Calorimetric methods are reported from several centres, including the microcalorimetric method of measuring beamed radiation using thermistors to measure the temperature rise in lead absorbers. The development of 'Perspex' dosimeters for measuring high dose-rates in an electron beam is also discussed. At the other end of the scale it has been found that sealing a solid or liquid sample in intimate contact with a phosphor within a plastic sheath provides a simple and easy method for estimating alpha-ray activity in very weak alpha-emitting substances.

As the population as a whole becomes more and more 'radiation conscious' it is important that the effect of low levels of radio-activity applied to large populations should be studied as well as the techniques for general protection of workers dealing with what may prove to be dangerous amounts of activity. Some of the main hazards to the latter are those relating to handling metals, which may become fixed in bone with subsequent irradiation of that bone and the consequent risk of irradiation-induced neoplasms. The investigation of certain chelating agents as an aid to the removal of these radionuclides is reported. Film-badge monitoring using different types of film holders is now widely used and in many centres the continuous wearing of film badges is obligatory for all staff likely to be exposed to any ionizing radiations. The development of a whole-body gamma-ray monitor for measuring the body burden in case of the accidental ingestion or inhalation of radioactive substances is proceeding. From Australia comes a report of the variation in the radioactivity of rainwater which has been correlated with tests of atomic weapons at the testing range some 600 miles away.

There is not a great deal of special note in the field of cancer morphology. Experience with the diagnosis of cancer of the cervix by exfoliative cytology is reported from two centres, the most detailed and provocative coming from Birmingham. Among 4,000 gynæcological out-patients fifty-three cases of cancer of the cervix were recognized by ordinary clinical methods. To these, cytological examination added three cases of frank invasive cancer and fourteen of carcinoma *in situ* or pre-invasive cancer. At the same time there were twenty-two false positive and three false negative reports. The 'pick-up' rate is low in this series, and Prof. H. C. MacLaren doubts whether the method justifies its cost except for research purposes. The Newcastle figures, however, show twenty-one invasive cases and fifteen carcinomata *in situ* 'picked up' in 2,500 smears. Such differences probably reflect differences in the material submitted, which might be related to geographical or social difference in the incidence of cancer of the cervix, or more probably differences in the type of clinic involved and the efficiency of its screening procedure. It is, however, also possible that they reflect differences in the efficiency of the cytologist, or in their criteria of abnormality, or even differences in the histological criteria of invasiveness which are the ultimate standards by which the accuracy of the cytologist's diagnosis must be judged. There has been some criticism of the use in Birmingham of a cytologist without medical qualification in charge of the reporting of smears, but it is most improbable that this is the cause of the low 'pick-up' rate. In any event, if the method is ever to become economically possible on a large scale, it will have to be organized in some such way as this. These comparatively unfavourable figures from Birmingham need not perhaps be taken too seriously, but they sound a necessary warning against too uncritical acceptance of the worth of cytological screening in cancer of the cervix.

Dr. P. M. F. Bishop (Guy's Hospital) reports a laborious investigation which seems to brand as a fallacy the long-held view that therapeutic œstrogen may be a significant factor in the production of cancer of the uterine body or the breast. Of 420 cases known to have been so treated, followed up for 4–20 years, only one had developed endometrial cancer. Follow-up of cases with presumed high endogenous output of œstrogen, and retrospective survey of the previous œstrogen treatment of cases of endometrial cancer, gave equally non-significant results.

The work of the Cancer Register recently established at Kampala, Uganda, continues, and it is to be hoped that it will soon be making a major contribution to the many problems raised by the distribution of different types of cancer in Africa. This year's harvest is, however, limited to observations on bone changes in Kaposi's sarcoma, and on jaw tumours in Africans. The latter reach the remarkable figure of 5·6 per cent of all tumours seen at Kampala, the commonest kinds being sarcoma (type unspecified, but not osteosarcoma or osteoclastoma), adamantinoma, carcinoma, and mixed salivary tumour of the palate. An international conference on cancer of the liver was held at Kampala in 1956, but the survey of its findings presented in the report is too brief to be very illuminating: the most important point that emerges is that in the absence of any generally agreed definition of cirrhosis the criteria used in the pathological diagnosis of that condition vary so greatly from place to place that comparative statistics of the incidence of cirrhosis, and thus of the relation of cancer to cirrhosis, in different parts of the world are of very little value at present.

These annual reports would be greatly enhanced in value by a subject index. They present a unique compendium of information on current research in very many fields more or less directly related to cancer. However, they are arranged geographically, by departments, rather than in any logical order, and it is not easy to assemble all the aspects of one problem. The summary with which the volume begins acts as a guide to its contents, but it makes a poor preface, for it is so impartial and comprehensive that it is nearly unreadable. A thoughtful preface with some attempt to sum up the year's progress and direct attention to its main achievements would form a better advertisement of the aims and policies of the Campaign and a far more attractive introduction to its report, while its function as guide might well, as suggested, be far better performed by an index. It is very noticeable that an account by Sir Ernest Kennaway of a visit to the United States to discuss tobacco and lung cancer is the least formal article in the report, and also the most readable.

POLYMORPHISM IN PLANTS, ANIMALS AND MAN

By Dr. E. B. FORD, F.R.S.

Genetics Laboratory, Department of Zoology, University Museum, Oxford

AT all stages of plant evolution polyploidy and changes in the content of the chromosome-set have played a decisive part in the supply, and indeed in the control, of heritable variation. Their analysis into a unified concept of chromosome-genetics is due principally to Darlington[1]. A corresponding study of the animal kingdom is not as yet available. For many reasons, which include the rarity of asexual reproduction and self-fertilization, it is likely to provide a less-definitive picture, but it remains an outstanding need. For against such a background the Mendelian phenomena must be set, and it is they which supply the bulk of heritable diversity within freely interbreeding populations. This is controlled in three principal ways, the significance of which is not always fully appreciated even by geneticists, certainly not by biologists in general. That is to say, it may be : (*a*) polygenic ; (*b*) the result of major genes eliminated by selection and maintained in the population by recurrent mutation ; or (*c*) polymorphic.

Polygenic qualities, such as human height, are due to the action of a large number of genes having small, approximately similar and cumulative effects. These, of course, interact with environmental differences, as in all genetic variation.

When, on the other hand, a major gene mutates, the new allelomorph will generally be disadvantageous. The reasons for this are sufficiently obvious. Mutations are random changes relative to the needs of the organism, and when these occur within any highly organized system (and such is the body of an animal or plant), they are more likely to be harmful than useful. Now the genes have multiple effects. It would indeed be difficult to suppose that the chemical and embryological processes connecting a gene with a particular character should in no way modify the general development, whether or not the end result in question is of importance. Thus all the major genes studied in *Drosophila melanogaster*, though normally identified by their influence on such apparently trivial qualities as wing-venation or eye-colour, react upon the viability (length of life, vigour or reproductive capacity) of the fly. They must, therefore, affect the physiology of the organism and, from what has just been said, usually in an unfavourable way.

In polymorphism, on the other hand, we are concerned with the fate of initially advantageous major genes. Logically, one must also envisage the situation in which a mutant gene is neutral as regards survival value. However, Fisher[3] has shown that the balance of advantage and disadvantage between the allelomorphs concerned must be extraordinarily exact to produce that situation. Therefore, such selective neutrality is both rare and of short duration. For the frequency of such a gene can have increased but little by mere chance before the delicate balance required for its neutrality is upset by changes in the environment or in the gene-complex of the organism. Thus if a character controlled by a major gene occupies even 1 or 2 per cent of a population, then that gene must have some advantage.

Polymorphism was defined by Ford[2] as the occurrence together in the same habitat of two or more discontinuous forms of a species in such proportions that the rarest of them cannot be maintained merely by recurrent mutation. That is to say, it excludes geographical races, rare disadvantageous mutants and continuous variation falling, for example, within a curve of normal distribution and controlled by polygenes. It arises in the following way. Mutation, though very rare, is a recurrent phenomenon, so that genes are given opportunities, repeated at long intervals, for success or failure. Any one of them will begin to spread if since its previous origin as a mutant its effects have acquired an overall advantage owing to a change in the environment or in the average gene-complex of a population. Yet it is very improbable that all the results of its action will be useful since these are diverse and, as already noticed in another connexion, the chance of fitting each of them harmoniously into the highly organized system of the body will be remote. Those favoured by selection will become dominant and those opposed by it will become recessive, these processes occurring with increasing rapidity as the gene-frequency rises. Thus the heterozygote will come to have none but favourable effects and will be at an advantage compared with both homozygotes, each of which will evoke some desirable and some undesirable qualities[4].

Consequently, the spread of a major gene will frequently generate a polymorphism, in which distinct genetically controlled forms will reach an equilibrium in the population. They will do so when the advantage of the heterozygote is balanced by the disadvantage that it fails to breed true. Thus it is to be noticed that the heterozygote is bound to gain a superiority, in itself sufficient to produce polymorphism, even when a balance of contrasted types is ensured ecologically. Thus the Batesian mimicry of butterflies, in which relatively palatable species obtain protection by copying those which are relatively distasteful, tends to produce polymorphism. It does so because the advantage involved wanes and is converted into a disadvantage as the numbers of a mimic increase relative to those of its model. Selection then favours the evolution of several distinct forms under genetic control, and these should become stabilized at such proportions that they all receive equal protection : indeed, we find that their relative abundance varies from one locality to another in relation to that of their respective models. This situation in itself generates diversity within the population ; yet, in addition and providing as it were a double basis for polymorphism, the heterozygotes are at an advantage compared with their corresponding homozygotes—a condition which also supplies all that is needed to maintain a polymorphism.

Mimicry is perfected by selection operating upon the gene-complex, within the ambit of the major gene which acts as a switch-mechanism. It does so just as, at a different genetic level, the characteristics of each sex are open to gradual evolution, though subject also to a switch-control deciding whether the individual be male or female.

The most striking instance of evolution ever actually witnessed is that of 'industrial melanism', in which blackish forms of more than sixty species of moths have been, or are, spreading in the industrial areas of Britain and elsewhere. They are under direct genetic control, the black phase being almost invariably a simple dominant. These species are all cryptically coloured and derive protection from active predation by birds owing to their resemblance respectively to pale bark and lichen in the normal countryside, and to the blackened tree trunks in the areas polluted by smoke[5,14]. Yet in view of what has already been said, we should expect this distinction to involve physiological as well as visible changes, and evidence is already accumulating to indicate that the (melanic) heterozygotes are hardier than the normal pale forms[13,6].

We are here witnessing the rapid spread of a gene (transient polymorphism) in response to a cataclysm unparalleled heretofore: the effect of industry upon the countryside. In numerous manufacturing districts the melanics have reached 95 per cent of the population (a gene-frequency of 77·6 per cent assuming equal viability of the genotypes, but somewhat less in view of the superiority of the heterozygotes) and even up to 98 per cent. Yet we are not to suppose that the genes responsible for them will anywhere spread until their once 'normal' allelomorphs are maintained solely by mutation pressure, giving rise only to one pale specimen in many thousands. On the contrary, they should now pass from a 'transient' to a true or 'balanced' polymorphism, in which the frequencies of the allelomorphs will be maintained by contending selective advantages and disadvantages.

In both mimicry and industrial melanism the features by which polymorphism is recognized are of obvious selective importance. They may, on the other hand, be of no apparent significance, but we cannot, therefore, suppose that the genes controlling them are of neutral survival value. Indeed, we can be certain that this is not so. One type of evidence which may be used for substantiating that view can be illustrated from work on the Scarlet Tiger moth, *Panaxia dominula*.

An isolated colony of that insect at Cothill, Berkshire, is polymorphic for a small variation in colour-pattern. The heterozygotes, though recognizable, have usually to be examined carefully to reveal it, but the rare homozygotes are much darker than the normal form and consequently are relatively conspicuous when at rest. This colony has been more fully quantified than has any other population of animals upon earth. The species is single brooded, and at Cothill the numbers have been estimated each season for many years by the method of marking, release and recapture. At the same time, since all three genotypes are distinguishable, the gene-frequency of the polymorphism concerned has been ascertained.

It is possible to calculate to what extent a change in the ratio between a gene and its allelomorph can occur by chance provided the gene-frequency and the size of the population be known[7]. In this instance, both these requirements are fulfilled, and it can be shown that the observed fluctuations in the polymorphism ratios are too great to be fortuitous: they must be the result of selection, changing in intensity and in direction from season to season[8,9]. That is to say, we have evidence that, as deduced by theory, the genes controlling this polymorphism, trivial as it appears, are of importance to the species, being subject to selective advantages and disadvantages.

In the example provided by the Scarlet Tiger moth, polymorphism appears principally to be maintained by selection operating upon qualities other than those which are visible. But even such superficial features are not always available for its recognition. The variation involved is than *concealed*, and in such circumstances apparently similar individuals differ from one another in ways affecting their viability which, although important, can be detected only by cytological or physiological means. Yet the genes responsible for it segregate and contribute to the variable background against which the environment as well as other genes operate. Such concealed polymorphism is therefore bound to influence some of their effects.

In many species of the fly *Drosophila* numerous chromosome inversions can be recognized. This situation has been analysed with much success by Dobzhansky[10] working especially upon *D. pseudoobscura* and *D. persimilis*. He finds it possible to identify certain inverted segments, a considerable series of which is known especially in the third chromosome. Since their frequencies vary characteristically in natural populations, both from place to place and cyclically from one time of year to another, it is evident that they are balanced by contending advantages and disadvantages. This is substantiated by laboratory experiments, demonstrating that the relative superiority of one compared with another gene-arrangements varies, for example, with temperature. As is to be expected, heterozygous inversions are favoured compared with either of the homozygotes, so maintaining diversity and providing a reserve of adaptations to meet different sets of conditions. But the various types, important as they are, can be distinguished only by cytological means; except in that known as 'sex ratio', which causes the X-chromosome in males to divide twice at meiosis and the Y to be lost, so giving rise almost exclusively to female progeny[11]. Thus these inversions generally constitute a concealed polymorphism. The controlling unit here is not a single gene but a group of closely linked genes acting as a switch-mechanism; that is to say, a super-gene[12].

From the functional point of view the inversions, reducing as they do crossing-over between unlike segments, serve to hold together those genes which co-operate to produce useful effects. It may well be inquired why these should chance to occur near one another on the same chromosome so that they can be included within an inverted segment. The answer is that their proximity has been *evolved*, and here we reach a concept of importance in polymorphism as a whole. If two or more genes interact favourably it will be advantageous to keep them together, just as it will be to transmit in a block a gene and those 'modifiers' which improve its effects. Apart from any other counterbalancing disadvantages which may be involved, selection, therefore, will favour those translocations which bring such genes into the same chromosome and, afterwards, such mechanisms as prevent their scatter: it does so by reducing crossing-over between them. This may be achieved by inverting a segment containing them, but that is not the only means available: alternatively, there may be a direct reduction in the chiasma-frequency rearrangements. Even if the genes in question should initially be on the same chromosome by chance, their adjustment to give favourable chromosome-types must be due to selection. In general, it may therefore be said that there is a tendency for the unit controlling a polymorphism to evolve from a single major gene to a super-gene.

That conclusion doubtless applies to the examples already mentioned. Two of them, the polymorphism of *Panaxia dominula* in one isolated colony, and the phenomena of industrial melanism, are probably too recent for it to be detectable. However, the work of Clarke and Sheppard is at last beginning to throw light on the genetics of butterfly mimicry, and they inform me that several of the mimetic forms of the African *Papilio dardanus* behave as if controlled by multiple allelomorphs. This, as they fully realize, is suggestive. For very close linkage can give the effect of allelomorphism or an approach to it.

However, apart from the theoretical necessity of that concept, the control of polymorphism by means of super-genes is not in doubt; we can examine the process both when complete and during its evolution. Before proceeding further, it is worth while to quote instances in which these stages can be detected in lower organisms.

The polymorphism of heterostyly became famous when Darwin studied it in the primrose and the cowslip[13]. In these species the flowers are of two types. They are about equally common and are borne on separate plants: that is to say, 'thrums' with anthers at the top of the corolla tube and the stigma at the bottom, and 'pins' in which the positions of these floral parts are reversed. Moreover, thrums have larger pollen grains than pins; they have also a stigma of a different shape and with shorter papillae. This diversity provides an outbreeding mechanism because, as Darwin showed, cross-pollination by insects can occur more easily between dissimilar (pin and thrum) than similar flowers. He recognized also that its effects are enhanced by differences in fertility. For even when crossing between like types takes place, it is a relative failure: pollen produced by a pin plant requires the environment provided by the female parts of a thrum flower for successful growth, and the reverse.

Thrum behaves as a simple dominant to pin, but the crossing of unlike types in natural conditions ensures that the thrums are normally heterozygotes. The genetic switch-mechanism involved is, in fact, that of a super-gene: a group of very closely linked genes controlling pollen-size, anther-height, style-length and type of stigma. Crossing-over between them is very rare. When it does occur it can separate and interchange the constituent units, so producing short homostyles and long homostyles. In the latter, the male parts are those of a thrum flower and the female parts those of a pin; thus the anthers clasp the stigma at the top of the corolla tube. This type is therefore fully self-fertile as its selfing is equivalent to a cross between a pin and a thrum. The result is an inbreeding mechanism which can be substituted for the outbreeding one of heterostyly when the evolutionary situation demands it, and this is in fact happening in two districts in southern England to-day[14].

In the heterostyle–homostyle mechanism, which naturally is widespread among plants, the evolution of the super-gene mechanism seems generally to be perfected. A stage in its production is illustrated by the snail *Cepaea nemoralis*, in which Cain and Sheppard[15] have demonstrated with great success the working of natural selection. The species is polymorphic both for colour and banding. Yellow shells are recessive to those of the brownish shades while the possession of bands is recessive to their absence. Yellow shells are less conspicuous upon light soil as on a chalk down, and upon green herbage, and in such localities they are relatively common. The brownish shells are the better concealed in a beech wood and upon dead vegetation in general, and here it is they which predominate. Similarly, the banded shells have an advantage upon a diversified background, such as a mixed hedgerow, and the plain upon a more uniform one. The shells are preyed upon by thrushes which carry them to favourite stones where they break them open, and in each type of habitat the remains contain an unduly high proportion of the inappropriately coloured and banded forms: the birds are, in fact, powerful selective agents.

We may feel confident it is not fortuitous that there is linkage between the two pairs of allelomorphs concerned. The cross-over value between them may be as high as 20 per cent, yet there is evidence that the amount of linkage varies significantly in different populations[16]. This is exactly the situation which could lead to the formation of a super-gene. One of the great needs in genetic research at the present time is to study the evolution of close linkage by means of selection experiments, and *Cepaea nemoralis* exemplifies the type of material required for that purpose.

There is yet another way in which linkage affects polymorphism. One of the commonest forms of mutation is that producing recessive lethals or semi-lethals. These accumulate in the immediate neighbourhood of the controlling gene or super-gene owing to the high frequency of its heterozygous genotype in which, as recessives, they remain protected from selection because in single dose. Only when they are sufficiently far along the chromosome to be at all often separated from the switch-unit by crossing-over will they lose the shelter it affords. Clearly such linkage must magnify the already-mentioned superiority of the heterozygote but in respect only of one of its homozygous genotypes: that is to say, the 'dominant'. The disadvantage of the other is ensured by the absence of the quality for which selection is operating.

It is for this reason that dominant polymorphic traits are so frequently reported as 'linked with a lethal'. A well-known example is provided by the white female phase of the butterfly *Colias philodice*, in which it is difficult to establish a strain of homozygous whites for this reason[17].

The features of polymorphism here described are general principles applicable wherever that condition is found, as are the far-reaching deductions to which they lead. They can therefore be extended to the human race, for man is one of the most polymorphic animals known.

When the blood groups were first treated as examples of balanced polymorphism[18], the significance of that step did not at once attract attention though it received emphatic approval from R. A. Fisher. In fact, some time elapsed before it gained any wide acceptance: even after ten years Dobzhansky[19] could see no reason to regard the blood-group genes as of other than neutral survival value. Yet theoretical considerations inevitably demonstrate the contrary and show that they must be maintained in the population by contending advantages and disadvantages: so does their occurrence in the great apes, indicating a diversity long continued. Indeed, it was suggested by Ford, in March 1940, that these genes must have unknown effects for which they are selected[8] even before the discovery, by Levine and Katzin in October of that year, that dangerous rhesus incompatibility can arise between mother and fœtus[19].

The concept of polymorphism when applied to man leads to further deductions in the field of serology. Since the blood group genes must have multiple effects, favourable and unfavourable, by which they are balanced, they are bound to influence the general physiology, and in such a way as to produce characteristic responses to stimuli of various kinds and to the onset of changes in the body. Ford[20] therefore pointed out that individuals belonging to the different blood groups would not be equally susceptible to certain specific diseases. That prediction was confirmed six years later when Struthers[21] discovered that a larger proportion of group *A* than of group *O* babies die of broncho-pneumonia during the first two years of life. The results are fully significant but require to be corroborated on further sets of data. Aird, Bentall and Fraser Roberts[22] then showed that a significantly high proportion of those who suffer from cancer of the stomach belong to blood group *A*. An important further step was taken when Clarke *et al.*[23,24] demonstrated that duodenal ulcer is unduly common both in individuals belonging to group *O* and in those who fail to secrete the *ABO* antigens into their saliva. This latter condition constitutes another polymorphism. It is controlled as a simple recessive and in Britain affects about 22 per cent of the population, while the remainder of the community secrete these substances in large quantities. Further work along these lines is revealing other associations between pathological states (for example, pernicious anæmia, fracture of the hip in old age) and the different *ABO* blood groups.

So far such investigations have largely been confined to that series, owing partly to a deplorable lack at the present time of most of the other sera (except those of the commoner rhesus types). When the necessary facilities are available, it should be possible also to detect correlations between other groups and the incidence of certain diseases. This indeed should be demonstrable for all forms of polymorphism, including the newly discovered human 'physiological' types. For example, nodular goitre patients include a significant excess of those unable to taste phenyl-thio-urea[25] (confirmed by Clarke *et al.*, in the press). That compound is intensely bitter to about 70–80 per cent of the population in Europe and the Near East and tasteless (except in large concentrations) to the remainder. In this curious diversity the inability to taste is a simple recessive, subject to minor complications due to modifiers. It also exists as a polymorphism among anthropoid apes[26]; a fact which suggests that it has been maintained from a remote and pre-human period.

The value of the blood groups in anthropology has been recognized for nearly forty years but, at least until recently, for the wrong reason. By a curious inversion of logical thought, it was held that their occurrence in distinct and characteristic proportions in the different races of mankind was specially important because the variation involved was selectively neutral. Precisely the contrary is true. The fact that the genes concerned are balanced by selection at optimum frequencies, which differ from race to race, is the one which gives them significance as a criterion of relationship. It does so because in these circumstances their proportions are influenced by the average genotype of the population in which they occur.

Applying the theory of polymorphism to human examples, we can be sure that in man the heterozygotes are at an advantage compared with the homozygous types. Not only has this been demonstrated in one noteworthy group of instances but also in them the nature of that advantage has been revealed[27].

Sickle-celled anæmia is the homozygous expression of a gene which merely produces the innocuous sickling 'trait' when heterozygous. In the homozygotes, the normal hæmoglobin is replaced principally by an abnormal type, but up to 20 per cent of the ordinary fœtal hæmoglobin may also be present. This leads to the formation of irregular 'sickle-shaped' red corpuscles and produces hæmolysis severe enough to cause an extreme and generally fatal anæmia. Indeed, the fertility of this genotype is less than one-quarter that of the heterozygotes. These latter are quite healthy, but their hæmoglobin consists of the normal and abnormal types in approximately equal quantities. Their red corpuscles are unaffected while in circulation but they assume the sickle-shape, though to a less extreme degree, if the oxygen tension of a drop of blood be lowered by the use of ascorbic acid or by other means. Thus the heterozygotes can be identified. Though generally absent or of extreme rarity, they constitute a considerable proportion of the population in a few regions, and they amount even to 40 per cent in some African tribes. Evidently in these places, and there alone, they possess an advantage so considerable as to outweigh the heavy destruction of the homozygotes. The nature of this has been discovered[28], for the sickling trait confers marked immunity to subtertian malaria. The polymorphism is established only where that disease is common; for there the heterozygote is favoured compared with either homozygote, so ensuring diversity.

A glance at any work on the human blood groups will show that several of them are controlled by a switch-mechanism already identified as a group fo closely linked genes. That is to say, the expected evolution of super-genes has taken place in man. In other instances it may be so complete that it has not yet been distinguished from allelomorphism: a situation which may be true of the well-known *ABO* system itself.

It has already been pointed out that there is great need to study the evolution of linkage and of super-genes experimentally. Possibly those processes can be examined in another way: by observing their occurrence in human populations. Two opportunities for doing so may be mentioned here. The first is provided by the Henshaw blood group, which is principally found in African Negroes. The gene controlling it is extremely closely linked to that responsible for the well-known *MNL* groups, but in a way which differs in different regions: for in West Africa, but not elsewhere, the Henshaw gene is always carried in the same chromosome with that producing group *N*. Secondly, there is good, though perhaps not decisive, evidence that the genes controlling the Lewis and Lutheran groups are near one another on the same chromosome (a cross-over value of 5·6 between them has been assessed). They might show different degrees of linkage if examined in widely separated human races.

The theory of polymorphism is a logical deduction from the facts of particulate inheritance, especially as analysed by R. A. Fisher. It has been extended and developed from a study of lower organisms, in particular the Lepidoptera. The association of the blood groups with specific diseases was predicted in advance of its discovery because it follows as a consequence of that theory. Its verification is opening up a new branch of medicine the results of which may be of value in diagnosis and conceivably in treatment.

SCIENCE OF METALS AT OXFORD

AT a meeting of Congregation held on November 5, the University of Oxford accepted with gratitude the generous gift of £65,000 made by Mr. Isaac Wolfson to establish a professorship in metallurgy, and by a decree passed on November 19 Dr. W. Hume-Rothery, of Magdalen College, was elected as the first Isaac Wolfson professor, with effect from January 1, 1958.

Metallurgical research work at Oxford was started by Dr. Hume-Rothery in 1926 in temporary accommodation provided by the late Prof. W. H. Perkin. After a few years, the subject was transferred to the Inorganic Chemistry Laboratory where one, and later two, rooms were made available by the late Prof. F. Soddy. Working with one or two research students, a series of papers on copper, silver, and magnesium alloys was published. Later, owing to the continual interest of Professor (now Sir Cyril) Hinshelwood the laboratory accommodation was gradually increased, and a lectureship in metallurgical chemistry was awarded in 1938. During the Second World War, the research work was extended to include the structures of ternary and quaternary alloys of aluminium, and alloys of transition metals were also studied. Although lectures were given, metallurgical work remained a postgraduate research subject until 1949, when metallography was added to the list of supplementary subjects in the Final Honour School of Natural Science.

Metallurgical work at Oxford received a great stimulus when in 1954 the George Kelley readership in metallurgy was endowed by the Pressed Steel Company, Ltd., in memory of its late managing director. At the same time an appeal to metallurgical industry organized by the late Major A. Pam gave part of the money needed to set up metallurgy as an independent subject in the University, and the remainder was generously provided by the University Grants Committee. At the moment, the Department of Metallurgy exists as an independent department in rooms in the Old Physiology Building. A new laboratory has been designed as part of the Keble Triangle scheme, and the building of this is to begin before the end of this year.

In June 1956 the University established a new Honour School in the Science of Metals, and students are now being accepted for this. The creation of the Wolfson chair of metallurgy thus means that the subject is properly established in the University, with permanently endowed professorship and readership, and a modern laboratory the building of which is about to begin. In view of the shortage of metallurgists in Great Britain, this expansion of metallurgical facilities at Oxford is much to be welcomed.

Metallurgical industry is one of the oldest of the arts but one of the youngest of the sciences. Whereas in chemical industry many processes are the earlier laboratory experiments done on a large scale, metallurgical industry has developed mainly from the older arts and crafts. It is only in comparatively recent times that any considerable fundamental work has been carried out on metals and alloys. The progress made since the First World War has been enormous, and there are now well-established and rapidly growing branches of science which are related to metallurgical industry in the same way that the science of chemistry is related to chemical industry.

The intention of the Oxford honour course in the science of metals is to combine a training in the science of chemistry with a knowledge of the fundamental science of metals and alloys. Technology as such is not taught, although much of the work in the science of metals course is related to industrial processes.

The new honour course involves four years of study, and is combined with part of the existing Honour Chemistry course. In the first three years the student reads the full Oxford course in inorganic and physical chemistry, but organic chemistry is dropped at the end of the first year, and is replaced by the science of metals. At the end of the third year, the student takes Part I of the Final Honour Examination, which consists of the normal written papers and practical examinations in inorganic and physical chemistry, together with written papers and practical examinations in the science of metals. The passing of this examination enables the student to take the B.A. degree, but to obtain classified honours a fourth year must be spent at research work on an approved metallurgical subject.

The four-years course outlined above should be of high scientific value. It brings the student into contact with all three branches of chemistry, two of which are studied to an advanced level, together with some branches of physics and of the newer sciences of the solid state. It is also directly related to the industrial practices of metallurgy. The inorganic chemistry should enable the graduate to understand the principles underlying the extraction and smelting of metals. The physical chemistry should make him familiar with the principles of chemical equilibrium and reaction kinetics, and so enable him to understand processes such as slag/metal equilibria, fuel/gas reactions, etc. Finally, the metal-science part of the course should teach the student much about the structure and properties of metals and alloys, and their relation to processes involved in industrial practice. It is hoped that a graduate trained on these lines will be a useful man (or woman) in many ways. If he enters industry, he will, of course, have to learn the technology of his subject. This is the case with graduates in physics or chemistry whose university training is in pure science, and it is hoped that metallurgical industry will find many uses for men trained in the sciences of chemistry and of metals.

The Department of Metallurgy at Oxford also offers facilities for postgraduate research work for the B.Sc. and D.Phil. degrees. The laboratory is well equipped for thermal analysis, microscopical metallography, X-ray metallography, and electron microscopy. The staff at present consists of one reader, Dr. W. Hume-Rothery, two lecturers, Dr. J. W. Christian and Dr. J. W. Martin, and one graduate assistant, Dr. A. Hellawell.

OBITUARIES

Prof. Frank Horton, F.R.S.

Prof. Frank Horton, emeritus professor of physics in the University of London, died on October 31, at his home in Cambridge. He was the eldest son of Albert Horton, of Olton, Warwickshire, and was born on August 20, 1878; his mother's maiden name was Kate Louisa Carley.

Horton began his academic career at King Edward VI Grammar School, Birmingham, and even at that early date began to devise and carry out experiments in physics. Leaving school, he proceeded to Mason College (later the University of), Birmingham. Here he obtained first-class honours degrees in both physics and chemistry, and then began a series of researches on the elastic properties of wires and quartz. In this work, directed by Prof. Poynting, use was made of a variation of the 'method of coincidences' for determining a periodic time. An account of this work appeared in the *Philosophical Transactions of the Royal Society* and earned for Horton his first doctorate at the University of London in 1903.

In 1901 Horton went to St. John's College, Cambridge, as an 1851 Exhibition Research Scholar. For his research work with Sir J. J. Thomson, during which Horton became interested in the production of high vacua, he was elected a Mackinnon Research Student of the Royal Society in 1903. Among their other activities, Thomson and Horton found time to edit the important series of Physics Monographs, published by Longmans, Green and Co., Ltd. In 1905 Horton was made a Fellow of St. John's and during 1905–13 was a lecturer at the Cavendish Laboratory.

At the age of thirty-five, Horton was elected to the chair of physics at the Royal Holloway College, Englefield Green, Surrey. The earlier occupants of this chair were Prof. H. L. Callendar, Prof. W. Cassie and Prof. P. V. Bevan. Prof. Horton's work at Cambridge had equipped him with the tools necessary to carry on fundamental work on electronics and soft X-rays. During the First World War he investigated, among other things, the effect of helium on the stability of electron emission from heated filaments.

In 1911 Frank Horton married Miss Vera Fulton, of New Zealand, where the marriage ceremony took place, and his daughter, Ngaire, now Mrs. Bajko, survives him. She lives in New Zealand and has a son, Michael.

In 1923 Prof. Horton was elected a Fellow of the Royal Society and two years later, as a member of the Senate of the University of London, found himself in the thick of many controversies then current in academic circles; he was always a champion of the rights of university teachers. As chairman of many university bodies he was meticulous in the dispatch of business. He was dean of the Faculty of Science during 1930–34 and in 1932 was elected a member of the Court of the University. In September 1939 he became vice-chancellor, a post which he held until 1945—such was the measure of the confidence his colleagues had in him as an administrator of the highest order. Earlier in 1939 he married one of his former students and a co-research worker, Miss Ann Catherine Davies, who was staff lecturer in physics at the Royal Holloway College during 1922–29, when she left to take up a post at Newnham College, Cambridge, where she is now vice-principal. Mrs. Horton is an active member of the Council of Royal Holloway College, and this enabled Prof. Horton to keep in contact with the scene of his former labours when he retired in 1946 from his chair of physics and went to live in Cambridge.

His successor, Prof. S. Tolansky, found the laboratories in the department which Horton had helped to design in the middle 'twenties well equipped to meet the needs of present-day workers in physics. These laboratories form part of a block which houses both the Botany and Physics Departments of the College, and when they were opened in 1928, Prof. Horton paid high tribute to Dr. Margaret Benson, head of the Botany Department during 1893–1922 (she occupied the chair during 1912–22), for it was she who had conceived the idea for the erection of a new building and had done so much to bring it to fruition.

Horton was a physicist gifted with remarkable experimental skill, and those who worked with him were inspired by the dextrous and confident manner in which he would handle and adjust highly sensitive instruments. He was never more pleased than when he could watch an undergraduate carrying out an experiment with meticulous care.

The funeral service was held on November 2 at St. John's College Chapel, and the large attendance on that occasion testified to the high esteem in which Prof. Frank Horton was held. C. J. Smith

Dr. Paul D. Merica

We regret to announce the death of Dr. Paul D. Merica, of the International Nickel Co. of Canada, in New York on October 20. Dr. Merica was born in Warsaw, Indiana, in 1889. He attended De Pauw University during 1904–7, graduated from the University of Wisconsin in the following year, and received his Ph.D. from the University of Berlin in 1914. During 1914–19 he was associated with the metallurgical division of the U.S. Bureau of Standards in Washington. Dr. Merica carried out a number of researches on duralumin and other aluminium alloys and developed his theory of the precipitation hardening of metals and alloys.

Dr. Merica first became associated with the International Nickel Co. in 1919, becoming director of research and later assistant manager of the Development and Research Department. He was made president of the company in May 1952, retiring from the last post in April 1954.

For his contribution in the field of metallurgy and outstanding leadership in physical metallurgy, Dr. Merica, who was a member of the U.S. National Academy of Sciences, was awarded the James Douglas Medal in 1929, the John Fritz Medal in 1938, the Institute of Metals Medal in 1941, the Franklin Institute Medal in 1942, and American Society for Metals Gold Medal in 1951. Dr. Merica was an honorary member of the American Institute of Mining and Metallurgical Engineers, of which he was a former vice-president and director, as well as of the American Society for Metals.

NEWS and VIEWS

Metallurgy at Oxford :
Prof. W. Hume-Rothery, O.B.E., F.R.S.

The development of metallurgical science at Oxford has been continuously associated with the work of Dr. Hume-Rothery, and his many friends will warmly welcome his appointment as the first Isaac Wolfson professor of metallurgy (see p. 1319 of this issue). Dr. Hume-Rothery was at the beginning of an army career when a serious illness left him totally deaf. Despite this affliction, he obtained a first in chemistry at Oxford and a Ph.D. at the Imperial College of Science and Technology, London, before returning to Oxford to found the research school in alloy theory, which soon became internationally famous. He was elected a Fellow of the Royal Society in 1937, and he was Warren Research Fellow of the Society during 1932–55, when he became the first holder of the George Kelley readership. Post-war developments in the teaching of metallurgy are largely the result of his enthusiasm and hard work. Dr. Hume-Rothery's early experimental work led to our present understanding of many of the factors governing the form of metallurgical equilibrium diagrams. Perhaps the best-known results are the discovery of the 'electron compounds' and the enunciation of the famous size-factor rule. During the War, his group worked on complex aluminium alloys, and since then his main interest has been in high melting point alloys of the transition metals. He is equally distinguished as the author of five text-books, and his very successful expositions of modern theories have been translated into many languages. Dr. Hume-Rothery was awarded the platinum medal of the Institute of Metals in 1949, and has also received awards from scientific societies in the United States, the Netherlands and Italy.

Reports of the Nationalized Industries in Britain

In a debate in the House of Commons on November 26, which took note of the annual reports and statements of accounts of the Gas and Electricity Industries, the Paymaster-General, Mr. R. Maudling, as representing the Minister of Power, said that the surplus of £3·8 million shown in the latest report of the gas industry is due to the increased efficiency of the industry. The number of units in the industry have been reduced from 1,050 at vesting day to 611; the thermal efficiency has been increased to 77·8 per cent, and although the cost of coal and manual labour has risen by 65 per cent since 1950, the price of gas, which represents two-thirds of the industry's sales, has risen by only 47 per cent, and that of coke and by-products by 78 per cent. Mr. Maudling referred to the increasing competition of electricity and the increasing scarcity and cost of good-quality coking coal. The industry is accordingly seeking to exploit lower-grade cheaper coal, and much work is being done on the Lurgi process of complete gasification and on the hydrogenation of oil and coal. The Lurgi process, however, yields gas of low calorific value, and it has not yet been fully proved with grades of coal available in Britain; but if the work of the North Western Board on hydrogenation is successful, it should be possible to produce gas of good quality from a wide range of comparatively low-quality, low-priced coal. Both the Lurgi process and hydrogenation have the advantage of producing no coke, of which there is at present a surplus. The industry is also examining the use of surplus products from the oil refineries, as well as of imported oil, and, besides prospecting for natural gas in Britain, is studying the import of liquefied methane, the use of coke-oven gas and, in co-operation with the National Coal Board, the use of methane from coal pits, as well as both the long-distance transmission and the storage of gas.

Turning to the electricity industry, Mr. Maudling said that total sales last year increased by 6·7 per cent, and sales to farms by 18 per cent, while the average price of electricity sold by the Central Electricity Board increased by 4·7 per cent. Since 1948 the cost of fuel has risen by 55 per cent, but the price per unit has risen by only 26 per cent. It is expected that the reduction in oil-firing will result in an increase in the consumption of coal by about 2·5–3 million tons a year in the 1960's. Mr. Maudling did not think that there should then be an embarrassing surplus of small coal, but other uses of small coal are being investigated. As regards capital investment, the present rising level of investment in electricity will continue but at a lower rate than previously planned. In the nuclear power programme, the development of Bradwell, Berkeley, Hinkley Point and Hunterston will proceed as planned, but there will be some delay in starting the later stations in the programme and the net effect will be to delay the completion of the full programme by one year. In repeating the assurances previously given in the White Paper and elsewhere that the accident at Windscale could not occur in the power stations being built for the Central Electricity Authority, Mr. Maudling emphasized that this applies equally to the power stations which the industry is offering for sale abroad. He added that a reactor safety committee has been established on which Lloyd's and the British insurance industry are represented, and a formal safety code for the design and operation of nuclear power stations is being prepared. As regards the siting of nuclear power stations, Mr. Maudling argued that there is neither the time nor the trained staff for a complete survey of the United Kingdom before decisions are taken, but he did not meet the objection that such a survey is only demanded when ti is proposed to invade national parks or like areas.

Brussels Universal and International Exhibition, 1958

Work on the 500-acre site for the Brussels Universal Exhibition continues apace, and the majority of the structures are ahead of schedule. Most of the buildings have taken their final shape, and work is now in progress on interiors and exhibits. About 8,000 men are at present working on the site. Two of the nine spheres of the 'Atomium' have been completed, and three others have their main structure in position. Work has begun on the topmost sphere, and the lift mechanism has been installed in the central column.

Details are also available of some of the plans for the International Hall of Science, sponsored by fifteen nations. All the exhibits are to be of a collective and non-national character. The hall will have four sections: The Atom; The Crystal; The Molecule; The Living Cell. The Atom Section will include displays of radioactive elements, nuclear and thermonuclear reactions and solar energy. There will be models of accelerators from the European Nuclear Energy Centre at Geneva, a demonstration of the direct use of solar energy in a furnace, and a fully operating experimental reactor. The Crystal Section will contain, among other things, a model of a crystal 13 ft. × 13 ft., containing 800 lights showing the basic elements of the crystal. The Molecule Section will explain analytical, synthetic and physical chemistry. Its main feature will be a model of a crystallized virus. The Living Cell Section will allow the public to see, by means of a prototype colour-television set, essential cell activities otherwise only visible by microscope. There will also be illustrations dealing with chromosomes, heredity, blood groups, cell division, and photosynthesis.

Nordic Institute for Theoretical Atomic Physics

The five Nordic countries (Denmark, Finland, Iceland, Norway and Sweden) have set up a joint organization, under the chairmanship of Prof. Niels Bohr, for the purpose of strengthening scientific co-operation in the field of atomic physics. One of the main objects of the organization is the establishment of the Nordisk Institut for Teoretisk Atomfysik in Copenhagen in a building which will be erected by the Danish Government in connexion with the existing premises of the Institute for Theoretical Physics of the University of Copenhagen. Further activities envisaged are exchange of Nordic scientists, organization of symposia, and visits of scientists from other countries to Nordic physics institutions.

Research work and educational activities will be the task of the staff of the Nordic Institute. Facilities will be provided for a number of younger physicists from the member States to receive advanced training in the field of theoretical atomic physics. For the interim period, until a formal agreement has been established by the participating governments, C. Møller has been appointed director of the Institute (during his absence on a visit to the United States, T. Gustafson is acting as director), assisted by G. Källén, B. Mottelson and S. Rozental. On February 1, L. Rosenfeld will join the permanent staff of the Institute.

Journal of Mental Deficiency Research

The causation of mental disease of all types has tended to attract research workers perhaps less than in any other branch of medicine, and only the truly devoted have turned their energies into trying to discover the causes of mental deficiency. At first sight the mental defective seems so hopeless, so finally damaged, that one feels despair. Nevertheless, research is worth while, and the realization that certain of the acute specific fevers can injure the fœtus has aroused new hope. Those who work on these problems tend to be scattered in mental deficiency hospitals and work a great deal isolated from others engaged in similar activities. It is an excellent thing, and one which will be most welcome, to find that a journal has been founded to record their researches (*Journal of Mental Deficiency Research*, 1, No. 1 (July 1957). Pp. 65. Published half-yearly. Annual subscription rate: 15*s*. Single issues 7*s*. 6*d*. or 1.50 dollars. Publishing manager: Mr. A. Highfield, 10 Shendon Way, Sevenoaks; 1957). The first number contains an excellent article by Penfield on "The Genetics of Anencephaly", a paper by Claridge and O'Connor on "The Relationship between Incentive, Personality Type and Improvement in Performance of Imbeciles" and "A Survey of Mental Deficiency Types in the United States of America". A paper is contributed by Mittwoch on "Some Observations on the Leucocytes in Mongolism", and there is another article on phenylketonuria by Hsia, Paine and Driscoll. It is hoped that this valuable journal will have a long life and will be able to maintain the high standard of its initial number. It is essential to all who are interested in mental deficiency and will be consulted by anyone who hopes to further research.

Annales de l'Institut Phytopathologique Benaki

There is nothing in the first number of a new series of the *Annales de l'Institut Phytopathologique Benaki* (Nouvelle Série, 1, No. 1, 1957. Pp. 90. Kifissia-Athenes: Institut Phytopathologique Benaki, 1957), which is well produced, with large print and generous margins, to show whether it is typical of what is to come. Its ninety pages consist solely of a thesis presented for a doctorate by D. G. Zachos to L'École de Hautes Études Agronomiques d'Athènes. The work described was done at the Station Centrale de Pathologie Végétale, Versailles, and falls into three parts: the first deals with the movement of tobacco mosaic and potato X-viruses in tomato plants, the second with interactions between the two viruses which together cause streak of tomatoes, and the third with the effects of infection on certain oxidizing systems. The most striking phenomenon reported is that, in plants simultaneously infected with tobacco mosaic virus, potato virus X may reach more than three times the concentration it reaches in plants infected with it alone, but considerable evidence is also presented indicating a correlation between virus multiplication and the activity of three oxidases, with catalase activity varying inversely with that of the oxidases.

Microrecording in Libraries

The Library Association has recently published as Pamphlet No. 17, entitled "Microrecording in Libraries", by J. Burkett (Pp. 55. London: Library Association, 1957. 8s. 6d.), a review of present practice which provides a most useful and concise account of the various types of microrecord and ancillary apparatus with a discussion of their advantages as well as their limitations. Publishing facilities are summarized and there is a section on uses of microphotography, including a note on the use of microrecording in university and other libraries in Britain. Guidance is given on the choice of both process and reader, and there is a good bibliography. Although the pamphlet is well up to date, it just misses including a reference to the new and greatly improved portable microfilm and microfiche 'Dagner' reader, developed by J. H. Mullens of The Hague, which on price grounds alone has special claims on the interest of the university or technical college libraries.

Research Guide

"Scientific Research in British Universities, 1956–57" (pp. vii + 405. London: H.M. Stationery Office, 1957. 22s. 6d.), like the previous volumes in this series, provides brief notes on scientific research in progress in British universities and university colleges during the period in question, describing the nature of the projects in sufficient detail to indicate the scope of the research. Under each entry the departmental head is named, together with those of members of the staff engaged in supervising research, and the entries are arranged alphabetically, first by universities and university colleges and then by subject. There are alphabetical name and subject indexes. The material has been collected by the British Council from heads of university departments.

Science in the Primary School

A useful introduction to science has been described by B. L. H. Hampson, of Thomas Street School, West Gorton, Manchester (*School Nature Study*, 52; October 1957). He suggests that science teaching in the primary schools should no longer be restricted to Nature study, and that there should be substituted instead a logical starting-point for a general science training and the establishment by progressive stages of a comprehensive foundation of general science knowledge from which any secondary phase of science education could be developed. Ways in which these principles have been put into practice in his own school are described as well as the conclusions reached by Hampson after six years experience. Recent reports have shown that the principles enunciated have been applied in both junior and infant schools in other parts of Britain.

Further Education in the North of England

The tenth annual report of the Northern Advisory Council for Further Education contains interesting information about the way the pattern of technical education in the north of England has changed recently. Between 1954–55 and 1956–57 the number of full-time students increased from 3,797 to 4,640; part-time day students increased from 21,882 to 26,482. In evening classes at technical colleges, however, the increase in the number of students was very slight, from 27,179 to 29,179; in evening institutes the number of students decreased from 75,328 to 62,680. These changes were reflected in the kind of courses for which students enrolled. The number of students taking the more advanced studies—degree, higher national, diploma, college diploma, or higher national certificate—increased from 2,403 in 1954–55 to 3,040 in 1956–57. The report may be obtained from the Secretary, 5 Grosvenor Villas, Newcastle upon Tyne.

Transistors

Extensive research and development work on semiconductors, in particular on transistors and related devices, and on their applications, has recently been carried out within the Radio Corporation of America, which has agreed to publish a selection of papers describing the work as it applies to the theory, fabrication and application of transistors. The first volume has now been issued (Transistors I: R.C.A. Laboratories. Second printing, 1957). It consists of published and unpublished papers and abstracts. Two review articles deal with basic transistor device concepts and new advances in the junction transistor. In other papers the concepts are further extended and applied to new and improved devices. For example, the limitations of diffusion phenomena on the frequency response of transistors, and the drift transistor.

Lighting, Heating and Ventilation of Museums

In the *Museums Journal* of October, Messrs. W. E. Rawson-Bottom and B. S. Cooper contribute an important paper on the use of both natural and artificial lighting in museums. Following a brief review of early attempts in lighting, its present value as one of the essential factors of effective display is stressed. The first author deals with general lighting in the museum and favours the standard fluorescent batten unit for one or two lamps with louvres in short lengths of moulded plastic material which clip to the lamps. He also feels that the incandescent lamp is still useful in many places; for example, geological specimens and jewels tend to lose brilliance and gold can look like brass in fluorescent lighting. He then deals with the lighting to be adopted with various types of museum cases: in art gallery lighting he advocates fluorescent lighting in trough reflectors with 75-watt tungsten lamps for colour correction. The second author is concerned with the effects of photochemical deterioration and concludes that the removal of ultra-violet radiation by means of suitable filters, while in some instances an advantage, usually leads to only an insignificant increase in the photochemical stability of the illuminated material.

In the same issue of the *Museums Journal*, another paper, on the heating and ventilation of museums, by Dr. A. E. A. Werner, Research Laboratory at the British Museum, discusses a complex subject previously viewed in a rather empirical way. The author outlines the basic principles concerned in determining a reasonable atmospheric environment in museums and considers the practical problems involved in air-conditioning, and the various types of apparatus employed both for exhibition and storage areas. The three essentials—humidity, temperature and air movement—are considered and reasonable limits are defined. The paper is illustrated by graphs, diagrams and photographs of apparatus.

Museum of Applied Arts and Sciences, Sydney

THE annual report for 1956 of the Museum of Applied Arts and Sciences at Sydney is a purely factual statement concerning a year of progress of this well-known institution. Such is the popularity of the planetarium that serious consideration is being given to the replacement of the present projector and dome with a larger unit accommodating at least a hundred people. The chief exhibit acquired in 1956 consists of five dioramas and a flow chart presented by the Petroleum Information Bureau (Australia). The dioramas illustrate the origin of oil, exploration of potential areas, drilling processes, recovery of oil from wells, transport to refinery and uses of oil in the home. The flow chart depicts the refining of crude oil by fractional distillation. The reputation of this Museum for scientific research, especially in the field of the botany and chemistry of the essential oil-bearing flora of Australia, is being pursued, and many papers have been published.

Solar Energy and the Depth of the Earth

SINCE 1946 N. V. Belov and V. I. Lebedev have published a number of articles in which they have developed their hypothesis of the probable source of energy of endogenetic processes, and now they have presented their final and comprehensive outline of this hypothesis (Belov, N. V., and Lebedev, V. I. *Priroda*, No. 5, 11; 1957). It is based mainly on a characteristic fact in leptology (crystal chemistry), namely, that in the minerals occurring in superficial sedimentary rocks, such as the clays, aluminium is surrounded by six oxygen atoms in octahedral co-ordination, with the Al–O distances of the order of 1·9 A., while in the minerals of the deep-seated igneous and metamorphic rocks, such as the felspars, aluminium is surrounded by four oxygen atoms in a tetrahedral co-ordination, with the Al–O distance of the order of 1·7 A. The contraction of this distance during the downward movement of the Earth's crust is, according to the authors, an important source (the effect of radioactive disintegration not overlooked) of energy which produces the rise of temperature in depth, and is consequently responsible for the processes of metamorphism and magmation. Thus, aluminium and oxygen, as well as other cations, are acting as accumulators of solar energy, the charging of this 'geochemical accumulator' taking place in the zone of weathering, and its discharge in the depth of the Earth's crust. Similar conclusions have been reached by V. A. Saul (*Geochim. et Cosmochim. Acta*, 8, 86; 1955) entirely on the basis of the data of thermochemistry.

International Union of Pure and Applied Physics

AT the ninth General Assembly of the International Union of Pure and Applied Physics held in Rome during September 17–20 the U.S.S.R., Austria and Bulgaria were formally admitted to the Union. The number of countries now adhering to the Union is thirty. For the period 1957–60 the Executive Committee of the Union has the following members: *President*, E. Amaldi (Rome); *Former Presidents*, N. F. Mott (Cambridge), M. Siegbahn (Stockholm); *Vice-Presidents*, J. de Boer (Amsterdam), R. B. Brode (Berkeley), M. Kotani (Tokyo), J. H. Van Vleck (Cambridge, Mass.), G. Herzberg (Ottawa), A. Joffe (Leningrad), E. Rasmussen (Copenhagen), H. Staub (Zurich), F. C. A. Trendelenburg (Erlangen), J. Weyssenhoff (Cracow); *Secretary General*, P. Fleury (Paris).

Eight specialized Commissions were authorized to develop international co-operation in the following fields (names of presidents and secretaries are indicated in brackets, with the addresses of the secretaries): Symbols, units and nomenclature (H. H. Nielsen, Columbus, Ohio; J. de Boer, Fineenstraat 28, Amsterdam, Netherlands); thermodynamics and statistical mechanics (J. Yvon, Paris; G. Careri, Universita degli Studi, Rome); cosmic rays (B. Rossi, Cambridge, Mass.; C. F. Powell, H. H. Wills Physical Laboratory, Royal Fort, Bristol 8); very low temperatures (C. J. Gorter, Leyden; D. Shoenberg, Cavendish Laboratory, Cambridge); publications (J. H. Awbery, London; G. A. Boutry, 292 rue Saint-Martin, Paris 3°); acoustics (W. Furrer, Berne; C. W. Kosten, Mijnbouwplein 11, Delft, Netherlands); solid state physics (this commission is composed of three sub-groups): general study (J. C. Slater, Cambridge, Mass.; C. Kittel, Department of Physics, University of California, Berkeley 4, California); semiconductors (A. Joffe, Leningrad; R. A. Smith, Royal Radar Establishment, Malvern); magnetism (L. Néel, Grenoble; L. F. Bates, Department of Physics, University of Nottingham); high-energy physics (C. J. Bakker, CERN, Geneva; R. E. Marshak, University of Rochester, U.S.A.).

International Collegium for Neuro-Psycho-Pharmacology

A MEETING was held in Zurich on September 3 during the Second International Congress for Psychiatry of investigators from different countries for the purpose of founding an International Collegium for Neuro-Psycho-Pharmacology. It was decided unanimously that such a Collegium should be formed with the objects of promoting research and the exchange of ideas, as well as collaboration in the fields of experimental and clinical neuro-psychopharmacology. It is proposed to organize special symposia as well as general meetings. Prof. E. Rothlin (Switzerland) was elected president, and Profs. Trabucchi (Italy), Hoch (United States), Delay (France), Delgado (Peru), Hoff (Austria) and Dr. Shepherd (United Kingdom) as vice-presidents. It is hoped that it will be possible to hold the first international meeting of the Collegium in 1958, and an executive committee, consisting of

Profs. Rothlin and Trabucchi, together with Drs. Deniker (France), Denber (United States), Bradley (United Kingdom) and Radouco-Thomas (Switzerland), was appointed to make the necessary arrangements.

Canadian Federation of Biological Societies

The Canadian Federation of Biological Societies was instituted in Ottawa on October 11. The Federation comprises four member societies: the Canadian Physiological Society, the Pharmacological Society of Canada, the Canadian Association of Anatomists and the Canadian Biochemical Society. The Canadian Physiological Society has been active since 1935. The other three societies have been founded in the past two years; many of their members already belong to the Canadian Physiological Society. However, the rapid growth of these sciences has made it desirable to form societies for the individual disciplines not only to further their development in Canada but also to meet international obligations. The purposes of the Federation are to bring together persons who are interested in teaching and research in the biological sciences, to disseminate information on the results of biological research through scientific meetings and through publication, to encourage exchange of information between constituent societies, and to act for the member societies when it is agreed that concerted action is desirable. At the invitation of Queen's University, the Canadian Federation of Biological Societies will hold its first annual meeting in Kingston, Ontario, in June 1958.

Meteorites Conference in Moscow

A brief report on the seventh Meteorite Conference, which was held in Moscow towards the end of 1956, is published by E. L. Krinov (*Priroda*, No. 7, 57; 1957). The Conference was attended by about a hundred delegates, and thirty papers were read and discussed. A number of papers dealt with the calculation of the orbits of meteorites, which in all cases proved to be elliptical; this suggests that meteorites are derived from bodies belonging to the solar system, most probably asteroids. On the basis of a large number of chemical analyses of meteorites, A. A. Yavnel has concluded that these may be referred to five distinct groups, each group probably corresponding to a parent asteroid. Other topics discussed included meteorite dust, isotopes in meteorites and age of meteorites. A full report will appear in the journal *Meteoritica*.

Harwell Reactor School

The Reactor School at Harwell is to increase the number of courses to be held each year. Four standard courses will be held instead of three, each lasting sixteen weeks (beginning in January, April, September and October), and there will also be two courses for senior technical executives, each lasting nine days (in May and September). Further details can be obtained from the Principal, Reactor School, Atomic Energy Research Establishment, Harwell, Didcot, Berkshire. Applications must be submitted three months before each course begins; the January course has already been filled.

Scholarships Abroad

More than one hundred scholarships are being offered to British students by nineteen foreign countries for study abroad during the academic year 1958–59. The countries offering the scholarships are: Austria, Belgium, Brazil, Denmark, Finland, France, Germany, Iceland, Iran, Italy, Japan, The Netherlands, Norway, Poland, Portugal, Spain, Sweden, Switzerland and Yugoslavia. Most of the scholarships correspond to awards made by the British Council to students from these countries for study in the United Kingdom. The British Council assists in publicizing the offers and in most cases in the recruitment of candidates. Closing dates for applications vary according to the country concerned, the earliest being February 1, 1958. Further information and application forms, for which a stamped addressed foolscap envelope should be sent, can be obtained from any British Council office, or from the Director, Universities Department, British Council, 65 Davies Street, London, W.1.

Announcements

The Order of Merit has been conferred on Lord Waverley, chairman of the Port of London Authority, formerly Lord President of the Council (as Sir John Anderson).

Dr. H. G. Kuhn, reader in physics, University of Oxford, has been awarded a Cherwell Fellowship by the William Waldorf Astor Foundation of New York to enable him to work for a few months at the University of California, Berkeley.

The annual conference of the Geographical Association will be held at the London School of Economics, Houghton Street, London, W.C.2, during December 31–January 3. Further information can be obtained from R. C. Honeybone, University of London Institute of Education, Malet Street, London, W.C.1.

The Radio Industry Council offers six premiums of 25 guineas each, for articles on electronics published in 1957, to any writer not earning his living wholly or mainly by writing. Articles for consideration should be sent to the Secretary of the Radio Industry Council, 59 Russell Square, London, W.C.1, before the end of the year. Six copies, with a signed declaration of the eligibility of the writer or writers, should be submitted.

A post-doctorate fellowship, to commence in the summer of 1958, is available in the Physics Department at Dalhousie University. The fields of research under investigation are acoustics, high-frequency gas discharges, nuclear physics, solid-state physics and theoretical physics. Further information can be obtained from the Physics Department, Dalhousie University, Halifax, Nova Scotia, Canada.

Errata. In the communication entitled "Triphosphopyridine Nucleotide as a Catalyst for Photosynthetic Phosphorylation" in *Nature* of July 27, p. 182, the following corrections are necessary: (1) p. 183, col. 1, line 2, after "vitamin K" insert "(a high concentration of either riboflavin phosphate or vitamin K masks the requirement for triphosphopyridine nucleotide; details will be presented elsewhere)"; col. 2, last sentence in the middle paragraph should read "The reduction of triphosphopyridine nucleotide was not specific; diphosphopyridine nucleotide was also reduced, but in our case at a lower rate (compare ref. 12)"; Table 2, third column units for "(μmoles)" read "(μatoms)".

QUALITY CONTROL IN FOODS

A JOINT meeting of the Association of Public Analysts and the Food Group of the Society of Chemical Industry was held in London during October 3–4 to discuss quality control of food.

The term 'quality control' was intentionally given a very wide interpretation and a diversity of points of view and experience were expressed, including those of the manufacturer, the consumer, and the analyst.

There were three papers concerned primarily with statistics. Dr. E. C. Wood started the series with a relatively simple explanation of the basic concepts, explained many of the terms likely to be used during the symposium, and illustrated simple applications of statistical methods to experimental results. A later paper by Dr. E. H. Steiner went more deeply into the three main sources of error, those due to analysis, sampling and natural variation, and the separation of errors by the analysis of variance. This included valuable advice on sampling procedures appropriate to situations either where the acceptable degree of risk has been predetermined or where there is no previous knowledge of the variation expected.

Mr. J. H. Harries spoke on the validity of organoleptic tests as a means of quality control. He stressed the importance of putting the right kind of question to taste panels, and illustrated his points by reference to a number of score sheets of individual design for the analytical comparison of the qualities of various foods. He directed attention to the possibility of applying multivariate analysis to an examination of the step values in arbitrary scales, and also referred to techniques for avoiding numerical intervals without losing the advantages of statistical interpretation of the data obtained.

A paper on the practical application of statistics to the bacteriological control of canned meats, by Dr. H. Riemann, of the Danish Meat Research Institute at Roskilde, was read by his colleague, Mrs. E. Blomquist, who later gave a paper of her own on another practical example of statistical quality control in the production of luncheon meat. The former directed attention to the relation between batch size, the number of samples tested and the degree of confidence with which it could be assumed that the samples gave an accurate measure of the bacterial quality of the batch. It was pointed out that the sampling methods discussed might give a good picture of general quality, but to safeguard against the occurrence of such dangerous organisms as *Clostridium botulinum*, the number of samples necessary might be unpractical. A most careful watch on raw materials and ingredients and efficient supervision of processes were necessary. The example described in Mrs. Blomquist's paper, although mainly concerned with the mathematics of variations in tare and net weight of cans and the operation of quality control charts, also dealt with some of the practical details, and indicated that such methods are worth while if the findings are used appropriately by the management, and can then be of considerable financial benefit.

Six of the papers were given by technologists from different branches of the food industry. Dr. A. G. Lipscomb described the practical application of quality control methods in the chocolate and confectionery industry. It is necessary to ensure that raw materials conformed to specification in composition and were of the expected flavour; proportioning and processing must be kept within budget limits; the product must reach the standard expected by the consumer and have an adequate shelf-life without loss of appearance or flavour. Physical assessments such as determinations of fat or the particle size in chocolate lend themselves to statistical treatment and to the use of quality charts as a means of judging performance. Comparisons of means and deviations could be utilized to diagnose errors in machine settings. Subjective assessment of raw materials and finished products is essential. Practical advice on experiment design and the management of taste panels was given. The intersection of the curves of cost of production and sale price when plotted against quality show only a restricted area of profitable operation, so quality control alone does not ensure dividends.

Dr. W. B. Adam said that fruit and vegetable canners made only limited use of statistical methods in routine control, but nevertheless such methods had been valuable for specific investigations. He referred particularly to the variability of can weights and filled weights, and the difference between the original weight of fruit in a can and the subsequent drained weight. Subjective assessment, allied to suitably designed score cards, is of great assistance in recording the quality of canned fruit or vegetables, but experienced buyers rely on mental integration of their observations rather than on mathematical calculations. Mechanical aids such as the tenderometer used for forecasting the optimum maturity of a pea crop were briefly described and explained.

Dr. R. J. MacWalter spoke on quality control in milk and dairy products. The relations between producer and buyer of milk are somewhat unusual, since apart from the brief judgment of an expert nose the quality of milk is probably not known until after it has been accepted, bulked, pasteurized and passed on. Nevertheless, a number of tests are applied to samples before distribution to ensure conformity with legal requirements, efficiency of heat treatment, freedom from contamination and control of measure in bottle. Reference was made to the problems of sampling evaporated or sterilized milk products in order to reach an adequate degree of assurance that the product is safe and the spoilage rate minimized. Grading methods for cheese and butter were mentioned. A graphic illustration was given of the relationship between bacterial contamination counts and standards of factory hygiene in rival creameries.

Quality control of open packed meat products was discussed by Mr. S. Brightwell. Variability in availability of raw material complicates the maintenance of uniform quality in sausages. Several sensory qualities by which they are judged—such as juiciness, texture and flavour—are not easily assessed numerically or given definite weighting. It is important to trace the causes of reported variations in quality. It was noted that tasters' views on saltiness do not necessarily agree with chemical analyses, and a seasonal variation in the sensitivity of panels to saltiness was mentioned. A sensory assessment by an expert might be accepted in preference to a laboratory report where these were in conflict.

It is difficult to measure dough so accurately that after baking all loaves or all biscuits will fall within a narrow weight-range. Dr. R. Falconer described how control charts could profitably be used to give warning that re-adjustment of machines was desirable, and spoke of the possibility of extending the application of appropriate methods to other observations necessary for good management in the baking industry.

The fish industry depends in no small measure on the Department of Scientific and Industrial Research for technical guidance. Industry has felt a need for better methods of control of quality, and practical help has been given by introducing well-organized subjective assessments and by compiling scientific data. Dr. C. L. Cutting mentioned in particular a system of grading kippers which the industry has welcomed and which may lead to improved quality. The occurrence of parasitic worms in fish from certain fishing grounds has been studied statistically and constructive recommendations formulated.

An interesting paper from quite a different aspect of the subject was given by Dr. R. A. Scott on the automatic control of proportioning and mixing. He gave details of practical methods of measuring liquids and powders, and of various types of automatic weighing and delivery devices, culminating in explanatory diagrams of fully automatic plant for weighing, delivering and mixing six or more ingredients according to formulæ fed to a control panel on a punched card. In such systems there are devices designed to eliminate as many as possible of the known causes of undesirable variation.

The factory manager's outlook on quality control was indicated by Mr. M. Bogod. Such control is welcome where it is an aid to economical production, improved service to customers or conformity with legal obligations. So far as possible, interference with the flow of production should be avoided. Sometimes the nature of the control can be designed so that automatic adjustments can be made to correct undesirable trends. Great importance is attached to cordial co-operation from operational and supervisory staff. This can be achieved only where they understand how quality control can improve matters. The spot judgment of expert individuals is usually preferable to that of taste panels in detecting deviations from the normal in flavour or appearance.

Public analysts exercise quite a different form of quality control. Mr. E. G. Whittle expressed their point of view. They are concerned first with compliance with legal requirements, and secondly that foods conform to what the customer is led to expect. It is often difficult to decide desirable limits of variation of quality in foods, but the Association of Public Analysts has a part in helping the Foods Standards Committee to reach conclusions on these matters. Statistics have been valuable to analysts in agreeing on the natural limits for the freezing point of milk and to a lesser extent in accounting for the effects of natural variation in raw materials used in food such as jams. The work of a magistrate's court would not, however, be made easier if a public analyst expressed his findings in terms of statistical probabilities.

Mr. D. H. Pickard brought to the symposium his views on quality as a market research worker. He pointed out that the consumer in his judgment of quality uses very different criteria from those of the manufacturer or public analyst. They are influenced not only by the inherent qualities of a food product but also by imputed qualities. Appearance, for example, affects taste discrimination. Imputed qualities may sometimes appear to be irrational, but they are of real importance. Mr. Pickard described statistical methods of market research which are relevant to ascertaining consumers' ideas of quality. The importance of directing research to the asking of the right questions was illustrated.

There was a short discussion at the end of each session and a general discussion on the last afternoon before Dr. A. J. Amos gave a final summing up.

It was evident that not all food technologists were expert in mathematics, and the suggestion naturally arose that opportunities should be provided for teaching them statistics. It was agreed that the various forms of quality control used should be explained to all production personnel. The colleges of food technology teach students these methods, but factory staff in general can best be reached by instruction given within their firms.

The advantages of early consultation with statisticians in the design of experiments was recognized. Co-operation between statisticians and food technologists might be necessary when using the less-simple techniques and both should know something of the others' subject. In some factories quality control has led to the elimination of excessive overweight once necessary to compensate for possible inaccuracies, and reduced costings have more than offset the cost of control.

Fatigue and bias among tasters were discussed. For some routine purposes fatigue did not reach critical importance, but where special discrimination was needed the number of samples compared should be small, possibly not more than two or three at a session.

In checking the composition of products such as jams or meat or fish pastes, analysts allow for some variation in the composition of raw materials. Manufacturers sometimes find that quite genuine raw materials occasionally fall short of the usual lower limits for some characteristic, and they suggest that analysts should therefore take wider limits as a basis for their calculations. Public analysts, on the contrary, suggest that raw material should not be used if it is of abnormally poor quality, however genuine. A fear was expressed that the setting of minimum standards may cause a decline of average quality towards that minimum. Although it was suggested that the need for standards was sometimes over-emphasized, the general view seemed to be that standards usefully show what the most indiscriminating customer has a right to expect, but do not necessarily represent what the discriminating customer wants. The manufacturer may be tempted by the complaisant consumer into a debasement of quality, and the analyst must strengthen the resolution not to succumb. Some quality-conscious people may be difficult to satisfy because their tastes are not sufficiently widely shared. It would be regrettable if standardization, in protecting the heedless, reduces the competition between manufacturers, thus depriving the good housewife of the pleasure of exercising individual skilful selection.

This symposium undoubtedly helped participants to realize that both public analysts and food manufacturers are interested in their own ways in service to the public. Co-existence may be the happier as a result of better appreciation of the reasons underlying each other's actions.

BIOCLIMATOLOGY AND BIOMETEOROLOGY

THE International Society for Bioclimatology and Biometeorology, which was founded in 1956 for the purpose of bringing together all kinds of people interested in the effects of climate on life, held its first congress in Vienna during September 23–27. The congress was attended by about one hundred scientists from most parts of the world, and it provided an opportunity for set talks on selected topics, short communications and lively discussions.

One of the aspects of climate which has been so far little-understood is ionization of the atmosphere. The term itself is vague, and it was obvious that ionization could mean cosmic rays, or normal components of the air electrically charged, or small suspended particles of the order of $0 \cdot 1\mu$ in diameter which can be detected by their electrical charges, or even ordinary dust. Experiments to study how specific sensations are related to ionization are difficult to control, but some work in the United States has suggested that sensations of 'stuffiness' in rooms are connected with ionization of the air, and good evidence was presented that attacks of bronchial asthma are related not so much to the presence of allergens in the air as to the simultaneous presence of allergens and certain conditions of ionization. Contributions on this subject by Dr. J. C. Beckett, of San Francisco, Dr. I. H. Kornblueh, of the University of Pennsylvania, and Dr. S. W. Tromp, of Leyden, made it seem probable that this may develop into an exciting field of investigation, not into an outlet for cranks smelling electricity.

Zoologists and botanists are becoming increasingly concerned with microclimate and its effects on life. Thus the temperature, humidity, air movement and heat radiation near the ground can be so widely different from conditions prevailing near the tree-tops in a forest that it is useless to consider only the climate of a forest as a whole, and microclimate must be studied in detail. Dr. R. B. Platt, of Emory University, Georgia, provided data about gradients of temperature and humidity in woods and in open fields, and Dr. V. Pasak, from Czechoslovakia, presented evidence that weeds growing in neglected woodlands interfere with the growth of new trees by their unfavourable effects on the microclimate near the soil. Outstanding among the zoologists' contributions was a well-illustrated account by Dr. R. C. Ramey, of London, of locust migration in Africa, which showed that the only relevant factor in directing locusts towards one area or another is the wind, while the insects in the swarm fly about apparently aimlessly and in circles. Another valuable contribution originating in Africa was that of Dr. Cloudsley-Thompson, of the Department of Zoology, King's College, London, who has studied the behaviour of some terrestrial arthropods which, like woodlice, lose water easily, and who produced evidence that the habits and habitats of such arthropods are related to their needs for preserving body water.

The tremendous possibilities for bioclimatological studies in tropical veterinary medicine were skilfully reviewed by Dr. J. D. Findlay, of Ayr, Scotland, who showed how milk yields could suffer at high temperatures and described some of the physiological work carried out at the Hannah Dairy Research Institute in Ayr, while another stimulating talk by Dr. R. Koller, from Austria, reviewed the problem in relation to animal husbandry in a temperate country with a cold winter and concluded that cattle did better, on the whole, in stables than out of doors when the weather was cool.

A particularly valuable aspect of such a conference is the possibility of discussing intricate problems which have a bearing on several fields of research. Town planning in relation to climate is such a problem, and outstanding contributions about this came from Dr. Vigan, of France, who discussed plans for workers' cities being built in the Sahara, and from Mr. Page, of the University of Liverpool, who surveyed problems of environmental comfort in houses not only from the engineering, physiological and æsthetic aspects, but also in relation to what is considered comfortable by different people. An interesting point made by Dr. Vigan, in reply to a question, was that tropical neuroses are infrequent among workers in the Sahara; this he attributed to the fact that the workers were there to do a useful job (though this could be connected with the fact that the weather in the Sahara is less uniformly warm than in equatorial regions, where neuroses are common).

The problem of adaptation to environment was approached in several ways. Prof. Pichotka, of Germany, showed not only that slices of potato metabolized at a lower rate in a cool medium than in a warm one, but also that they continued at a lower metabolic rate after leaving the cool medium, or at a higher rate after leaving the warm medium. This was particularly interesting, because these findings, obtained in cross-over experiments, resembled similarly crossed-over data obtained in mice and men and presented by Dr. J. S. Weiner, of the Medical Research Council Climate and Working Efficiency Laboratories, Oxford, who showed, among other things, that mice reared in a hot environment survive heat stress better than those reared in a temperate one. Though some adaptations, especially those in potato slices, must be brought about by changes in enzyme systems, the central nervous system appears to play a fundamental part in adaptation to climate in man, and evidence about this was presented by Dr. E. M. Glaser, of the London Hospital Medical College. Other evidence which implied the existence of central nervous adaptation came from Dr. H. Jungmann, of Germany, and Dr. M. Halhuber, of Austria, who had jointly studied acclimatization in the Alps at moderately high altitudes.

When considering the general effects of weather on health and sensations, speakers were perhaps on slightly more shaky ground, and this was forcibly pointed out by several speakers, including Prof. H. Berg, of Germany, one of the vice-presidents of the Society. Statistical evidence was produced, for example, that certain conditions, such as emboli of the heart, are more frequent in some than in other kinds of weather, but both the material and its statistical treatment were inconsistent, and the very definitions of the weather with which the clinical findings have been correlated were unsatisfactory. This branch of bioclimatology suffers, more than any other, from obscure terminology and meaningless notions such as 'sensitivity to weather' (*Wetterfühligkeit*), 'vagotonia' or 'meteorological fronts'. But the congress did some good in discouraging notions or lines of research which are unintelligible without an excess of imagination. One of the most valuable aspects of the congress was that it provided an opportunity of revising fundamental notions borrowed from other branches of science which have been modified or invalidated by recent work.

The chairman of the congress was Dr. Fred Sargent, professor of physiology in the University of Illinois (who is now spending one year at the Medical Research Council Climate and Working Efficiency Research Unit in Oxford). Dr. J. L. Cloudsley-Thompson, of the Department of Zoology, King's College, London, was elected to the Council of the Society. The Society has begun publishing the *International Journal of Bioclimatology and Biometeorology*, and the proceedings of its first congress will appear in that journal. The second international congress of bioclimatology will be held in 1960, and England and Scotland have been mentioned as possible places for it. Information about the Society can be obtained from its secretary, Dr. S. W. Tromp, Hofbrouckerlaan 54, Oegstgeest, Leyden, Holland, or from its representative in Great Britain, Dr. E. M. Glaser, Department of Physiology, London Hospital Medical College, Turner Street, E.1. Candidates for election must be actively engaged in some field of bioclimatology or biometeorology, they must be proposed by two members, and they must be approved by the Council. The business of the Society is transacted mostly in English. E. M. GLASER

TRANSISTOR TECHNOLOGY

A CONFERENCE on transistors, organized by the Electronics Group of the Institute of Physics, was held at the Brunel College of Technology, Acton, during September 27–28.

In almost every field of endeavour, the rate of progress largely depends on the facilities that exist for discussion and for exchanging information. This is particularly true when the available resources are scattered over a large number of industries, government and educational organizations, as is the case with the work on transistors. In the United States, professional societies and educational establishments seem to delight in organizing symposia and conferences, whereas in Britain there appears to be less inclination for activities of this kind; one hopes, therefore, that the success of this conference will provide a suitable stimulus to others.

Dr. M. E. Haine, chairman of the Electronics Group, explained that the topics had been chosen in such a way as to provide a broad picture of the wide range of activities that are embraced by transistor technology. Thus, the conference was less concerned with thrashing out points of detail than with providing an opportunity for those who are concerned with the details themselves to see a general picture.

The first paper, on "The Effect of Physical Properties of a Semiconductor on Device Characteristics", was given by Mr. D. D. Jones (General Electric Co.). In discussing the high-frequency performance of alloy transistors, he showed that the mobilities of both the majority and the minority carriers must be taken into account; the relative merits of *n-p-n* and *p-n-p* structures largely depend on the degree of avalanche multiplication that is characteristic of the carrier-depletion regions of thin collector junctions. Mr. Jones indicated which physical properties are important in the design of high-speed switching transistors and of power transistors. He also discussed the relative merits of germanium and silicon as transistor materials.

In the next paper, Dr. W. Bardsley (Royal Radar Establishment) discussed "Defects in Transistor Materials", and, in particular, mentioned the effects of chemical impurities, particle bombardment, and dislocations in the crystal structure. A typical chemical defect, that can have a marked effect on the electrical performance of the semiconductor, is the presence of oxygen in silicon. Defects created by particle bombardment, for example, by means of neutrons, can often be removed by annealing. Dr. Bardsley described various techniques, such as etching and the use of X-rays, for revealing the presence of dislocations in crystals. Finally, he spoke of interactions between defects; thus interactions between dislocations and oxygen content can affect the heat treatment properties of silicon.

Mr. J. G. Cressell (Marconi) opened his paper on "Power Transistors" by recounting the main steps by which progress has been made in this field. First, there was Webster's analysis of the variation of current gain with emitter current, which showed how emitter efficiency, bulk recombination and surface recombination play their part. The development of new alloys to give high emitter efficiency and of techniques to produce thin base regions were two practical steps of major importance. Fletcher's study of the transverse field in the base region led to a reconsideration of the optimum geometrical arrangement. Mr. Cressell then described how both carrier life-time and surface recombination velocity can show substantial variations with emitter current, and how these effects become important in high-power transistors.

The design of high-frequency transistors presents a considerable challenge. In describing "A New High-frequency Germanium Transistor", Mr. J. S. Lamming (General Electric Co.) first discussed the principle of Kroemer's drift transistor; in this a gradation in the conductivity of the base region creates a drift field which reduces the transit-time for minority carriers. One of the most attractive ways of producing a graded base region is to diffuse the impurity atoms into the region. In Mr. Lamming's technique of 'post-alloy diffusion' the emitter is alloyed on to a base region of uniform conductivity. The emitter alloy is made to contain known quantities of *p* and *n* impurities, the segregation and diffusion coefficients of which are carefully chosen. After alloying, the emitter is *p*-type. The structure is then heated to such a temperature that diffusion takes place, the coefficients being such that the diffusion is predominantly that of the *n* impurities. This technique enables very narrow base regions, with the desired gradation of conductivity, to be achieved.

Dr. J. T. Kendall (Texas Instruments) reviewed the situation of "Silicon Transistors". He mentioned how the difficulty in producing silicon of adequate purity and of keeping it pure during subsequent processing had delayed the development of these devices. The alloy process, so successful with germanium, had proved difficult with silicon and, as a result, most of the progress has been achieved with other processes, such as double-doping during crystal growing, grown-diffusion, melt-back diffusion, and double-diffusion. Dr. Kendall also made an objective comparison of silicon and germanium transistors, stressing the advantages of the former in high-temperature applications.

In a conference where one often heard of the need for semiconductor materials of high quality, it was interesting to hear of some of the chemist's difficulties in Mr. J. M. Wilson's (Standard Telephone Laboratories) paper on "The Preparation of Very High Purity Silicon". The high segregation coefficient of boron makes it very difficult to purify by means of the zone-refining technique, which has been used so successfully with germanium. After reviewing a number of methods, Mr. Wilson described his work on a process which starts with the thermal decomposition of silane (SiH_4). The silicon can be produced in a crystalline form without having to use crucibles; this feature is attractive in view of the high reactivity of silicon with the crucible materials.

Dr. A. F. Gibson (Royal Radar Establishment) dealt with "Avalanche Injection" and the possibility of utilizing it in certain devices. When the field across a filament of *n*-type germanium exceeds a critical value, avalanche multiplication gives rise to a rapid increase in conductivity; as a result, the voltage–current characteristic exhibits a negative resistance region, similar to that obtained with a gas discharge tube. In order to limit the current, and hence the dissipation, in the high-current condition, the area of one of the contacts to the germanium is made small. Dr. Gibson then discussed a device, having two $n+$ contacts and one $p+$ contact to the germanium, which is analogous to the thyratron, and in which the current flowing into the $p+$ contact controls the voltage-current characteristic at the other two.

Dr. D. F. Taylor (Ferranti), in a paper on "Improved Junction Fabrication", dealt mainly with the problems of making alloyed junctions in silicon. He considered the conditions that are necessary for regrowth to take place. He showed that, when alloying an aluminium wire to a silicon wafer, if, during the cooling cycle, the wire is maintained at a higher temperature than the molten region no regrowth takes place; Dr. Taylor suggested that the reason why good diode characteristics are obtained under these conditions is that diffusion takes place at the alloy/silicon interface during the alloying. Finally, he considered some aspects of the 'limited' type of alloy process, such as takes place when a small 'dot' is alloyed to a silicon wafer.

The last paper in the conference was given by Dr. M. Smollett (Mullard), whose subject was "Germanium Photo-transistors". After considering the creation of hole–electron pairs in germanium when light shines on it, he described the photo-electric properties, including the spectral response, of a *p–n* junction diode in which the *p*-region is made very thin. He then analysed the operation of the photo-transistor, which differs from the diode in that it can produce substantial multiplication of the current that is produced by the hole–electron pairs that are generated by the incident light. Possibly their main disadvantage is the fact that hole–electron pairs produced by thermal agitation also contribute to the output current; Dr. Smollett indicated ways of minimizing this.

Each paper was followed by a discussion, during which many useful and stimulating comments were made.

HERRING IN THE NORTH SEA

In 1955 the East Anglian herring fishery failed. This is a drift-net fishery which exploits different populations during October and November, and its success is to a large extent dependent on the dates of the full moons which, though not propitious for the 1955 season, could not possibly provide the complete reason for the failure. However, several changes had taken place since the Second World War. In 1948 the Danes started trawling for young immature herring and they were followed by the Germans, Dutch and French. These 'industrial' herrings were used for processing into fish meal. While the catches were at first insignificant they increased enormously during the following seven years until the number of herrings trawled far outnumbered those caught during the East Anglian fishery. Another rapid development since 1951 was the trawl fishery for adult herring in the Channel and North Sea Southern Bight by German, French, Dutch, Belgian, Polish and Icelandic fishermen. The landings from this new fishery have led to what might appear to be a shift from the fish being landed by drifters to being landed by trawlers. Coincident with these changes in the fisheries there have been changes in the environment (for example, the amount of food (*Calanus*) available) and in the biological characters of the herrings (as, for example, the mean length at various ages and, apparently, age at first maturity).

In a recent fishery investigation, published under the title "On the Herring of the Southern North Sea"*, Dr. D. H. Cushing and Mr. A. C. Burd have attempted to sort out these complexities, about which fishery biologists and fishermen have strong and divided views.

Their paper consists of four parts, the first of which, by Dr. Cushing, is concerned with the homogeneity and character of the Southern Bight stocks. In the second part he considers the natural changes that have occurred in the populations, changes among others, in age distribution, length, nature of recruitment, in the environment and in the fishery. Part 3, by Mr. Burd, discusses the changes that can be ascribed to fishing, while in the last section Dr. Cushing considers the effect of fishing on the stock. It is impossible in a review of this length to discuss their evidence in detail, but it leads them to believe that, through the advance in maturity, the fish are caught sooner in their life and this reduces the older age-groups which, together with the southern North Sea and Channel trawl fishery, reduces the November East Anglian catches of older fish. The danger caused by 'industrial' fishing of immature herrings receives a verdict of 'not-proven'. These conclusions should be put in perspective by pointing out that Dr. W. C. Hodgson, and many of the fishermen themselves, believe that this 'industrial' fishing to the north provides at least part of the explanation of the failure, and probably a large part.

Perhaps the wisest words in this paper are in Mr. Michael Graham's preface: "Dogmatism is out of place in this subject, . . . and in addition, data on highly migratory fisheries are always difficult to interpret".

T. B. Bagenal

VIGILANCE AND THE INSPECTION PROBLEM

A STUDY of continued alertness and its implications for examining work in industry has been made by W. P. Colquhoun, of the Applied Psychology Research Unit, Medical Research Council (*Personnel Management*, 39, No. 341; September 1957).

Laboratory studies of vigilance tasks have demonstrated conclusively that the ability to detect small changes in a display declines considerably within thirty minutes of beginning a watch. Circumstances which have been shown to enhance the effect are the presence of ambient noise, high environmental temperature, and loss of sleep beforehand. Alterations in illumination of visual tasks do not prevent deterioration with time, but produce differences in the over-all level of efficiency. Differences in over-all efficiency have also been found to exist between individuals, and have not, so far, been accounted for. Individuals also vary in the extent of the time decrement they show, but this appears to be unrelated to initial ability. The effects of isolation of the observer have been shown to be deleterious; but, on the other hand, the presence of too many other people tends to distract the worker from his task.

Earlier researches investigated the effects of changes in the externally imposed conditions under which the task was performed; the importance of both environmental and motivational factors were discovered. More recently, interest has centred on the determinants of efficiency that are inherent in the work-situation. It has been shown that uneven spacing of the signals along the time-scale is one of the most important factors likely to cause loss of alertness during prolonged work.

Understanding of the causes of the decline in efficiency of signal detection with time is by no means complete. It is well known that 'mental' fatigue, a state that arises with continued performance of the same task, is characterized by a fall in work output, a widening of subjective tolerance and an increased variability in both accuracy and in the timing of responses. In the vigilance situation, responses are usually of the all-or-none variety, and work-output a difficult concept to apply; but a widening of subjective tolerances might result in an increased effective threshold to display changes, so that differences must be larger before they are detected.

Colquhoun reviews the extent to which these experimental findings are relevant to the practical problems of examination and checking in the factory itself.

The response required of the examiner is rather more elaborate than it is in the laboratory; thus he must either pick up the defective article and place it aside, sort the objects in some way, or mark the defective part of a large article with chalk or similar material. He may also be required to enter his observations on a work sheet. If the object is of any size or complexity he may have to manipulate it so that all parts of it are examined.

Noise, atmospheric conditions and lighting may be expected to vary widely between workplaces, as do the actual layouts of particular jobs. Though there are cases where the inspection is completely machine paced, more often the examiner has a degree of control over his speed of work which allows him to take rests in addition to those officially sanctioned. If a quality bonus system is in operation it becomes important not only to detect faults, but also to avoid rejecting good items.

Information about the efficiency of his work only reaches the examiner after a considerable time delay, either from subsequent check inspection, the occurrence of later processing faults or from customers' complaints.

The main difference in the internal structure of the tasks lies in the greatly increased number of signals, mainly 'unwanted' ones, that arrive in a given time.

It is quite common for one examiner to check thousands of items in a day's work, in which the number of rejects may vary from one to hundreds. Although the temporal occurrence of faults is unpredictable, the mean interval between them may sometimes be only of the order of seconds, as compared with the minutes usual in laboratory and military tasks. The accuracy of the discriminations required, on the other hand, may be extremely fine, but these fine discriminations may only be necessary at relatively infrequent intervals, particularly if the defect being sought varies in magnitude over a wide range. These latter factors in turn affect the nature of the response. It may not be sufficient for the examiner to divide the items into 'passes' and 'rejects'; he may be required to grade them into several categories, both of 'good' and 'bad', and also to sort them into kinds of defect. This kind of activity requires decision-taking and the exercise of judgment.

In inspection work only signals which fall outside given tolerance limits are responded to. Tolerance limits are normally laid down in the specification of the particular article being examined, but in many cases they can be varied from time to time to match fluctuations in general trade, or to suit the requirements of a particular customer. Here there is clearly room for a considerable degree of subjective estimation. It appears that the examiner's work is considerably more complex than is the subject's in the sort of task that has usually been set in experimental studies of vigilance. Relatively little study has in the past been devoted to the inspection problem from this point of view.

More information is needed on the effects of various conditions on inspection efficiency. To this end a device has been constructed at the Applied Psychology Research Unit of the Medical Research Council which presents a simulated visual examination task to the subject. The flexibility and comparative simplicity of the apparatus make it suitable for the study of a wide range of inspection problems which include:

(1) *Inherent task-conditions.* Under this heading it will be possible to investigate the effects on efficiency of varying: (*a*) the frequency of faults; (*b*) the type of fault; (*c*) the difficulty of the discrimination required; (*d*) the number of objects displayed simultaneously; (*e*) the number of dimensions on which the objects vary; (*f*) the temporal structure of the sequence of faults; (*g*) the distribution of faults of different kinds and degrees; (*h*) the 'meaningfulness' of the task, that is, the nature of the objects to be examined; (*i*) the number of classes into which the objects must be sorted; (*j*) the number and nature

of 'additional' operations required (for example, 'booking').

(2) *External conditions*. These include variables like: (*a*) the speed at which the task must be performed; (*b*) the total length of the task; (*c*) the frequency of the rest-pauses; (*d*) the effects of various kinds of interpolated activity during breaks on subsequent performance; (*e*) the degree of isolation of the subject; (*f*) illumination, contrast, noise and atmospheric conditions; (*g*) time of day or night, lack of sleep; (*h*) knowledge of results, that is, awareness of performance efficiency; (*i*) amount and nature of reward, that is, incentive systems; (*j*) presence or absence of objective reference standards, and their intermittent variation.

(3) *Individual variability*. It is predicted that subjects will vary widely in their performances. It is hoped to relate these differences to measures of intelligence and personality, and to the extent of previous experience at similar tasks.

It is hoped that initial experiments will disclose the more important conditions which can then be studied in more detail. The laboratory studies will be followed up, where possible, by actual observations 'on the job'. Any information on the efficiency of inspection would have a value for industry where inspection processes will rise as production becomes more automatic.

In order to ensure that people work at their maximum efficiency it is essential to understand both the nature of the inspection process and the optimum conditions under which it should be carried out.

DOSE-RATE EFFECTS IN RADIATION-INDUCED CHEMICAL REACTIONS

By Dr. H. C. SUTTON and Prof. J. ROTBLAT

Physics Department, The Medical College of St. Bartholomew's Hospital, London, E.C.1

THE initial stages of chemical reactions induced by ionizing radiations are usually assumed to be independent of the dose-rate. Thus, in the case of a simple reaction in aqueous solution, such as the oxidation of ferrous sulphate induced by high-energy radiations, the yield remains constant at the highest dose-rate hitherto studied[1], namely, 10^6 rads/sec. If, however, the radiation intensity is increased to such a degree that the reaction zones of clusters of radicals formed by neighbouring ionizing particles overlap, then the yield of the reaction should show a dose-rate dependence due to the increase of concentration of radicals. Dose-rates much higher than the above value can be produced in the travelling wave linear accelerator, in which the acceleration of electrons takes place in pulses of short duration.

The 15 MeV. linear accelerator at St. Bartholomew's Hospital[2] is capable of producing beams of electrons in pulses 1·3 μsec. wide, and at dose-rates up to 20,000 rads per pulse. A continuous variation of the dose-rate by a factor of 10^4 can be achieved by decreasing the current through the gun filament. Another facility provided in this machine is a variable repetition-rate of the pulses.

This accelerator was employed in an experiment to study the variation of yields of chemical reactions with dose-rate. Two reactions were studied: the reduction of aerated solutions of ceric ammonium sulphate in 0·8 *N* sulphuric acid, and the oxidation of ferrous ammonium sulphate in an identical solvent. Possible errors in dosimetry were avoided by passing the electron beam through a system of two cylindrical 'Pyrex' vessels, joined by a common wall. The rear vessel, which was always filled with ferrous sulphate, was employed as a chemical monitor, while the near vessel was alternatively filled with ceric and ferrous sulphate. In order to avoid errors associated with intensity variations across the beam, the diameter of the vessels was made considerably larger than the beam width. In consequence, the solutions were exposed to a range of dose-rates distributed in the same manner in each experiment. The dose-rate given in Fig. 1 is the energy-averaged value in the near vessel, during each pulse. The dose-rate at any point did not exceed twice this value, and more than 85 per cent of the total energy was delivered at dose-rates greater than 40 per cent of the average value. A dose of not more than 30,000 rads over the irradiated volume was delivered at a time. The number of pulses needed to give this dose varied from 1 to 10^4 depending on the dose-rate. When larger total doses were required the solutions were stirred between exposures. At each dose-rate the ratio of the yields of the iron and cerium reactions, G^{Fe}/G^{Ce}, was determined. The results are shown in Fig. 1, from which it is seen that this ratio decreases steadily, starting from a dose-rate of about 10^7 rads/sec.

We attribute this effect to an increase in radical concentration with increasing dose-rate resulting from the overlapping of the reaction zones of radical clusters. The following evidence supports this interpretation.

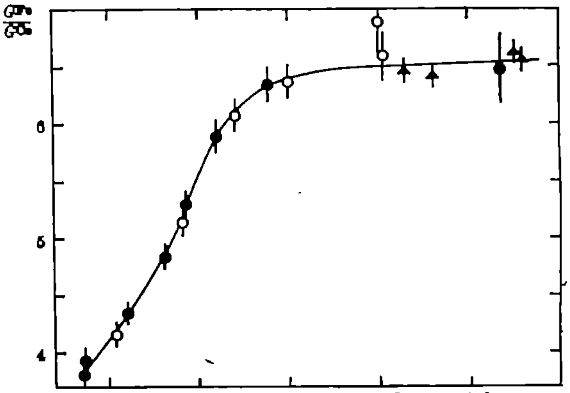

Fig. 1. The effect of dose-rate on G^{Fe}/G^{Ce}. Solutions were irradiated in vessels: 2 cm. diameter, ●; 5 cm. diameter, ○; and 1 cm. width in a uniform radiation field, ▲

(1) If such overlap occurs, then the yield of inter-radical reactions to form the molecular products hydrogen and hydrogen peroxide should increase with dose-rate, at the expense of radical–solute reactions. This would cause the ratio $G^{\mathrm{Fe}}/G^{\mathrm{Ce}}$ to decrease with increasing dose-rate, as observed.

(2) The yield obtained with radiation of low ion density but high dose-rate should simulate that produced by radiation at a low dose-rate but high ion density. For X-rays producing secondary electrons of average energy of about 20 keV. a value of 4·9 for the ratio $G^{\mathrm{Fe}}/G^{\mathrm{Ce}}$ has been observed[3]. At this low energy the ion density is approximately 16 ion clusters per micron of electron path, giving an initial mean distance between the centres of adjacent radical clusters in the same electron track of about 625 A. In our experiment this value of the ratio of $G^{\mathrm{Fe}}/G^{\mathrm{Ce}}$ was observed at a dose-rate of 2,800 rads per pulse. Assuming a mean energy expenditure[4] per cluster of 110 eV., and that the mean life-time of the clusters is long compared with the pulse duration, we obtain a mean distance between cluster centres at the end of each pulse of 860 A., in good agreement with the above value.

(3) The assumed competition between radical–radical and radical–solute reactions in overlapping zones should be influenced by variations not only of dose-rates but also of solute concentrations. In confirmation of this we have observed (*a*) that the addition of 5×10^{-3} *M* cerous sulphate to a ceric sulphate solution before irradiation lowers G^{Ce} to 66 per cent of its normal value at 10^{10} rads/sec.; at dose-rates lower than 10^{7} rads/sec. the corresponding decrease was only to 93 per cent, and (*b*) if a ferrous sulphate solution is equilibrated with oxygen instead of air before irradiation, then G^{Fe} is raised by 13 per cent at $1 \cdot 3 \times 10^{10}$ rads/sec. as compared with 2·5 per cent at low dose-rates. Variations of the ceric ion and ferrous ion concentration have little effect. We conclude that the solute competing for hydroxyl radicals in the cerium system is cerous sulphate, at least when present in excess; and that the solute competing for hydrogen atoms is dissolved oxygen.

(4) It might be argued that accumulation of hydrogen peroxide at high dose-rates may be responsible for the variation of $G^{\mathrm{Fe}}/G^{\mathrm{Ce}}$. This is easily refuted by consideration of the life-time of hydrogen peroxide in the irradiated solution in relation to the total treatment time, and by the further observation (see below) that $G^{\mathrm{Fe}}/G^{\mathrm{Ce}}$ is not influenced by variations of the interval between pulses.

In the experiment described, only the yield ratios of the two reactions could be determined. A method has since been developed, using a different type of irradiation vessel, to determine the variation of the two reactions separately. Preliminary results show that most of the observed variation with dose-rate is due to the cerium system. This is as to be expected, since a small fractional increase in the yields of the molecular products hydrogen and hydrogen peroxide would influence G^{Ce} more than G^{Fe}. This is also in accord with the observations mentioned under (3) above. A detailed study of the two systems is in progress.

Apart from establishing the dose-rate effect, these experiments enable us also to make some guesses about the life-times of the radicals. From considerations of the time required for radicals to diffuse the distance between clusters, we can obtain a minimum value for their life-time on the assumption that a reaction occurs at every collision of two radicals from neighbouring clusters. From the shape of the curve in Fig. 1, together with an assumed value for the diffusion coefficient of the radicals (2×10^{-5} cm.^{2} sec.$^{-1}$), we deduce that this minimum value is 0·5 μsec.; the actual value is probably much greater than this. On the other hand, from the observed fact that a variation of the pulse repetition-frequency from 400 per sec. to 1 per 20 sec. did not affect the value of the ratio $G^{\mathrm{Fe}}/G^{\mathrm{Ce}}$, we conclude that the radicals formed in one pulse must be destroyed in less than 1/400 sec.; this gives an upper limit for the life-time of 2·5 msec. Experiments are now in preparation to narrow down these limits.

These investigations form part of a programme of research carried out with the aid of grants provided by the Treasurer and the Board of Governors from the Discretionary Fund of St. Bartholomew's Hospital, to whom we wish to express our gratitude.

INSECTICIDE RESISTANCE IN *ANOPHELES SUNDAICUS*

By G. DAVIDSON

Ross Institute of Tropical Hygiene, London

RESISTANCE to DDT in *Anopheles sundaicus* in Java was first reported by Crandell[1] in 1954 in an area where house-spraying with this insecticide had been carried out for the previous three years. Chow[2] later confirmed such resistance in another area, and I was privileged to visit the island in 1955 and report on the situation for the World Health Organization.

In July 1956, Prof. C. Y. Chow, World Health Organization entomologist, was kind enough to send to the Ross Institute in London eggs of DDT-resistant *A. sundaicus* from yet another area of Java where resistant mosquitoes had recently appeared. A thriving colony of this strain was soon established in London. Repeated attempts by Mr. S. Sundararaman, World Health Organization entomologist, to dispatch eggs of susceptible mosquitoes of the same species from Java to London met with no success, however. A susceptible strain of *A. sundaicus* was eventually obtained from Malaya, through the courtesy and repeated efforts of Mr. J. A. Reid of the Institute for Medical Research. Great difficulty was experienced in colonizing this susceptible strain, and it is only in recent weeks that sufficient numbers of mosquitoes have been reared to enable a solution of the problem of resistance in this species to be achieved.

Table 1. Median Lethal Concentrations (percentages in Risella Oil) of various Insecticides when Susceptible and Resistant Strains of *Anopheles sundaicus* are exposed for One Hour

Numbers of mosquitoes tested at concentrations giving more than 0 and less than 100 per cent mortalities are given in brackets

Insecticide	Susceptible		Resistant	
	Java strain (in Java)	Malaya strain (London colony)	Java strain (in Java)	Java strain (London colony)
DDT	0·5 (159)	0·3 (278)	9·0 (165)*	> 4·0 (565)
Dieldrin	0·065 (206)	0·032 (321)	0·08 (527)	0·038 (420)
Gamma-BHC	0·008 (86)	0·003 (290)	0·0085 (151)	0·006 (192)
Aldrin	0·37 (101)		0·4 (171)	

* Interpolated from logarithmic-probability graph from only two mortalities.

The two strains of the same species have now been compared for their susceptibilities to a range of insecticides using the technique described by Busvine in an annex to the Fifth Report of the World Health Organization Expert Committee on Malaria[6]. This technique involves the exposure of mosquitoes to filter paper impregnated with various concentrations of insecticides in Risella oil for 1 hr. and recording mortalities 24 hr. later. Table 1 records the median lethal concentrations of four insecticides after this 1-hr. exposure, both in the laboratory colonies and in the field.

The resistant strain is seen to be resistant to DDT but not to the other three insecticides. The differences between the field and laboratory results can be accounted for by the fact that, in the field, wild-caught, blood-fed, semi-gravid and gravid females were used for the tests, while in the laboratory the more susceptible unfed females and males were used.

In addition to these insecticides, laboratory-reared mosquitoes of the two strains were exposed to three DDT-analogues with the following percentage mortalities (numbers of mosquitoes exposed are given in brackets):

Table 2

Insecticides	Susceptible	Resistant
1 per cent methoxychlor	89 (36)	24 (39)
2 per cent dichloro-diphenyl-dichloroethane ('Rhothane')	100 (27)	3 (37)
4 per cent diethyl-diphenyl-dichloroethane ('Perthane')	100 (18)	16 (25)

Like the DDT-resistant strains of other insect species, then, cross-resistance extends to closely related compounds but not to the cyclodiene compounds, dieldrin, aldrin, etc., or to BHC.

The degree of resistance to DDT in *A. sundaicus* is considerably less than that of *A. gambiae* to dieldrin[4]. According to Crandell[1], it is of the order of twenty-five times. From my estimations in Java it was of the order of eighteen times. A comparison of the Malayan and Javanese laboratory colonies in London indicates a resistance of some forty times. 103 mosquitoes of the Malayan strain showed a 50 per cent mortality after exposure to 0·1 per cent DDT for 2 hr., and 255 mosquitoes of the Javanese resistant strain showed a 58 per cent mortality after an exposure of 2 hr. to 4 per cent DDT.

Reciprocal crosses between the laboratory-susceptible and resistant strains produce hybrids only slightly more resistant than the susceptible strain (see Table 3). It was not possible, therefore, to choose a discriminating dosage of the insecticide which would kill susceptibles and not hybrids, as it was with dieldrin-resistant *A. gambiae*[5]. What was possible, however, was to choose one discriminating dosage, 2·5 per cent DDT, which would kill almost all susceptibles and hybrids but very few of the resistant strain (see Table 3).

Unlike most of the *A. gambiae* hybrids[5], *A. sundaicus* hybrids readily interbreed. The F_2 generations exposed to the discriminating dosage show an approximate 75 per cent kill (Table 3), indicating simple Mendelian inheritance. This has been confirmed by back-crossing the hybrids with the susceptible and resistant parent strains. The offspring of the back-crosses to the resistant parent showed approximately the expected 50 per cent kill after exposure to the discriminating dosage. The offspring of the back-crosses to the susceptible parent showed an almost complete kill (Table 3).

These findings indicate that this resistance is inherited by a simple monofactorial mechanism. One homozygote displays a marked resistance. The heterozygote resembles the susceptible homozygote, resistance being virtually recessive. Only two degrees of susceptibility or resistance can therefore be found, whereas in the dieldrin-BHC-resistant *A. gambiae* three phenotypes were found. It is almost certain that the heterozygote *A. sundaicus* would be killed by field dosages of the insecticide and this may explain why DDT-resistance in anophelines has always been much slower to appear in the field than was dieldrin-BHC-resistance in *A. gambiae*, where the hybrids, themselves being significantly resistant, almost certainly survive.

Resistance to DDT which has these characteristics would probably not be detectable when homozygote

Table 3. Mortalities at Varying Percentages of DDT in Risella Oil among Susceptible, Resistant, Hybrid, Interbred Hybrid and Backcross Offspring of *A. sundaicus*

Numbers of mosquitoes tested are given in brackets

Percentage DDT in Risella oil	Susceptible strain (S)	Resistant strain (R)	Hybrid I R♂ × S♀	Hybrid II S♂ × R♀	Offspring of Hybrid I	Offspring of Hybrid II	Backcross R♂ × Hybrid II♀	Backcross Hybrid II♂ × R♀	Backcross R♂ × Hybrid I♀	Backcross S♂ × Hybrid II♀	Backcross Hybrid II♂ × S♀
0·25					87 (359)						
0·5	73 (67)		31 (39)		56 (120)	16 (43)	6 (47)	18 (40)	3 (30)		
1·0	100 (47)	0 (63)		39 (70)	70 (67)	33 (45)	29 (24)				
1·5	100 (22)			76 (68)	70 (40)	58 (33)	31 (26)				
2·0	98 (56)	8 (84)	80 (54)	97 (123)	82 (70)	67 (45)	48 (23)				
2·5	93 (86)	3 (39)	98 (61)	99 (236)	82 (176)	74 (205)	53 (126)	56 (206)		95 (218)	94 (69)
3·0		10 (59)			87 (74)						
4·0		8 (383)			81 (107)	76 (51)	51 (41)	67 (33)	41 (27)		
Check	2 (62)	4 (267)	9 (35)	4 (48)	4 (113)	3 (32)	0 (29)	11 (28)	0 (16)	5 (22)	13 (16)

The dotted line indicates the discriminating dosage, 2·5 per cent DDT, which kills hybrids and susceptibles but not resistants resistant members were few in number, because hybrids cannot in practice be identified. Moreover, a female, suspected to be homozygote resistant, but caught in Nature after fertilization by an unknown male, might produce apparently susceptible progeny. If the mother were resistant this progeny would correspond to one of the following groupings: 100 per cent resistant; 50 per cent resistant and 50 per cent hybrid; and 100 per cent hybrid; and the last of these, all succumbing to the discriminating dose, might give the impression that they were derived from two susceptible parents. An F_2 generation derived from them would include 25 per cent resistant, 50 per cent hybrid, and 25 per cent susceptible members. The resistant members would be detectable, and their ancestry could be traced from this generation. In field observations, therefore, the presence of many survivors of a discriminating dose would indicate resistance, and the presence of a few would give rise to a suspicion of it, to be followed by the rearing and testing of progeny from them, and if possible the rearing and resting of a second generation.

I gratefully acknowledge the assistance given me by Miss C. E. Jackson and the skill and untiring work of Miss W. J. Wall and the technicians of this Institute, whose efforts overcame the great difficulties in establishment of the colonies studied.

FLUORESCENCE MICROSCOPY IN THE STUDY OF NUCLEIC ACIDS

Histochemical Observations on Cellular and Virus Nucleic Acids

RECENT inquiry into the histochemical significance of tissue fluorescence induced by acridine fluorochromes[1] led us to consider the possibilities of this aspect of fluorescence microscopy for studies on the intracellular phase of virus infection. If thin sections of Carnoy-fixed animal tissues are treated with a dilute and suitably buffered solution of acridine orange (or its 5-phenyl derivative, acridine orange *R*) it is possible with the fluorescence microscope to identify readily the distribution of nucleic acids within the tissue, and further, to distinguish between ribonucleic acid and deoxyribonucleic acid. Normal tissues prepared in this way acquire strong polychromatic fluorescent properties, best activated by irradiation with intense blue-violet light. With acridine orange in the *p*H range of 1·5–3·5, nuclear chromatin containing deoxyribonucleic acid emits strong greenish-yellow fluorescence, while a characteristic flame-red colour is seen in those parts of the cell cytoplasm and in the nucleolus which have an appreciable content of ribonucleic acid. With acridine orange *R*, corresponding results are obtained in the *p*H range of 3·5–5·0.

The connexion between the normal components of the host cell and infective virus material forms one of the central problems in virus research. It is now recognized that all viruses contain either deoxyribonucleic or ribonucleic acid as an essential constituent, and it therefore seemed possible that the acridine fluorescence technique could be utilized for revealing significant cytochemical changes during the phase of virus multiplication. Preliminary findings with some viruses of widely different character are reported here. Observations on two virus diseases of *Tipula paludosa* were possible through the kindness of Dr. Kenneth M. Smith, who provided us with some infected larvæ; the structure of both viruses has been studied recently by Dr. Smith and his collaborators with the electron microscope. *Tipula* iridescent virus[2] is a crystallizable agent containing deoxyribonucleic acid producing gross lesions of the larval fat body. With the acridine orange technique, the cytoplasm of cells in the affected region of the fat body was seen to be distended with granular material emitting strong greenish-yellow fluorescence of the deoxyribonucleic acid type. Traces of the same material occurred in the body cavity of the larva, and abundantly in the cytoplasm of most of the epidermal cells of the body wall. Since deoxyribonucleic acid is not a normal constituent of cell cytoplasm, it is reasonable to suspect that accumulations of virus material containing deoxyribonucleic acid may account for this remarkable appearance. There was no obvious primary change in the cell nuclei other than enlargement of the nucleolus, which fluoresced a brilliant red. In larvæ infected with *Tipula polyhedrosis*, on the other hand, profound changes do occur in the nuclei. The cells chiefly involved are the hæmocytes of the blood.

Electron microscopy[3] has shown that virus rods appear in the cell nucleus and later accumulate within oval masses adherent to the nuclear membrane which are eventually discharged from the cell in the form of crescentic polyhedra or 'crystals'. In blood smears and whole sections through an infected larva examined with the fluorescence technique, few normal hæmocytes were present and the blood contained a profusion of crescentic, refractile polyhedra. In the least-affected blood cells there was an unusually dense network of intra-nuclear material showing strong greenish-yellow fluorescence, together with one or more spherical and homogeneous bodies emitting similar fluorescence of the deoxyribonucleic acid type. In other cells, part of the fluorescing material had become segregated to form bright greenish-yellow masses, oval in outline and attached to the nuclear membrane. A later stage is represented by cells in which the structures containing deoxyribonucleic acid had come to lie within the red fluorescing cell cytoplasm, but their homogeneous character was now lost and intense yellowish fluorescence restricted to their inner border, that is, the surface last in contact with the nuclear membrane. Extracellular polyhedra were outlined prominently as blue dark-ground images, showing only weak yellowish fluorescence.

These observations with the fluorescence microscope appear to present visible evidence of the incorporation of nuclear deoxyribonucleic acid into a remarkable and complex pattern of virus formation and are broadly in accord with the evidence of electron microscopy. It was also noted, however, that only a part of the abnormal deoxyribonucleic acid seems to be utilized for the developing polyhedra; much of it remains in granular form within the nuclear membrane and is released into the blood on disintegration of the cell.

Two members of the pox group, vaccinia and mouse ectromelia, have also given interesting results with the acridine orange technique. As expected on account of their known content of deoxyribonucleic acid, the elementary bodies in purified vaccinia preparations, for which we are indebted to Dr. D. McClean, exhibited greenish-yellow fluorescence, the fluorescent material being concentrated in the centre of each virus particle. Similarly in the liver cells of mice infected with ectromelia greenish-yellow bodies, varying from about 0·25μ to 1·0μ in diameter, were demonstrable in the cytoplasm of cells, most of which showed no other abnormality and looked quite normal in routine histological preparations. A quite different appearance was found in the liver of mice infected with mouse hepatitis virus[4]; here the hepatic cells at an early stage of infection contained abnormal accumulations of material fluorescing intensely red (ribonucleic acid) in their cytoplasm. In this instance, there is at present no biochemical evidence concerning the type of nucleic acid in the virus and the identity of the material containing ribonucleic acid is an open question.

The interpretation of an altered pattern of fluorescence in cells following virus infection is a complex problem, since changes in the amount and distribution of the host cell's own nucleic acids will almost inevitably accompany or result from the intracellular multiplication of virus, and histochemical evidence must, where possible, be correlated with that obtained with the electron microscope and from biochemical studies. The feasibility of distinguishing histologically between virus and cellular nucleic acids is suggested by experiments on their susceptibility to digestion by the specific nucleases. It was noted that the abnormal material containing deoxyribonucleic acid in the fat body cells of larvæ infected with *Tipula* iridescent virus was resistant to direct digestion by crystalline deoxyribonuclease, although the normal nuclear deoxyribonucleic acid of all cells in the test specimen was completely removed with consequent loss of the specific greenish-yellow fluorescence. Similar resistance was shown by the deoxyribonucleic acid of vaccinia and by the hepatic inclusions in ectromelia. Pre-treatment of the sections with 0·02 per cent pepsin at *p*H 2·0 for 2 hr. at 37° C. (which did not itself inhibit the specific deoxyribonucleic acid fluorescence) rendered the deoxyribonucleic acid susceptible to subsequent digestion by the specific nuclease. These findings parallel observations with the electron microscope on influenza and other myxoviruses[5], which showed that nuclease treatment did not affect the electron density of the virus particles unless preceded by treatment with a proteolytic enzyme. In the case of *Tipula polyhedrosis*, however, pre-treatment with pepsin had no such unmasking effect on the deoxyribonucleic acid of the infected blood cells and its nuclease resistance remained unbroken. There is at present insufficient evidence to indicate that nuclease resistance is likely to be encountered in all viruses, or at what stage in the formation of virus such protection is afforded to its nucleic acid. It is interesting to speculate on the possibility that a high degree of nuclease resistance, surviving even treatment with pepsin as in the case of *Tipula polyhedrosis*, may be a feature of an intra-nuclear site of virus formation.

Visual Observation of Deoxyribonucleic Acid Changes in Bacteria during Growth of Bacteriophage

Armstrong[1] demonstrated the specific fluorescences of ribonucleic acid and deoxyribonucleic acid when stained with acridine orange and, in collaboration with Niven[2], has now shown that such fluorescence can be used for following the development of virus nucleic acids in animal tissues. This prompted me to investigate the practicability of using the method to follow the development of deoxyribonucleic acid in bacteria during the growth of phage. A lysogenic culture of *S. typhi*, *Vi*-phage type *D*6, which carries type-determining phage d_6[3,4], was chosen as the test organism. The culture was exposed to ultra-violet radiation for 5 sec. in buffer solution at *p*H 7·0, 45 cm. from a 30 W. B.T.H. germicidal low-pressure mercury vapour lamp. This procedure has previously been shown to result in induction of more than 99 per cent of cells. An equal volume of double-strength nutrient broth was added to the irradiated cells and the resulting suspension was incubated at 37° C. The irradiated culture was also inoculated on to nutrient agar, which was incubated similarly. Sampling was carried out before and immediately after irradiation, and afterwards at 15, 30, 45, 60, 90, 120 and 180 min. Smears made on chemically cleaned slides were stained with Gurr's acridine orange at *p*H 5·0 and were examined by dark-ground fluorescence microscopy, the method being, with slight modifications, similar to that of Armstrong[1]. In our preparations the ribonucleic acid fluoresced red and the deoxyribonucleic acid yellow-green. The colour filters were adjusted so that a faint blue-green dark-ground image of the cell walls was visible. The nuclei were very distinct in uninduced (control) cells, and showed as bright subterminal yellow-green rods of morphology similar to that described by numerous workers (Fig. 1*A*). Most cells in the logarithmic phase of growth were binucleate, but organisms with four or more nuclei were common. When the nuclei were about to divide, the intensity of nuclear fluorescence increased and the rods became thicker and then separated into two, the separation often commencing at one nuclear pole, so that the familiar V formation was apparent.

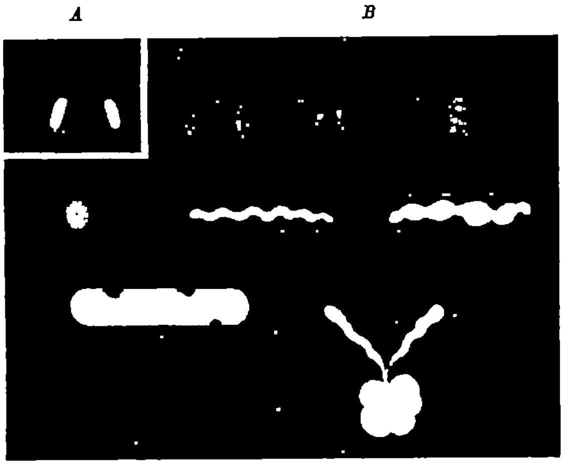

Fig. 1. *A*, normal cell of *Salmonella typhi*, type *D6*; *B*, changes observed in type *D6* after ultra-violet irradiation. Left to right: 5–15 min., 5–15 min., 15–30 min., 15–30 min., 30–45 min., 30–45 min., 45–60 min., 60 min. onwards

Fig. 1*B* is a diagrammatic representation of the sequence of events observed after irradiation. Within a few minutes the nuclear fluorescence was less intense and the nuclei became less compact, so that their long axes were no longer so clearly transverse. Where nuclei had recently divided but were still close to each other, their outlines soon fused with one another. Subterminal nuclei migrated to the centre of the cell, there to fuse into a single, rather dimly fluorescent mass of deoxyribonucleic acid. In longer cells which were quadrinucleate, that is, were probably in the process of dividing, the pairs of nuclei behaved as if they belonged to independent cells and fused into two masses, situated at the junctions of the thirds of the bacteria. The process of nuclear migration and fusion was well advanced within 15 min. of irradiation and was substantially complete after 30 min. Between 15 and 30 min. the central deoxyribonucleic acid mass became somewhat more compact and exhibited brighter fluorescence. At 30 min. many cells showed a fine axial filament of deoxyribonucleic acid, often wavy in outline, extending towards the bacterial poles on each side of the central mass. These filaments thickened and increased in brightness; 45 min. after induction, the great majority of bacteria showed such filaments, which had greatly increased in thickness and brilliance; their outline remained wavy or became heavily beaded. As the filaments thickened the central deoxyribonucleic acid mass disappeared. Although obvious division of the bacteria could rarely be found in the irradiated culture, increase in cell length took place, and by 45 min. after irradiation the mean cell length had almost doubled.

After 1 hr. most cells were virtually filled with deoxyribonucleic acid although the beading referred to above persisted. From this time onwards, cells in various stages of bursting were frequently seen. Although the actual rupture may have been due to the effect of making the smears on already fragile cells, it is nevertheless worth while recording its course. At first a localized bulge of the cell wall could be seen into which projected a small finger of deoxyribonucleic acid. The bulge increased in size until the wall ruptured and the deoxyribonucleic acid escaped; once this had occurred the brilliance of the deoxyribonucleic acid fluorescence increased considerably. In the early stages the extracellular deoxyribonucleic acid could clearly be seen to be attached to that still within the cell, and the latter diminished *pari passu* with the increase in amount of the former. Finally, all the deoxyribonucleic acid was extracellular and the empty cell was visible only as a faint dark-ground image.

Bursting cells were common from 1 hr. onwards after irradiation and their increase in number coincided with the rise in phage titre in liquid medium, the maximum of both being reached in about 1½–2 hr. after irradiation. At this time also, visible lysis occurred in the liquid medium, the resulting liquid exhibiting distinct birefringence, presumably due to the liberation of an excess of free deoxyribonucleic acid.

Two types of body made their appearance in smears prepared during and after the lysis period. The first showed as a pure dark-ground image, circular in outline, and about 0·2–0·3μ in diameter. The second fluoresced faintly as deoxyribonucleic acid and was circular or oval, with a long axis of about 0·5μ. The nature of these bodies, which became numerous when lysis was well advanced, is not yet known. When the primary (blue) filter was removed, so that the preparation could be examined by ordinary dark-field illumination, numerous small bodies, which showed only as dark-ground images, could be seen embedded in the deoxyribonucleic acid released from ruptured cells.

Three hours after irradiation, normal cells were reappearing and they afterwards increased in numbers to some extent, although the culture never reached an opacity of more than about one-quarter of that of the unirradiated controls.

Irradiation of a strain of *Vi*-phage type *A* of *S. typhi*, in which we have not so far been able to demonstrate lysogenicity, resulted in changes of a similar nature only up to the point of central migration and fusion of the nuclear deoxyribonucleic acid. The type *A* culture was lysogenized with phage d_6, the temperate determining phage carried by the type *D6* strain referred to earlier. This procedure converts type *A* into type *D6*[3,4]. Control samples of the new lysogenic strain showed the same nuclear appearances as the parent type *A*. After ultra-violet induction the train of events was closely similar to that already described in irradiated type *D6*, and many bursting cells releasing brightly fluorescent deoxyribonucleic acid were found from 1 hr. onwards after irradiation. Thus, the differences in deoxyribonucleic acid production in the lysogenized irradiated, as compared with the unlysogenized irradiated, culture were evidently connected with the presence of prophage d_6 in the cells.

The progress of infection of bacteria with a virulent phage has also been followed by this method; the changes in deoxyribonucleic acid have similarities to those outlined for the induced lysogenic culture, but will not be given in detail here.

Smears of a purified pellet of *Vi*-phage II, suspended in a minimum of buffer, fluoresced yellow-green after staining with acridine orange. Preparations of normal bacteria, of induced lysogenic cells and of free phage, treated with deoxyribonuclease after fixation but before staining, did not show the yellow-green fluorescence characteristic of deoxyribonucleic acid. This is in contrast to the findings of Armstrong and Niven[5], who have observed that the deoxyribonucleic acid of several animal viruses has a degree of resistance to deoxyribonuclease.

This staining technique has also been employed for the study of the development of deoxyribonucleic acid in phage-infected *Escherichia coli* and *Bacillus megaterium*, and it has been shown that preparations stained with and without preliminary fixation present a similar picture. Our findings will be described in full at a later date.

Fluorescence microscopy, in combination with methods already in use, may add valuable information both to the study of bacterial cytology and to that of phage development. The simplicity of the technique makes it easy to carry out frequent sampling and the clear-cut difference between ribonucleic and deoxyribonucleic acid fluorescence facilitates rapid determination of the distribution of these two substances.

DISTRIBUTION OF RIBONUCLEIC ACID IN TUMOUR CELLS DURING MITOSIS

By Dr. ROBERT LOVE

Laboratory of Pathology, National Cancer Institute, National Institutes of Health, Bethesda, Maryland

SOME forms of ribonucleic acid are virtually unstained in fixed tissues by dilute solutions of toluidine blue, but can be visualized by subsequent treatment with a molybdate–ferrocyanide solution[1]. Further investigation has shown that ferrocyanide is unnecessary; the staining of various sites of ribonucleic acid by the toluidine blue–molybdate method can be altered in a regular manner by extending the time of fixation in fixatives containing formalin. After short fixation in formalin-free fixatives that preserve ribonucleic acid, the same sequence of staining can be achieved by progressive deamination in dilute solutions of nitrous acid. The entire range of ribonucleic acid staining can be demonstrated in mouse ascites tumours (Table 1) as follows: Wet smears are fixed for periods of 5, 10 and 60 min., 24 hr. and 14 days in formol sublimate at 37° C. After treatment with Lugol's iodine and 5 per cent sodium thiosulphate, the slides are stained in a 0·01 per cent solution of toluidine blue (Coleman Bell Co., dye content 66 per cent) in McIlvaine's buffer at pH 3·0 for 30 min., washed for 10 sec. in tap water, and placed in a 5 per cent solution of ammonium molybdate for 30 min. (The effects of fixation or deamination may be simulated to some extent by increasing the concentration of dye or of molybdate. When toluidine blue samples of high dye content are used, lower concentrations of dye or molybdate, or both, may be required to demonstrate all types of ribonucleic acid by this method.) The smears are then rinsed for 10 sec. in running water and dehydrated in tertiary butyl alcohol, cleared in xylol and mounted in 'Permount'. Paraffin sections (10μ thick) prepared from small blocks of tissue from the solid Krebs mouse tumour, sarcoma 180, and from HeLa tumours grown in irradiated rats[2] can be stained in the same fashion. The tissues are fixed for one hour in formol sublimate at 20° C. and the sections are mordanted in formol sublimate at 37° C. as described.

The cells do not stain at all after extraction of nucleic acids with hot trichloracetic acid[3]. Only minimal staining of deoxyribonucleic acid remains when the slides are exposed to 0·1 per cent aqueous ribonuclease for 2 hr. at 37° C. prior to staining.

In cells of the Krebs ascites tumour, ribonucleic acid is stained as shown in Table 1.

Stage I (Fig. 1,*a*,*b*,*c*). Ribonucleic acid is coloured uniformly green in the cytoplasm (diffuse cytoplasmic ribonucleic acid) and blue-green in the nucleolus. The nucleolus decreases in size during prophase, at the end of which nucleolar fragments are sometimes released into the cytoplasm, where they rapidly disintegrate[1]. Finely granular and diffuse parachromatin[1] in the interphase nucleus is stained purple. During prophase large parachromatin bodies are formed, and an increased amount of ill-defined metachromatic material (diffuse parachromatin) accumulates between the chromosomes. In metaphase, this metachromatic material surrounds the pale green chromosomes, while the parachromatin bodies are scattered throughout the cytoplasm (Fig. 1*b*). Some of the diffuse parachromatin is carried over with the chromosomes into the telophase nucleus, but most of it, together with all the parachromatin bodies, persists in the cytoplasm; the parachromatin loses its affinity for stain during the last stages of telophase.

Stage II (Fig. 1,*d*,*e*,*f*). The diffuse cytoplasmic ribonucleic acid and the nucleolus are stained pale green and the intranuclear parachromatin is less intensely stained. The parachromatin granules in

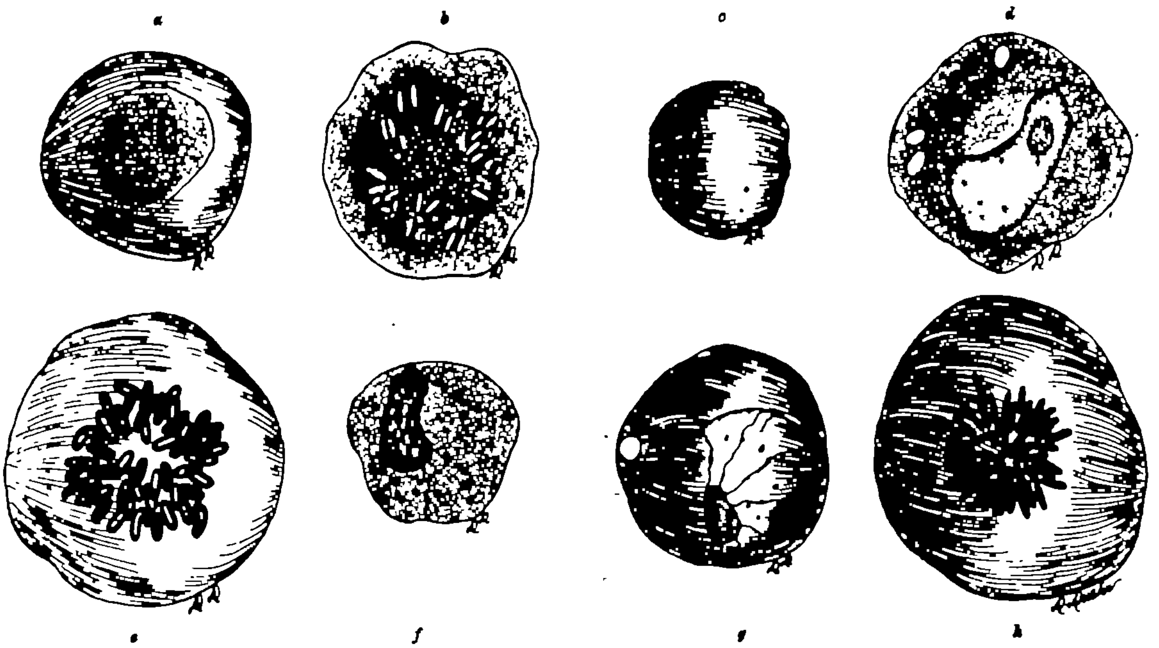

Fig. 1. *a*, Stage I, interphase. green cytoplasm, blue-green nucleolus and finely granular and diffuse purple parachromatin in the nucleus. *b*, Stage I, metaphase: diffuse purple parachromatin around the pale green chromosomes. Large parachromatin bodies in the light green cytoplasm. *c*, Stage I, telophase: finely granular purple parachromatin in the nucleus and parachromatin bodies in the pale green cytoplasm. *d*, Stage II, interphase: purple granular cytoplasmic ribonucleic acid and ill-defined perichromosomal ribonucleic acid. Light green nucleolus and cytoplasm. Pale-staining juxta-nuclear Golgi zone. The vacuoles are caused by lipid globules that have been removed by xylol. *e*, Stage II, metaphase: the chromosomes are surrounded by a well-defined metachromatic sheath which sometimes completely obscures the weakly staining central filament. No granular ribonucleic acid in the pale green cytoplasm. *f*, Stage II, telophase: large parachromatin bodies and finely granular cytoplasmic ribonucleic acid in the light green cytoplasm. Metachromatic perichromosomal ribonucleic acid. *g*, Stage III, interphase: diffuse purple cytoplasm and dark bluish-purple nucleolus. The chromatin (deoxyribonucleic acid) is weakly stained. *h*, Stage III, telophase: diffuse purple cytoplasm, slightly paler than that of the interphase cell. Bluish-purple thin chromosomes

the cytoplasm, especially in the later stages of mitosis, are still intensely stained (Fig. 1*f*). Innumerable minute granules of ribonucleic acid in the cytoplasm (cytoplasmic granular ribonucleic acid) and a diffusely staining form associated with the chromatin (perichromosomal ribonucleic acid) are stained metachromatically in the interphase cell (Fig. 1*d*). During prophase the cytoplasmic granular ribonucleic acid diminishes and the metachromatic ribonucleic acid around the chromosomes increases until, at metaphase, practically all the cytoplasmic granular ribonucleic acid is condensed to form a well-defined sheath around the chromosomes (Fig. 1*e*). This sheath is carried with the chromosomes into the telophase nucleus, where it is gradually replaced by the less well-defined perichromosomal ribonucleic acid of the interphase nucleus. The parachromatin bodies gradually become smaller in the cytoplasm during late telophase and may help to form the cytoplasmic granular ribonucleic acid which reappears at this time.

Stage III (Fig. 1*g* and *h*). After further fixation, the diffuse cytoplasmic ribonucleic acid and, to a lesser extent, the nucleolus stain metachromatically. The diffuse cytoplasmic ribonucleic acid differs from the granular form, which can no longer be recognized, in that it is practically unaltered during the mitotic cycle. The perichromosomal ribonucleic acid, which appears to be related to the cytoplasmic granular form, and all types of parachromatin are not stained.

The larger parachromatin bodies can be coloured faintly by more concentrated solutions of toluidine blue (without the use of molybdate), and, after brief fixation, they may also be demonstrated by various stains for amino-acids[1]. Deamination appears to liberate, from ribonucleoprotein, phosphate groups which bind toluidine blue. At a certain stage of deamination the amount and type of binding of toluidine blue is such that it is capable of reacting with molybdate to produce metachromatic staining.

In summary, an interchange of some forms of ribonucleic acid between the nucleus and cytoplasm appears to take place during mitosis. Nucleolar remnants are sometimes released into the cytoplasm at the onset of metaphase. The parachromatin of the nucleus is extruded into the cytoplasm at the end of prophase and may give rise to the cytoplasmic granular ribonucleic acid of the succeeding interphase. The granular ribonucleic acid that is stained in the cytoplasm of the interphase cell surrounds the chromosomes during prophase and metaphase and contributes to the ribonucleic acid content of the succeeding interphase nucleus. The diffusely staining cytoplasmic ribonucleic acid is altered little, possibly only by dilution during the increase in cell volume associated with mitosis. These observations are consistent with the theory, derived from biochemical studies[4], that there are two classes of ribonucleic acid in the cell: gene-dependent ribonucleic acid in the nucleus and in the cytoplasm, and gene-independent ribonucleic acid in the cytoplasm.

I wish to thank Mr. Roscoe H. Liles for valuable technical assistance and Miss Dohna J. Duehr for the drawings.

Molecular Weights and Physical Properties of Deoxyribonucleic Acid

IN the measurements of the molecular weight from light scattering and of other physical properties of deoxyribonucleic acid, an extraordinary variety of results has been obtained[1], even with samples prepared from a single source, namely, calf thymus. To some extent this might be accounted for as a result of fractionation of the material resulting from its physical heterogeneity, which has been demonstrated by Shooter and Butler[2], and by Schachman *et al.*[3]. It may also arise from small amounts of protein impurity, which have been shown[4] to affect the physical properties to a marked extent. In order to reduce the sources of discrepancy, it has been thought desirable to determine (1) light scattering, (2) intrinsic viscosity, (3) sedimentation coefficients, on identical solutions of calf thymus deoxyribonucleic acid treated in various ways. It has been found that centrifuging as a means of clarifying the solutions is made much more effective by reducing the concentration from 0·1 to 0·04 per cent. Table 1 shows the effect of centrifuging for 18 hr. at 20,000*g* at these two concentrations. The difference must be due to the greater viscosity of the stronger solution. The light-scattering molecular weight, especially of the more turbid samples, is markedly reduced by centrifuging in this way at the lower concentration, without any great change of either the intrinsic viscosity or of the sedimentation coefficients. This must mean that the component which gives rise to high turbidities in the unclarified solutions does not contribute appreciably to the viscosity and sedimentation coefficient. That the high turbidities of the unclarified solutions is not due to deoxyribonucleic acid has been demonstrated by the fact that the action of deoxyribonuclease on a clarified solution (*J*40) with molecular weight 4×10^6 reduced the light scattering to 20 per cent of its original value; while on a turbid solution (*J*38), having an apparent molecular weight of 17×10^6, the light scattering value was reduced by only 40 per cent, that is, to 10×10^6.

The results obtained with a number of preparations when treated in this way now agree very well with each other in most cases (Table 2), and in the exception (*J*38) it has been shown that the high value is not due to deoxyribonucleic acid itself. It will be seen, however, that the molecular weight determined from light scattering in the final solutions is less by a factor of 3 than that determined from the intrinsic viscosity and mean sedimentation coefficient by the equation of Mandelkern *et al.*[5]. The cause of this discrepancy may be (1) failure of the light scattering theory when applied to very long rods; (2) the effect of the heterogeneity weighting the intrinsic viscosity in favour of the larger particles. These possibilities require further study.

Optical Rotation and Infra-Red Spectra of some Polypeptide and Protein Films

IT is well known that the α-helix configuration of Pauling and Corey[1] is associated with a carbonyl stretching mode in the neighbourhood of 1,652–1,655 cm.$^{-1}$ in films of simple enantiomorphic polypeptides[2,3]. Since this frequency is also found in the infra-red spectra of films prepared from a number of native proteins[4–6] it is of interest to know whether other configurations besides the α-helix are associated with it, for some X-ray diffraction photographs of fibrous proteins suggest a mixture of crystalline and amorphous forms. In the case of water-soluble films of *Bombyx mori* silk fibroin[7], a completely amorphous X-ray diffraction pattern can be obtained, along with a carbonyl band in the infra-red spectrum at 1,660 cm.$^{-1}$. It is difficult to think that an α-helix arrangement would not produce sufficient order to reveal the characteristic intensity diffraction pattern of this helix.

The dispersion of optical rotation has recently been shown to be a very useful method for investigating the helical configuration of polypeptide molecules in solution[8–10], and we have found it possible to use this technique for examining solid films. Films of poly-L-alanine show the anomalous dispersion of the α-helix. It is interesting that Moffitt's b_0 term (which indicates the presence of anomalous dispersion of optical rotation) has the same negative sign and about the same magnitude for poly-L-alanine films as for other L-polypeptides in solution, although the specific rotation in sodium light has a large negative value in the film and a positive value in solution. This shows the great effect of environment on the magnitude and sign of the rotation, and the comparative invariance of b_0, as predicted by Moffitt. Poly-L-tyrosine, however, has a positive b_0 in solution in dimethylformamide and in pyridine; its sodium salt has also a positive b_0 (in film and in aqueous solution). We believe that the unusual sign of b_0 is a consequence of the presence of a strong chromophoric group near the β-carbon, so placed that it must to a great extent share the helical form of the core.

In films of water-soluble *Bombyx mori* silk fibroin, lysozyme and the sodium salt of poly-L-glutamic acid, the value of b_0 is so low as to be negligible, and this is taken as evidence of the absence, or at least low concentration, of the helical form. These films are not in the extended β-configuration however (as shown by the absence of a carbonyl band at 1,630 cm.$^{-1}$). The silk films, even after intensive drying, show no peak in the spectrum at 3,460 cm.$^{-1}$ (the 'free' NH stretching mode), and it must be concluded that substantially all the peptide hydrogen bands are formed, in what appears to be a disordered state.

It is clear from these observations that a carbonyl band at about 1,660 cm.$^{-1}$ is observed in polypeptide spectra not only with the α-helix and collagen folds[6,11] but also in what, in the absence of further evidence, seems to be a disordered state. In the case of some globular proteins, a certain amount of order presumably persists in solid films, but in lysozyme it is not of a kind which gives rise to anomalous dispersion of optical rotation. These results contrast with those found by Cohen and Szent-Gyorgi[12] in muscle proteins, where in aqueous solution the α-helix configuration appears to be dominant.

Mucopolysaccharides from Cartilage and Nucleus Pulposus

Meyer and Rapport[1] described the isolation from hyaline cartilage of two chondroitin sulphates, *A* and *C*. The only differences so far reported[2] between these are in the specific optical rotation and alcohol solubility of their calcium salts. Orr[3] found that chondroitin sulphate from cartilage gives an infra-red spectrum which suggests that the product is a mixture of two isomers, *A* and *B* (see below). By counter-current electrophoresis he was able to obtain the faster component of this mixture, which exhibited in the 700–1,000 cm.$^{-1}$ region 3 bands, at 928, 855 and 725 cm.$^{-1}$, respectively, and was called the *A* isomer. The *B* isomer, on the other hand, was isolated alone in a well-defined form from the nucleus pulposus and showed two bands at 825 and 775 cm.$^{-1}$, respectively. Meyer *et al.*[2] pointed out the similarity between Orr's *B* isomer and chondroitin sulphate *C*. On the other hand, both *A* types show the same optical rotation and origin. The following results seem to give a different picture of the mucopolysaccharides of cartilage and nucleus pulposus.

Extracts of (*a*) cartilage from horse nasal septum and (*b*) nucleus pulposus from human intervertebral disk were made using aqueous solutions of 30 per cent potassium chloride and 1 per cent potassium carbonate[4].

These were centrifuged, and the resulting solutions were dialysed. The retained soluble fractions were then precipitated with potassium acetate and alcohol at 0° C. The precipitates so obtained were purified by application of this technique three times; finally, the resulting specimens were dried with absolute alcohol and ether.

A preliminary paper electrophoresis of our preparations *MC* (from cartilage) and *MP* (from nucleus pulposus) showed the same main features, that is, two components were present and both stained metachromatically with toluidine blue. One component was stationary and the second one mobile and negatively charged. A previous investigation[5] showed that in *MC* the first component was mucoprotein, the second one being chondroitin sulphate. By analogy, the immobile component of *MP* was thought to be a protein–polysaccharide complex, the mobile one a mucopolysaccharide. The amino-acid composition of *MP* was shown, by paper chromatography, to be similar to that of *MC*, already reported elsewhere[5].

An infra-red investigation gave the following results. Both *MC* and *MP* showed the spectrum of Orr's *A* isomer. *MC* was repeatedly treated with kieselguhr to give a mucopolysaccharide free from mucoprotein which showed an *A*-type spectrum (Fig. 1). The same infra-red spectrum was obtained from a crystalline calcium chrondroitin sulphate[6] (which is a mixture of chondroitin sulphates *A* and *C*, following Meyer's criteria), and a preparation obtained by deproteinizing a mucoprotein from cartilage[7]. Therefore, we suggest that only one type of chondroitin sulphate is present in cartilage. This appears to confirm Meyer's hypothesis[2] that chondroitin sulphates *A* and *C* are only two fractions of the same polydisperse substance.

By treatment of *MP* with kieselguhr we obtained a free mucopolysaccharide which showed the *B* isomer spectrum (Fig. 2). Using paper chromatography and analytical methods, this mucopoly-

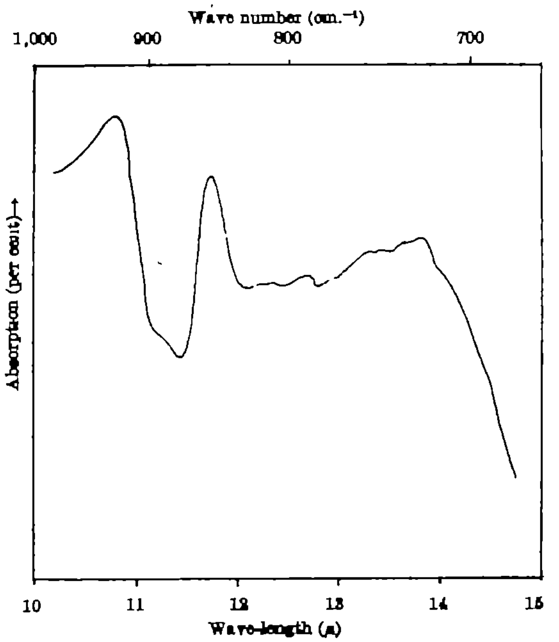

Fig. 1. Infra-red spectrum of chondroitin sulphate

saccharide was identified as keratosulphate (in agreement with a previous finding on a similar preparation[8]). It is reasonable to conclude, therefore, that *MP* is a mixture of a mucoprotein the carbohydrate component of which is chondroitin sulphate and a free mucopolysaccharide, keratosulphate. We cannot, however, exclude the presence as minor constituents of keratosulphate in mucoprotein or of chondroitin sulphate in the mobile component of *MP*. The lower intensity of the 1,736 cm.$^{-1}$ band in comparison with that at 1,560 cm.$^{-1}$ found by Orr in the *B* type as compared to the *A* type (attributed by him to a lower hexuronic acid : hexosamine ratio) is in agreement with our conclusions.

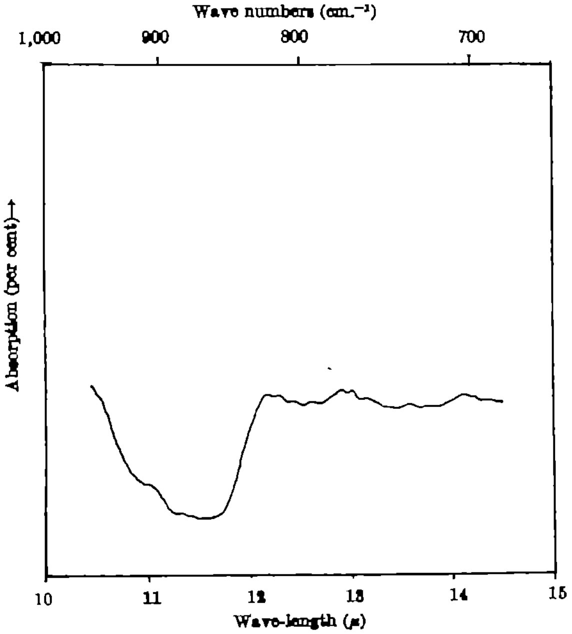

Fig. 2. Infra-red spectrum of keratosulphate

A more detailed presentation of this work will be given elsewhere in due course.

We are indebted to Prof. M. Schubert for the generous gift of samples of crystalline calcium chondroitin sulphate and mucoprotein, and to our colleague Mr. J. H. Keighley for valuable assistance in the infra-red investigations. One of us (G. B.) thanks the Bradford Education Authority and the Bradford Group *A* Hospital Management Committee for a joint scholarship to carry out this work.

Excitation of Molecular Spectra by Shock Waves

Several spectroscopic studies have recently been made of the light emitted from gases submitted to an intense shock wave[1-4], but little information is available about the emission from air and other permanent gases. The very high temperatures available make the shock tube a convenient device for study of spectra of astrophysical interest, and a knowledge of the spectrum of air is necessary in any consideration of its high-temperature emissivity which may be required for problems of supersonic flight at high altitude. We have studied emission from air, nitrogen, oxygen, carbon monoxide and carbon dioxide or mixtures of these with argon.

The shock tube, 5 ft. long and 2½ in. in diameter, is of copper, as this has a simple spectrum which does not interfere with that of the gas being studied. The emission was studied through quartz side-windows. For examination of the primary shock wave, a dump chamber was used for preventing its reflexion, while for the hotter reflected shock an end-plug was inserted close to the windows. Other features were similar to those used by Fairbairn and Gaydon[5]. Spectra were recorded photographically with a small $f/4$ 'Hilger' Raman spectrograph. Comparison of the variation in time of light emission of two spectrum lines was made by using two spectrometers set to view the same point of the shock from opposite sides; the spectrometers were fitted with photomultipliers, connected to a 'Cossor' 1038 double-beam oscillograph.

Strong reflected shocks through pure argon (99·8 per cent) give intense light emission[1], the spectrum showing argon lines superposed on a continuum

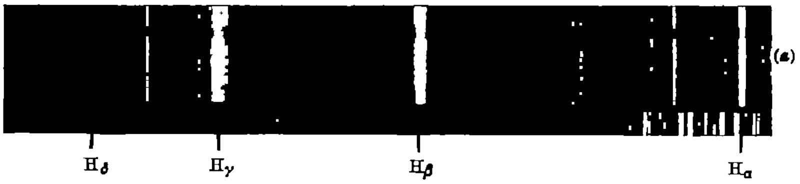

Fig. 1 (a). Spectrum of a reflected shock through argon + hydrogen, showing Balmer and argon lines Primary shock Mach No. 5·9. Neon comparison spectrum

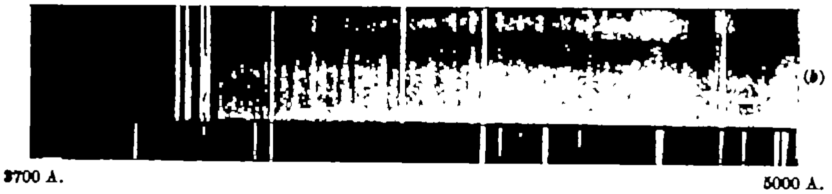

Fig. 1 (b). Shock through argon + oxygen, showing structure of Schumann–Runge bands. Neon comparison spectrum

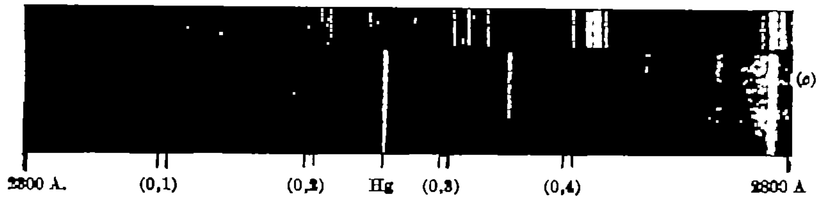

Fig. 1 (c). Shock through argon + air, showing NO γ-bands. Iron-arc comparison spectrum. Primary shock Mach No. 8·3

with a number of impurity lines, including the Balmer lines of H, lines of Hg, Na, Ca, Ca+ and K, and strong CN-bands. We attribute the hydrogen emission to residual molecular hydrogen in the tube and not, as has previously been suggested, to interaction of the hot gases of the reflected shock with the hydrogen driver-gas. Photo-electric records show H_β emission at the same instant as light in the region of the argon lines and the mercury lines. Addition of hydrogen to the argon strengthens the Balmer lines, H_α, H_β, H_γ and H_δ. As the intensity of the shock wave is increased, these lines broaden (Fig. 1a), H_γ and H_δ eventually becoming so broad as to be indistinguishable from the general continuum. The calculated temperature is about 12,000° K., and the breadth of the Balmer lines is consistent with this. The CN-violet bands appear to show very high rotational and vibrational temperatures, the 'tail bands' (15,15) to (11,11) being strong. The emission from a primary shock wave through argon is weak, but, at a calculated temperature of 6,000° K., we have photographed the spectrum using a wide slit, obtaining lines of Na, Ca and Ca+ and bands of CaO or CaOH on a continuous background. Simultaneous comparison of the sodium or calcium light emission with that of the continuum shows a significant delay of up to 30 μsec. for the former. The continuous radiation produces a small initial pulse, with a sharp leading edge; this decays for about 30 μsec., and then rises relatively slowly, before it is suddenly quenched by the contact surface. Pulses recording the sodium *D*-line, Ca 4226 A., and Ca+ 3933 A. and 3968 A. lines are much stronger (× 500), but occur later and correspond to the slow rise of the continuous radiation pulse. The leading pulse is attributed to rotational structure from C_2 bands. The main sodium, calcium, etc., emission and the slow rise in continuous emission are attributed to impurities scrubbed from the walls and drawn later into the hot gases. These alkali and alkaline earths cannot exist initially in the gas phase, and much of the luminosity, and possibly of the ionization, observed behind moderate shocks is due to impurities brought from the walls in this way; in steel tubes, lines of Fe and bands of FeO will be produced. This effect could give rise to the impression of a delay between the passage of a shock front and the onset of luminosity.

Shocks through oxygen show the Schumann–Runge bands of O_2. This has been reported previously[3]; but, with these clearer spectra, the structure is more evident and extends to 4300 A. (see Fig. 1b). Nitrogen/argon mixtures show the Second Positive system of N_2 and the First Negative system of N_2^+. Rose[4] suggested that the First Positive system was present, but we have not observed them on our plates. There is a good deal of continuum towards the red, and the bands of the red system of CN, as well as the violet system, occur as impurity.

Relatively mild shocks through argon/air show the Schumann–Runge bands of O_2 strongly, with about the same intensity as in pure oxygen. As the temperature is raised by increasing the strength of the shock, the N_2 Second Positive, N_2^+, CN-violet and CN-red, all superposed on the Schumann–Runge, are the most prominent features between 3000 and 7000 A. The 3360-A. band of NH, and the 2811 and 3064-A. bands of OH also occur. Below 3000 A., the NO system is prominent; this, contrary to Rose's anticipation[4], shows sharp heads and clearly resolved structure (Fig. 1c) with a high rotational temperature. We have not, however, observed any bands of the β-system of NO. The yellow-green continuum, due to association between NO and atomic oxygen (namely, air afterglow), is not observed; presumably the probability of the association, $NO + O = NO_2 + h\nu$, is too small to give much light in the short time available. In laboratory experiments, the CN-red bands in the near infra-red would probably contribute appreciably to the emissivity of air, although they might be absent from clean air.

As previously reported[3], both CO and CO_2 give very strong Swan bands of C_2. We have now observed CH from CO containing H_2 or H_2O (supporting formation of CH from C_2 + OH) and, in very hot shocks through CO, we have detected the Mulliken band of C_2 near 2325 A.; the C line at 2478 A. is strong and some bands of the Fourth Positive system of CO are visible. We have not observed either the strong Ångström or Third Positive systems of CO. The C_2 high-pressure bands, which might indicate formation of C_2 via a carbon-atom association process, are absent.

The spectra excited by shock waves are thus very different from those obtained by electrical discharges through similar mixtures. The Schumann–Runge bands, for example, occur in shock waves, but not in ordinary discharges, while the N_2 First Positive and the CO Third Positive and Ångström bands, which are such strong features of Geissler tube spectra, do not occur. In discharges, excitation is due mainly to electron impact, whereas molecular collisions are probably more important in the thermal excitation in shock waves. Shock tube spectra thus tend to resemble those excited in King furnaces. Temperatures in King furnaces are, however, limited to below about 3,000° C., whereas shock tubes enable us to reach temperatures nearer those of stellar sources.

Audio-frequency Nuclear-resonance Echoes

The principal expense and source of difficulty in equipment for nuclear magnetic resonance is the magnet to provide the large magnetic field. It has been shown that a nuclear-resonance signal can be obtained using only the Earth's field[1,2]. This is the so-called free-precession experiment, in which the nuclear system is first polarized at right angles to the Earth's field by means of a simple current-carrying coil. After removal of this field, the nuclear magnetization precesses about the Earth's field (approximately 0·48 gauss) and induces an alternating voltage in the same coil at a frequency of about 2 kc./s., which may be observed after suitable amplification. The polarizing field serves the double purpose of producing a nuclear magnetization appropriate to a large field and hence a stronger signal to be observed in the smaller field, and also produces this polarization at right angles to the small field. The signal is attenuated by loss of phase-coherence of the precessing nuclei, due both to interactions between them with a time constant T_2, and to inhomogeneity in the Earth's field ($T_2{}^*$). The method can be used for measuring the decay time, T_2, which is a property of the material, by observing the decay of the precession signal, provided the inhomogeneity of the Earth's field is sufficiently small for $T_2{}^* \gg T_2$. In many cases, for example, in liquids such as water containing mobile protons, T_2 may be several seconds and the corresponding field inhomogeneity must be less than 10 microgauss/cm. in order to measure T_2. This implies that the experiment cannot be performed in the laboratory and usually requires the sample coil to be placed out of doors away from all buildings (we have found a brick wall to be unacceptably magnetic in this sense).

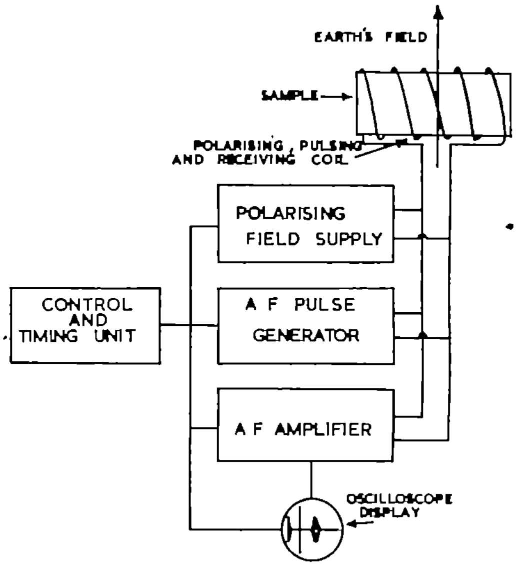

Fig. 1

In order to avoid this difficulty and to make it possible to carry out measurements in the laboratory without undue precautions and indeed to measure time-constants of such length that requirements of homogeneity would be excessive, we have devised a method of measurement which circumvents the difficulty due to the field inhomogeneity in a manner similar to that used at higher fields, namely, by a spin-echo technique[3]. In our experiment we apply the polarizing field at right angles to the Earth's field for a certain time, T, longer than T_1 and then remove it (Fig. 1). In passing, we note that a free-precession signal is observed (Fig. 2) which is attenuated by field in-

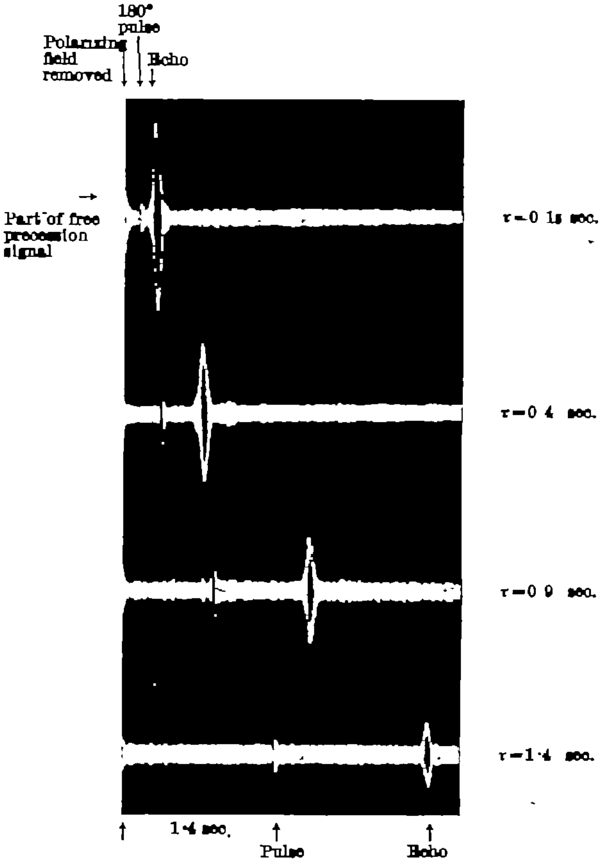

Fig. 2

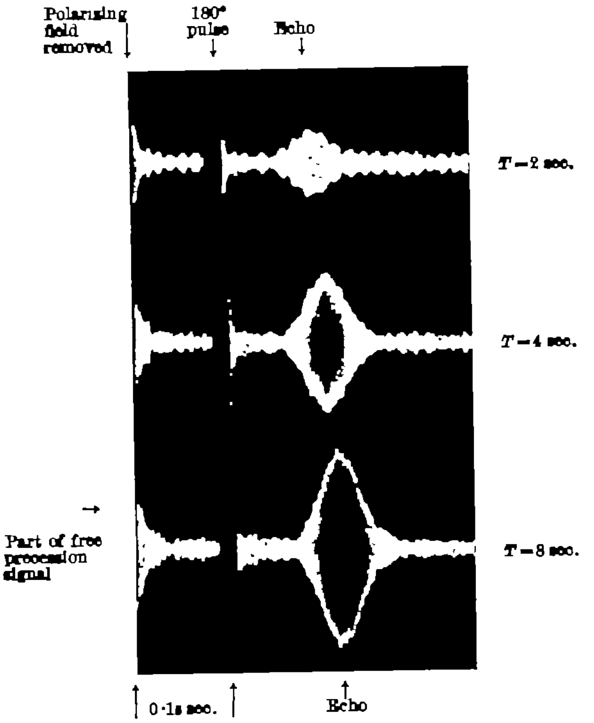

Fig. 3

inhomogeneities (75 microgauss/cm.). At a time τ later, we apply a '180°-pulse' at the resonant frequency in the Earth's field (actually 2 kc./s., 20 msec. and 0·1 V.). At a further time τ later, the echo pulse is observed on the oscilloscope. The width of the echo is inversely proportional to the field inhomogeneity. By varying the time τ, the delay of the pulse after the removal of the polarizing field, we observe echoes the amplitude of which is proportional to $\exp(-2\tau/T_2)$ This effect is shown in Fig. 2. We are thus able to derive a value of T_2 the true spin – spin relaxation time in the presence of field inhomogeneity just as in the echo experiment at high fields. We have also the advantage, usual in echo measurements, of observing our signals (a few microvolts) at times well removed from disturbing effects due to polarizing and pulse voltages. In the example shown the sample was double-distilled water, and we find $T_2 = 3 \cdot 5$ sec. which is the expected value, since T_1 at low fields is 3·5 sec[4] and we should have $T_1 = T_2$ in this case.

The free-precession experiment has also been used to measure T_1 the spin – lattice relaxation time in low fields[2,5]. In this experiment the amplitude of the free-precession signal is observed as a function of the time of application of the polarizing field, T, and is proportional to $\{1 - \exp(-T/T_1)\}$. This method suffers from the same difficulty as the precession method for T_2, but in less acute form, since it involves observing a free-precession signal immediately after switching off a large current in the coil with its attendant transients. Our method considerably simplifies this problem also, in that we again apply a '180°-pulse' but always at a fixed time, τ', after switching off the polarizing field and observe the amplitude of the echo—which should be proportional to $\{1 - \exp(-T/T_1)\}$—as a function of T. The effect is shown in Fig. 3. The derived value of T_1 in this case is 3·5 sec., and this is the value of T_1 for a field of 200 gauss (the polarizing field), which agrees with previous measurements[3] as well as with our value of T_2 as already mentioned.

In the experiments described a sample of 500 ml. of water was used, but we hope to be able to reduce this considerably in due course, since almost all the noise now observed is extraneous pick-up and it should be possible to shield it, albeit with difficulty.

We intend to use this method for measuring T_1 and T_2 and self-diffusion coefficients of liquids. For this purpose the apparatus is extremely cheap and simple, and there is, of course, the added interest of being able to measure the parameters T_1 and T_2 at low fields for materials in which they differ from the high-field values.

Note added in proof: We now get the same signal-to-noise ratio from a 100-ml. sample.

Multipole Radiation from High-Current Gas Discharges

Research in the field of high-current gas discharges is now being pursued vigorously[1]. In these discharges, where the gas is highly ionized, higher spectra can be predominantly excited (for example, O III, A II) and the pinch effect reduces the loss of ions to the walls. It is thus interesting to consider the possibility of detecting in the laboratory those forbidden lines which are of astrophysical importance.

In the past, very little success has been achieved in this direction. Nagaoka and Futagami[2] claim to have obtained forbidden lines of the N II, N III and O II spectra but not of the O III spectrum. Their paper is unfortunately completely devoid of any detailed spectral data. On the other hand, Emeléus, Sloane and Cathcart[3] were unable to obtain forbidden lines of ionized nitrogen, oxygen and neon in their discharges. The view has also been expressed that it is impossible to produce sufficient numbers of these ions in the requisite metastable levels to build up the intensities of the forbidden lines to observable values[4]. Here it is shown that there is a reasonable chance of detecting some forbidden lines (transition probability greater than 1 sec.$^{-1}$) of highly ionized atoms in the radiation from a high-current discharge using a conventional prism spectrograph of medium aperture.

We estimate the time required to record the forbidden line of a spark spectrum on a photographic plate in the following way. By comparing the exposure times required for the detection of permitted and forbidden lines of the same spectrum, we avoid the difficulty of estimating the population, N, of the metastable levels. The optical density of a spectral line (wave-length λ) on a photographic plate is a function of NAt/λ where A is the spontaneous transition probability and t the exposure time. Let us denote an optically permitted line by the subscript p and a forbidden line by the subscript f. We assume the ionized gas to be in thermal equilibrium at the temperature T. By applying Boltzmann's distribution law to the two atomic states in question with statistical weights g_p and g_f, and separated by an energy difference E_{pf},

$$t_f = \frac{g_p}{g_f}\,\frac{A_p}{A_f}\,\frac{\lambda_f}{\lambda_p}\exp\left(-\frac{E_{pf}}{kT}\right)\cdot t_p$$

provided that the density of the two lines is the same. Variations in spectral sensitivity and reciprocity failure of the photographic plate are neglected. The time t_f can therefore be estimated from the known exposure time of a permitted line under typical experimental conditions of a pulsed high-current discharge. For example, at a pressure of 3×10^{-3} mm. of mercury in nitrogen gas and an exposure time of 4×10^{-4} sec., the measured density of the permitted line N II λ 3,995·0 recorded with a Hilger prism spectrograph of focal ratio $f/7$ on an *HP*3 plate (by Ilford, Ltd.) was 1·4. Let kT be about 20 eV. and the forbidden line selected for comparison, [N II] λ 5,755. For this line, t_f is computed to be about 1×10^3 sec. This time represents an upper limit and will be less if thermal equilibrium does not exist. If the discharge is run at a reasonable duty cycle (for example, 0·02), it will take from several hours to about one day to produce a perceptible blackening on a photographic plate (for example, density 0·4) for some four forbidden lines of the ionized atoms of argon, neon and oxygen in addition to [N II] λ 5,755.

In high-current discharges operating at low pressures, thermodynamic equilibrium does not exist, nor is there as yet any conclusive evidence that the electrons and ions are in thermal equilibrium. However, on the basis that the populations of metastable ionized atoms in the ground configuration are governed by Boltzmann's distribution law (cf. the condition of gaseous nebulæ in the limit of high electron concentration), the electron temperature of the discharge can be estimated by measuring the relative intensities of two of the forbidden lines. The method is limited to temperatures up to about 10^5 deg. K. owing to the increasing insensitivity of the exponential factor in the Boltzmann distribution as the temperature rises. It may therefore be of greater value to low-current discharges in, say, the rare gases. Relative values of transition probabilities can possibly be determined, provided either an independent measurement of the electron temperature has been made or it is so high that the exponential factor can be taken as unity. A check could then be made of forbidden transition probabilities of astrophysical interest which have been determined either by calculation or from observations on nebular lines.

I am grateful to Dr. R. H. Garstang, University of London Observatory, for a discussion on forbidden lines, and to Mr. T. P. Hughes for measuring the densities of some spectral lines. Effect of High-Energy Radiation on Polypropylene

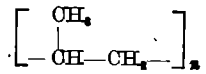
THE radiation chemistry of polypropylene is of particular interest because its chemical constitution :



$$\left[-\overset{\displaystyle CH_3}{\overset{|}{C}H}-CH_2-\right]_n$$

is intermediate between that of poly*iso*butylene, which exhibits molecular degradation, and that of polyethylene in which although some degradation occurs, cross-linking predominates. It has been reported in the literature that polypropylene undergoes cross-linking on exposure to high-energy radiation[1], but no information has hitherto been reported as to the extent to which molecular degradation takes place. For this reason we have undertaken an investigation of the radiation chemistry of polypropylene, the preliminary results of which are given below.

A specimen of polypropylene, prepared by the Ziegler process, was made available by courtesy of Montecatini of Milan. The number average molecular weight of the material, determined from the intrinsic viscosity by the method described by Ciampa[2] was found to be of the order of 90,000.

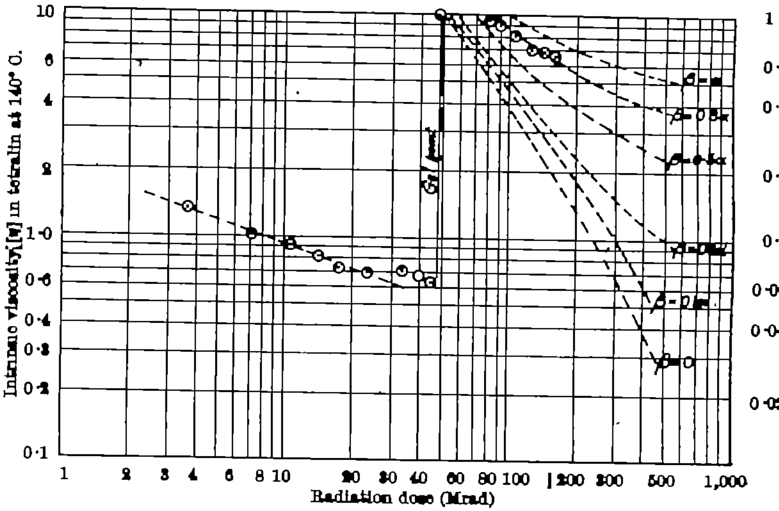


Fig. 1. Variation of intrinsic viscosity and sol fraction with radiation dose

Samples of the polymer were irradiated, while sealed under vacuum in polyethylene tubes, in a beam of 2-MeV. electrons from a Van de Graaff particle accelerator. Doses received by the polymer samples were estimated by carrying out elastic modulus measurements at 150° C. upon the polyethylene tubes which had contained the samples[3]. It was found that the number average molecular weight decreased steadily in a manner which may be deduced from the assumption that breaks occur in the main polymer chain at random, and that the number of breaks produced is, initially at least, directly proportional to the radiation dose given to the sample. After a radiation dose of about 50 Mrad, prolonged extraction of the polymer with boiling toluene led to the separation of a cross-linked gel fraction from the soluble, degraded, polymer. The gel showed appreciable swelling in the toluene and a log–log plot of the equilibrium swelling ratio at 25° C. against the radiation dose, corrected for the dose necessary to bring about gel formation, gave a straight-line relationship of gradient −5/3, which is in accordance with the Flory–Rehner relationship for the swelling of cross-linked polymer[4].

From a plot of the values of the sol fraction against radiation dose when compared with the theoretical sol values in the presence of various ratios of cross-linking to molecular degradation as derived by Charlesby[5], it would appear that for every cross-link formed during irradiation, about 1·6 bonds between monomer units are broken.

Fig. 1 shows the variation of the experimental values of the sol fractions with radiation dose; and, in addition, a plot of the intrinsic viscosity of a solution of the polymer up to the gel point.

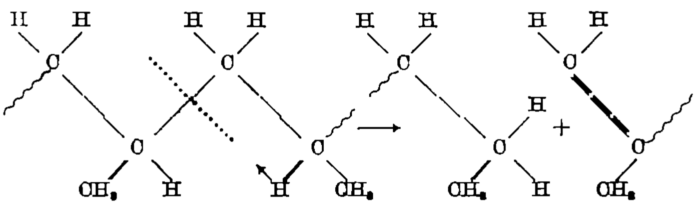
Approximate yields (G values) for an energy deposition of 100 eV. are given in Table 1, which compares the yields with those of polyethylene and poly*iso*butylene.

Table 1

Event	Events per 100 eV. deposition		
	Polyethylene	Poly*iso*butylene	Polypropylene
Cross-links	6 8	0	0 6
Double bonds	3 4	9 3	3 9
Bonds between monomers broken	3 0	5·0	0 9

An examination of the infra-red absorption spectrum of irradiated polypropylene has shown that the principal chemical change, other than cross-linking and chain fracture, is the introduction of unsaturation of the type $R.R'C{=}CH_2$ (vinylidene). There is some evidence for the presence of a small amount of vinyl unsaturation, $RCH{=}CHR'$, but the band is obscured by another absorption band which has not yet been assigned.

It is suggested that the molecular degradation proceeds by the following disproportionation mechanism :



It is hoped to report the results of this investigation more fully at a later stage.

We thank Miss D. E. Bowles for infra-red measurements, and Dr. L. G. Brazier, director of research and education, British Insulated Callender's Cables, Ltd., for permission to publish this communication

The Tanberg Effect

In a recent communication, Robson and von Engel[1] have suggested that Tanberg's explanation of the reaction force on the cathode of an arc in vacuum is incorrect, and that the mass used in his momentum equation should have been a hundred times larger, giving rise to a more 'reasonable' particle velocity of 10^4 cm./sec. rather than 10^6 cm./sec.

It is exceedingly difficult to reconcile this suggestion with the results of Easton, Lucas and Creedy[2], who obtained velocities which agreed fairly well with Tanberg's, by a method which did not directly involve the cathode, but measured the force on a vane facing the cathode some two centimetres away from it. Their results were obtained with rather a poor vacuum (40×10^{-3} mm. mercury).

Experiments have been made in these laboratories in which the force exerted on a vane mounted behind a perforated anode by vapour emitted from the cathode of a vacuum arc has been measured. The vacuum was better than 10^{-3} mm. mercury, the metal vapour cast sharp shadows, and the space potential at the vane was measured to be certain that electrostatic effects were not influencing the vane. The average velocity of the vapour jet from a cathode spot on magnesium was found to be about 2×10^6 cm./sec. and from a cathode spot on copper about 1×10^6 cm./sec. These figures agree well with those quoted by Easton, Lucas and Creedy. While the nature of the experiments is such that the results cannot be expected to be highly accurate, there seems no doubt that the orders of magnitude are correct and that vapour is in fact ejected from the neighbourhood of cathode spots in vacuum, although not necessarily from the metal surface, with these high velocities. These results have been discussed with Drs. Robson and von Engel, whose most recent views are expressed in a paper shortly to be published.

Growth of Sucrose Crystals

Layer growth on crystals was observed by Marcelin[1] and other workers. Steps on crystals could be produced by surface nucleation or by the presence of screw dislocations which terminate at the surface[2]. The layers on cadmium iodide growing in aqueous solution[3] were shown by Forty[4] to be steps originating from dislocations. While Bunn[5] was unable to find any layers on growing sucrose crystals, Powers[6] observed them but without seeing any definite signs that they were due to screw dislocations. We have made an extensive examination of the surface features of sucrose crystals grown in the temperature-range 15–30° C. and conclude that the normal growth process is that described by Frank[7]. Step systems in the form of growth hills have been shown to be present on all faces of sucrose crystals when grown in pure sucrose solution and in sucrose solution with added dextrose or lævulose as impurity. Crystals grown in sucrose solution with added dextrose (0·2 per cent by weight of the sucrose) have steps which generally are much larger (about 40 times) than those grown in pure solutions of sucrose or in solutions with added lævulose.

Fig. 1. 100-face of growing sucrose crystal showing: 1. simple growth spiral: 2, double spiral (× 60)

A photomicrograph (Fig. 1) was taken of the 100-face of a crystal while still growing. On it can be seen a simple growth spiral centred on a screw dislocation and also a double spiral with centres on a close pair of dislocations of like sign. On other crystals dislocation pairs of opposite sign give rise to closed loops of steps, and the shape of the loops on any one face is essentially constant. The shapes are asymmetric, those on the 100-face being roughly D-shaped, indicating that the edge free energy depends on the orientation. Radial lines are frequently observed on the growth hills and are provisionally ascribed to the interaction of number of growth centres in close proximity.

The rate of movement of the steps, the spacing between them and their heights can be measured under known conditions of supersaturation, temperature and stirring. On any one growth hill the rate of movement of steps is found to be constant. Our results are in broad agreement with the discussion of Burton, Cabrera and Frank[8] for monomolecular steps. From the measurements, the rate of vertical growth of the hill can be derived and is shown as a function of concentration in Fig. 2. It will be observed that growth ceases at an appreciable supersaturation: this effect has been observed a number of times and is attributed to the distance between dislocation centres being less than the dimension of the critical surface nucleus. Owing to the varying activities of the growth centres, equivalent faces of different crystals show different rates of vertical growth at the same supersaturation. This is in qualitative agreement with the unpublished work of Garner and Wischin, who found variations of up to 50 per cent in the gross rates of growth measured on single sucrose crystals.

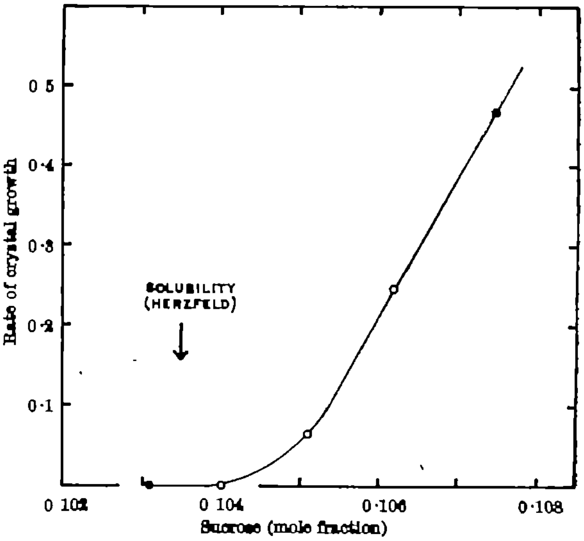

Fig. 2. Relative rate of vertical growth of 100-face as a function of the concentration of the solution

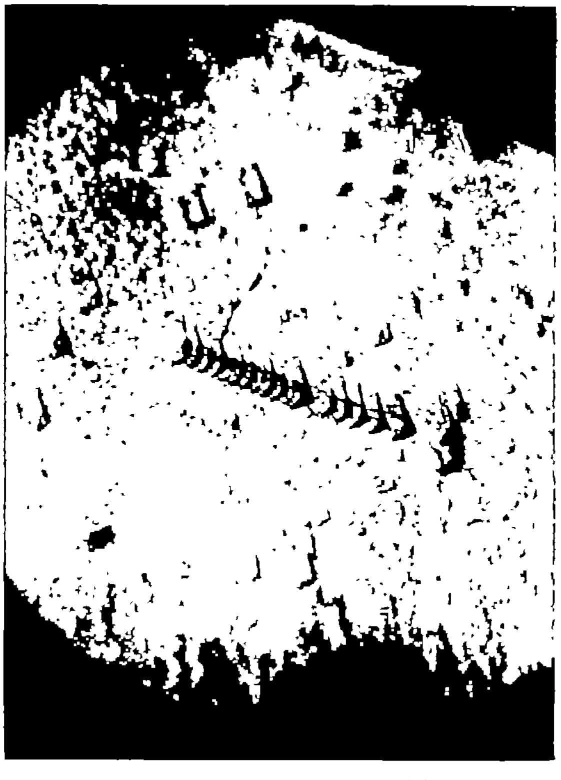

Fig. 3. Line of etch pits on a sucrose crystal (× 400)

On reducing the concentration of the solution to saturation and just below, the first sign of crystal dissolution is the formation of small etch pits at the ends of dislocations where the molecules are less firmly bound than on the rest of the crystal surface[7]. We have studied the formation and distribution of etch pits on sucrose crystals, and the linear arrangement seen in Fig. 3 is not uncommon. The number, position and size of the pits can be related to the conditions under which the crystal was grown.

We wish to thank Mr. H. C. S. de Whalley and the directors of Tate and Lyle, Ltd., for their interest and encouragement.

Photochemical Stability of Dyes in the Solid State

IT has recently been shown[1] that it is possible to produce level transparent dye films upon thin quartz plates by the method of vacuum deposition. This technique makes it possible to compare under similar conditions the photochemical stability of dyes in the solid state with their stability when present as a dyeing on a polymer film. For this purpose we have used several aminoanthraquinone compounds purified by repeated recrystallizations from ethyl alcohol. Polymer films were dyed with these compounds from an alcohol solution, and solid deposits upon small quartz plates were prepared with an Edwards high-vacuum coating unit. These samples were then sealed inside quartz cells through which it was possible to maintain a flow of dry oxygen or dry nitrogen (oxygen-free) continuously during exposure to a high-pressure mercury-vapour lamp (in glass) and while absorption measurements were being made on a Unicam *SP* 500 quartz spectrophotometer.

It was observed that the aminoanthraquinone compounds are much more stable to the action of near ultra-violet and visible light when present in the form of a solid film on quartz rather than as a dyeing on a polymer film. This difference in photochemical stability is illustrated in Fig. 1 by the absorption curves for 1-aminoanthraquinone on cellulose acetate film (deplasticized, British Celanese, 0·001 in. thick) and deposited on quartz, before and after exposure in dry oxygen for 2,500 hr. After irradiation the absorption of the dyed acetate film is considerably reduced at all four of the visible and ultra-violet absorption bands. Under similar exposure conditions, the changes produced in the spectrum of the solid deposit on quartz are much less. There are small reductions in the bands in the visible and near ultra-violet regions, but below 2800 A. there appears to be a slight increase in absorption. The difference in photochemical stability is even more marked with 1 : 4 diaminoanthraquinone. On cellulose acetate film there is a considerable change after irradiation in dry oxygen for 2,500 hr., with a reduction of nearly one half in the intensities of the twin absorption peaks in the visible region, yet after the same exposure period there is no change at all in the spectrum of the solid film on quartz.

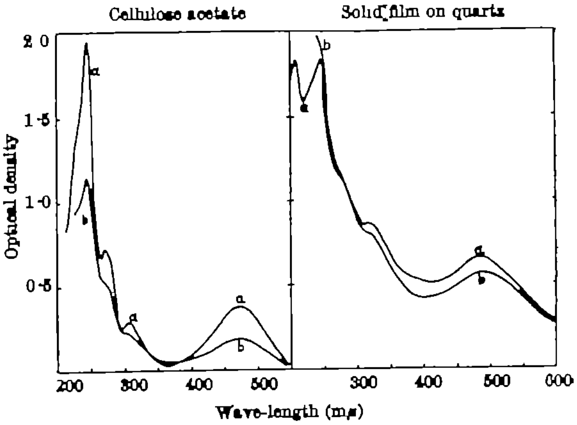

Fig. 1. 1-Aminoanthraquinone exposed to 400-W. high-pressure mercury-vapour lamp at 35° C.: *a*, unexposed; *b*, exposed 2,500 hr. in dry oxygen

The effect of the presence or absence of oxygen on the photochemical stability of these compounds also seems to differ considerably between the solid state and dispersion in a polymer film. The results in Table 1 refer to the percentage decrease which occurs in the visible absorption band of 2-amino- and 1 : 5-diamino-anthraquinone after irradiation in dry oxygen or dry nitrogen. The exposure period for the cellulose acetate dyeings was only 300 hr., as compared with 2,000 hr. for the solid film on quartz, yet in both atmospheres the fading of the aminoanthraquinone compound is substantially greater with the polymer film. On the latter substrate aminoanthraquinone compounds seem to fade quite considerably in dry nitrogen; particularly is this so with 2-aminoanthraquinone. The photochemical stability in dry nitrogen seems, however, to be much greater when the dye is in the solid state. The absorption maxima for 2-amino- and 1 : 5-diamino-anthraquinone on cellulose acetate film are at 4330 A. and 4870 A., respectively.

Table 1

Anthraquinone	Decrease in visible absorption band (per cent)			
	Cellulose acetate (300 hr.)		Solid film (2,000 hr.)	
	Nitrogen	Oxygen	Nitrogen	Oxygen
2-Amino-	74	57	9	43
1 5-Diamino-	17	51	0	13

The photochemical stability of these aminoanthraquinone compounds is presumably dependent *inter alia* upon the mode of attachment of the dye molecules either to themselves (in the solid state) or to the polymer substrate. In this respect the views of Weinstein and Wyman[2] seem to be of importance. They have suggested that the strong bathochromic shift which is observed with the spectrum of indigo in the solid phase[3] can be taken as indicating a considerable extension of the resonating system with the formation of dimers or higher polymers in the solid phase, held together by intermolecular hydrogen bonds. The formation of similar complexes between molecules of aminoanthraquinone compounds would seem to be possible in the solid state. The visible absorption maxima for 1-aminoanthraquinone are 4450 A. (hexane[4]) and 4900 A. (solid state), for 2-aminoanthraquinone 4800 A. (hexane[4]) and 4550 A. (solid state), and for 1 : 5-diaminoanthraquinone 4820 A. (dioxane[5]) and 5070 A. (solid state), so that there is a strong bathochromic shift in the solid state similar to that which occurs with indigo. The formation of intermolecular complexes may well be the reason for the marked improvement in the photochemical stability when the aminoanthraquinone compounds are present in the solid phase. It is worth noting, however, that when the complex occurs between the dye molecule and nylon substrate the light stability is poor. The aminoanthraquinone compounds do in fact show a marked bathochromatic shift on nylon similar to that given by the dye in the solid state, but presumably the unsymmetrical character of the complex formed is responsible for the poor photochemical stability.

Decrease in Fluorescence Intensity of a Solution of Fresh Cigarette Smoke Products on Exposure to Light

ATTENTION has been directed by Schmähl and Schneider[1] and Druckrey and Schmähl[2] to the decrease in intensity of fluorescence which occurs when a benzene solution of fresh cigarette smoke products is exposed to light. This decrease in fluorescence indicates one obvious difference between the smoke, which will contain unchanged products when inhaled by the smoker, and any solution of the smoke products which has been exposed to light and which is then used for chemical or biological tests.

Schmähl and Schneider[1] found that the rate of decrease of intensity of fluorescence is dependent on the intensity of the light, and that ultra-violet light could cause decrease below the end-value which could be reached with daylight. It was concluded that more than one 'labile' component existed. The chemical nature of the 'labile' components was not known; but they were not thought to be aromatic hydrocarbons or alkaloids and were non-polar.

The present findings are that the 'labile' fluorescent components are products of heating the tobacco and paper, since no decrease occurs in a benzene extract of unsmoked tobacco. On heating tobacco to temperatures of 200–300° C., distillates are obtained (boiling points below 200° C.). The fluorescence intensity of a benzene solution of these distillates decreases at a similar rate to that of tobacco smoke products when exposed to light.

This phenomenon is in fact not unique to tobacco, but appears to be common to many vegetable products heated to these temperatures. 'Cigarettes' were manufactured containing sawdust, cotton-wool, cellulose powder and the dried leaves of three common weeds. When these were smoked mechanically in the same way as ordinary cigarettes the fluorescence intensity of solutions of the smoke products in benzene decreased on exposure to light. Similarly, decrease occurred with cigarettes the tobacco in which had been exhaustively extracted with concentrated acid and alkali and organic solvents. The rates of decrease were similar to that of tobacco smoke products, but the percentage of the total fluorescent material which was labile varied for the various substances. However, tobacco is the only vegetable product commonly smoked and inhaled into the lungs in this manner, and therefore this decrease in fluorescence might still be significant.

Greene[3] stated that the formation of free radicals might be expected when organic material is subjected to treatment similar to that of tobacco in cigarette smoking. Photochemical reaction such as described above suggests also a free-radical mechanism or intermediate. It is possible that some of the tars or resins in cigarette smoke products might be products of free-radical initiated polymerization; however, anhydrous aluminium chloride, which is a catalyst for ionic polymerization, proved a much more effective catalyst for the precipitation of resins from solutions of cigarette smoke products than the free-radical polymerization-catalysts which were tested. Many authors have discussed the carcinogenicity of free radicals and of substances which can readily form radicals *in vivo*. It has been suggested that radicals might be detected in cigarette smoke products (Lyons, M. J., unpublished results). It is possible that the paramagnetic resonance methods of Commoner *et al.*[4] for detection of free radicals, in biological matter and in coal tar, in the presence of much diamagnetic material, might be applicable to cigarette smoke products.

I am indebted to Dr. P. R. Peacock for helpful suggestions and to the Medical Research Council for a grant.

Oxygen as a Donor Element in Germanium

THERE have been a number of studies of the germanium–oxygen system from the point of view of compound formation, thermodynamics and crystal structure. Some workers have studied the effects of oxide films on the surface properties of germanium, with particular reference to conduction and rectification. However, little seems to have been published on the behaviour of oxygen as a significant doping impurity in bulk germanium. Clarke[1] observed, during experiments on the effect of oxygen on surface conduction, that after repeated exposure to oxygen, followed by heating in a high vacuum, a high resistivity germanium sample acquired a permanent larger

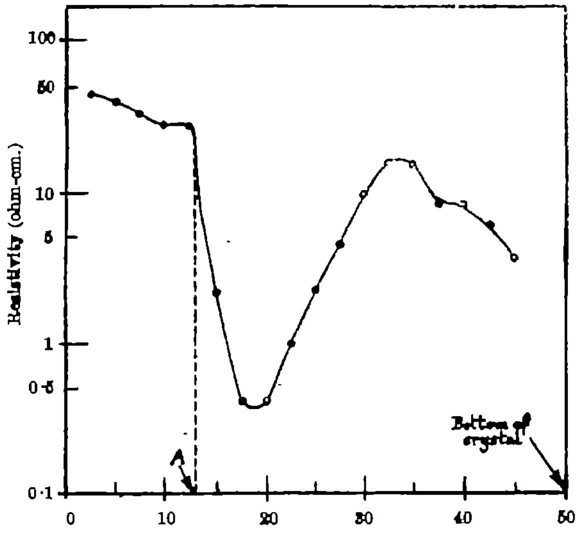

Fig. 1

n-type conductivity. This appeared to be due to the diffusion of n-type centres deep into the sample, and he suggested that oxygen might be responsible for these donor centres in the bulk while at the same time producing electron traps at the surface.

Evidence is now available that oxygen is an active donor element in germanium. This was first observed as a result of an air leak into a zone-refiner tube in which germanium was being processed in nitrogen. An intrinsic bar was converted to a very low n-type resistivity, below 0·05 ohm-cm. However, when this material was used for growing a single crystal in a hydrogen atmosphere, with a controlled amount of antimony added, the calculated resistivity, of 7 ohm-cm. near the top of the crystal, was obtained. The large amount of n-type doping agent in the original germanium had therefore been eliminated by crystal pulling in hydrogen. It was found that single crystals grown in both pure nitrogen and pure argon showed sudden changes of resistivity when small quantities of air were added to the atmosphere. The resistivity profile of a typical crystal is shown in Fig. 1. Air was admitted at point A along the length of the crystal, and the resistivity fell almost immediately from 25 to 2·1 ohm-cm., and shortly afterwards to 0·38 ohm-cm. n-type. The partial pressure of oxygen was about 15 mm. mercury. The rise in resistivity following the initial sharp drop suggests either the loss of doping agent from the melt by evaporation or a value of the distribution constant for oxygen greater than unity (compare the behaviour of boron, for example). Nitrogen is known to be inactive towards germanium in its normal molecular form[2] and is used as an inert atmosphere for processing. The activation energy of the oxygen donor level or levels remains to be determined. Armstrong, Tyler and Woodbury[3] have recently shown that selenium and tellurium, also in Group VI A, may act as double donors in germanium, and Kaiser and Keck[4] have explained donor action in silicon, associated with heat-treatment effects, as being due to the presence of oxygen. Thurmond, Guldner and Beach[5] have shown that germanium normally contains oxygen in concentrations of the order $1–3 \times 10^{18}$ atoms/cm.^{3}, together with hydrogen in concentrations of the order $3–8 \times 10^{18}$ atoms/cm.^{3} It is possible that the oxygen here may be combined with the hydrogen in the lattice and so rendered inactive. We have confirmed these figures of oxygen concentration by direct chlorination and weighing of oxide residues.

Changes of Organic Phosphate Esters during Glycolysis in Blood followed by a Paper Chromatography Method

THE blood glucose concentration decreases very rapidly during incubation of a sample of blood *in vitro* at 37° C.[1-3]. During this glycolytic process very substantial changes take place in the content of the organic phosphate esters. These changes are related to the decrease of blood glucose, as was suggested by Paysant and Wolf[3]. Many workers have studied the behaviour of the acid-soluble phosphorus fractions in blood during incubation *in vitro*, and they have observed an increase of inorganic phosphate, a decrease of easily hydrolysable phosphate esters (this fraction represents the phosphorus largely derived from adenosine triphosphate), a decrease of phosphate fraction hydrolysable with difficulty (phosphorus released largely from hexose phosphates) and a decrease of non-hydrolysable phosphate esters (this fraction consists mainly of the 2,3-diphosphoglycerate)[3-5].

In the present communication the changes of the organic phosphate compounds of human blood during glycolysis were followed by using the paper chromatography method. Further, the behaviour of the acid-insoluble phosphorus fraction of blood (which consists of phospholipids, phosphoproteins and of phosphorus of the ribonucleic acids) was also studied.

Ten heparinized venous blood samples from healthy subjects were aerobically incubated *in vitro* at 37° C. for 24 hr. The specimens for determination of glucose concentration and of the phosphorus fractions were drawn before incubation and at the 3rd, 6th, 9th, 12th and 24th hr. during incubation. For ascendant paper chromatography of acid-soluble phosphorus compounds 0·5 ml. of blood was deproteinized with 0·5 ml. cold 10 per cent trichloracetic acid. The filtrate was neutralized by the addition of one drop of ammonium hydroxide and 0·03–0·08 ml. was applied on Watman No. 1 filter paper washed with 1 N hydrochloric acid. The solutions of known organic phosphate esters were also applied simultaneously on paper. The chromatograms were run for 14–16 hr. at 4° C. using methanol : ammonium : water as a solvent mixture[6]. After development, the chromatograms were dried at room temperature and

Table 1. The Changes of the Phosphate Fractions of Blood during Glycolysis *in vitro*

Time (hr.)	Glucose (mgm. per cent)	Inorganic phosphate (mgm. per cent)	Hydrolysable with ease (mgm. per cent)	Hydrolysable with difficulty (mgm. per cent)	Non-hydrolysable (mgm. per cent)	Acid-insoluble (mgm. per cent)
0	119	2·60	5·15	3·44	15·22	10·70
3	78	2·50	5 12	2 85	15·25	10·20
6	31	4 45	3·65	3·85	14 22	10·20
9	20	9 30	3·41	2·61	11·23	9·20
12	16	21·30	0·20	0·97	0·6	9·40
24	12	26·50	0·10	1·13	1·65	9·20

sprayed with Hanes–Isherwood acid molybdate solution[7]. After hydrolysis the chromatograms were treated with a solution of tin chloride[8].

It was found, as observed by Rohdewald and Weber[9], that the acid-soluble phosphorus fraction of human blood contains adenosine triphosphate, fructose-1,6-diphosphate, triosephosphate (mainly 2,3-diphosphoglyceric acid) in addition to inorganic phosphate (Fig. 1). During glycolysis in blood a decrease amounting to total disappearance of adenosine triphosphate, fructose-diphosphate, triosophosphate and a large increase of inorganic phosphate were observed (Table 1, Fig. 1). The inorganic phosphate was released by the progressive hydrolysis of the organic phosphate esters when the blood-glucose concentration fell below 20 mgm. per cent. No significant or substantial changes were found in the acid-insoluble phosphate fraction of blood, which points to the fact that the acid-insoluble organic phosphate compounds probably do not participate directly in the metabolic pathways of phosphorus during glycolysis in blood.

Acknowledgments are made to Messrs. Sigma Chemical Company, St. Louis, for supplying the samples of adenosine triphosphate and adenosine diphosphate. I thank Miss M. Vansčák for technical assistance.

Classical Motion under a Morse Potential

Students of diatomic molecules and of related systems have long used the Morse potential function[1]

$$V(x)=D\{1-\exp(-ax)\}^2 \qquad (1)$$

where x is the stretch of the interatomic bond (with $V=0$ at the equilibrium configuration $x=0$), D is the dissociation energy, and a a constant parameter. For energies less than D and no rotation, Morse gave the quantum energy levels of (1), namely

$$E_n=(n+\tfrac{1}{2})h\nu_0-\{(n+\tfrac{1}{2})h\nu_0\}^2/4D, \quad n=0,\ 1,\ 2,\ldots \qquad (2)$$

where $\nu_0\equiv(a/2\pi)(2D/\mu)^{\frac{1}{2}}$ is the frequency of classical small vibrations, μ being the reduced mass of the two bonded atoms.

Just as the quantum levels (2) are closely related to those of the harmonic oscillator, so also there is a close relation between the classical Newtonian motion under (1) and that of the harmonic oscillator. I found that Prof. Morse was aware of this; but he suggested that it should be made more widely known. The classical energy equation for the relative rectilinear motion of the two atoms is

$$\tfrac{1}{2}\mu(dx/dt)^2+D\{1-\exp(-ax)\}^2=E \qquad (3)$$

If the energy E is less than D, then integration (for example, using $\exp(ax)$ as variable) gives

$$ax=\log[\{1-\cos\theta\cos(2\pi\nu_0 t\sin\theta)\}/\sin^2\theta] \qquad (4)$$

where $\cos^2\theta=E/D$, and the time t is measured from the position of minimum x. Thus the classical motion is periodic, and may be described as the logarithm of simple harmonic motion. The frequency of vibration at energy E is, from (4),

$$\nu=\nu_0\sin\theta=\nu_0\{(D-E)/D\}^{\frac{1}{2}}$$

tending to zero as E approaches D. If E has a value E_n as in (2), the classical motion has frequency

$$\nu=\nu_0\{1-(n+\tfrac{1}{2})h\nu_0/2D\}$$

depending linearly on the quantum number *n*.

For an energy *E* greater than *D*, the classical motion found from (3) is

$$ax = \log[\{\cosh\theta\cosh(2\pi\nu_0 t\sinh\theta) - 1\}/\sinh^2\theta)]$$

where now $\cosh^2\theta = E/D$. This non-oscillatory motion corresponds to dissociated states. The intermediate case $E = D$ gives classically

$$ax = \log\tfrac{1}{2}\{1 + (2\pi\nu_0 t)^2\}$$

This classical picture may usefully supplement the quantum-mechanical results.

Prediction of Critical Temperatures

IN cases where critical temperatures are unknown they can be calculated from a number of empirical or semi-empirical formulæ[1], the simplest but least-accurate being Guldberg's rule. More accurate equations exist for estimating values for hydrocarbons, for example, those of Jatkar and Lakshminarayanan[2] and Watson[3], but these are unsuitable for use with phenolic and basic organic compounds which occur in coal tar.

The critical temperatures of fourteen paraffins, twenty-five aromatic hydrocarbons, four phenols and seven organic bases[4–6] have been correlated in these laboratories with the boiling point and density of the respective compounds[7,8] by the method of least squares. As a result it was found that the following equation predicts values in the range 260–530° C. with an accuracy of ±20·8° C., that is, with an average of ±5 per cent, with 95 per cent confidence:

$$t_c = 221 \cdot 6 + 1 \cdot 029\, t_b\, d_{20}$$

where t_c is the critical temperature (°C.), t_b is the boiling point (°C.), and d_{20} is the density at 20° C. (gm./ml.). (In the case of solids, liquid values were extrapolated back to 20° C.)

The major discrepancies are given by five hydrocarbons the omission of which reduces the limits of error to ±14·2° C.

X-Ray Microscopy of Human Dental Pulp Vessels

MICRORADIOGRAPHIC studies of the human dental pulp vessels were prompted by the inadequate anatomical information on the pulpal vascular patterns, and by the statement that these vessels could not be visualized radiographically[1]. However, it has been shown that fine-contrast media of particle size 0·1–0·5μ (for example, 'Thorotrast', 'Micropaque') can be introduced by suction injection into the human dental pulp vessels and their vascular patterns demonstrated microradiographically[2].

Good results have been obtained by contact microradiography using a standard Philips 'Norelco' X-ray diffraction tube and an Ehrenberg–Hilger microfocus tube, with an effective focal spot of 1 mm. and 0·04 mm. respectively. The contact method, however, is limited partly by the size of the X-ray source and the grain-size of the recording emulsion, while the resolution cannot exceed that of the optical system used for enlarging the X-ray negative.

Recently better resolution and contrast, with consequently sharper image definition of all the vessels in the dental pulp, have been obtained by the projection method, using the X-ray projection microscope developed by Cosslett and Nixon[3]. The marked primary magnification (up to × 200 or higher) obtainable with this instrument, coupled with the high resolution afforded by its point source of X-ray emission (less than 1μ), makes it possible to image the smallest capillaries within the human tooth with great clarity.

This X-ray microscope has distinct advantages over the optical microscope in such dental studies by virtue of its penetration and depth of field. Its great focal depth results in all parts of the specimen being in focus, and permits the taking of stereomicrographs by shifting the specimen laterally between two exposures.

A section of human dental (bicuspid) pulp imaged in juxtaposition to a piece of 1,500 mesh silver grid,

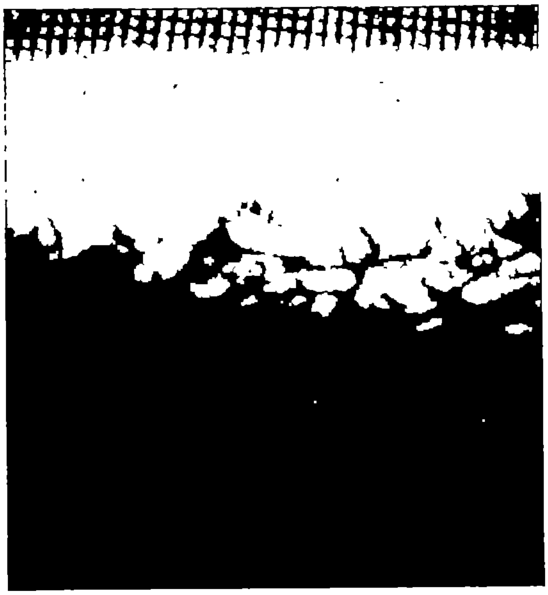

Fig. 1. X-ray micrograph of human dental pulp showing the capillaries of the subdentinal plexus imaged with 1 500 mesh silver grid

composed of 3μ bars with 17μ mesh spaces, illustrates the calibre of vessel demonstrable by X-ray microscopy (Fig. 1), showing as it does the smallest capillaries of the subdentinal plexus.

Other medical studies[4] have already made it clear that X-ray microscopy is capable of providing a detailed and dynamic picture of the minutest vessels that constitute the peripheral vascular system. New angiographic techniques used in conjunction with the X-ray projection microscope are now making it possible to observe vascular changes in living tissue (rabbit ear) under experimental treatment. This instrument produces microangiograms of even greater clarity than hitherto, and allows the demonstration of reactions in even the smallest vessels.

This work has been conducted under grants from the National Research Council of Canada. I wish to thank Dr. W. C. Nixon for many useful discussions, and also Miss R. M. Frye and Mr. C. K. Jackson for their help.

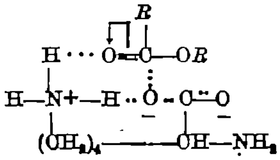
Chemical Model of a Biological Reaction

WE were searching for a model of an enzymatic reaction in the hope that the relatively simple chemistry of the model reaction might throw some light on the enzyme reaction itself. In particular, we were interested in finding a model which would duplicate some of the properties of lipases, notably their ability to catalyse the hydrolysis of lipids and the characteristic pH dependence of lipolytic activity which reaches a maximum near pH 8·5 with most lipases, and one just below pH 7 with some. Lipases being proteins, the model would have to be restricted to the functional groups available in proteins. The high potency of lipases, despite this restriction, together with the well-known chemical mechanism of ester hydrolysis, made us suspect that bifunctional catalysis[1] might play a decisive part.

Examination of high-precision atom models[2] disclosed the fact that the ϵ-ammonium group of lysine is sterically capable of forming a hydrogen bond with the carboxylate group of the same molecule, and that such a $—COO^- .. H_2N^+—$ bonded structure exactly fits an ester group in a fashion suitable for bifunctional catalysis, so that a proton of the ammonium group functions as an acidic catalyst at the carbonyl O of the ester and the carboxylate O of the lysine as a basic catalyst at the carbonyl O of the ester :



It stands to reason that the hydrogen bonds which the ϵ-ammonium group is to form with the carboxyl group of lysine and the O of the ester should be strongest when the N does not hold its hydrogens too tightly, because that is when they will be most readily donated for a hydrogen bond. Such would be the case just below the pH at which the ϵ-ammonium group of lysine loses a hydrogen and its positive charge. That happens at pH 9·5, so that lysine should be maximally active as a catalyst for ester hydrolysis around pH 8–9.

Similar reasoning could hold also for histidine, which, however, has no $—NH_3^+$, only two —NH— groups with one positive charge spread over them. If the H of either —NH— group is used up to form a (sterically possible) hydrogen bond with the histidine carboxyl, this H is no longer available for hydrogen bonding to the substrate, and the other —NH— is too far away to act in concert with the $— COO^-$. If histidine is to be lipolytic, its carboxyl group is more likely to be attracted to the positively charged ring as a whole, which leaves the —NH— groups free to form hydrogen bonds elsewhere. This arrangement is sterically able to catalyse ester hydrolysis but with less hydrogen bonding and poorer fit than lysine. Histidine should therefore be a weaker lipolytic agent, with an optimum somewhat below the isoionic point of histidine, that is, around pH 6–7.

The foregoing speculation was tested by measuring the rate of hydrolysis of tributyrin according to Alper's method[3] for the assay of lipases, but using lysine or histidine in 1 per cent concentration instead of lipase. As graphically shown in Fig. 1, the results bear out our expectations, inasmuch as both lysine and histidine are capable of catalysing the hydrolysis of the test lipid, tributyrin, lysine being far more potent, and both amino-acids having maximum activity exactly at the expected pH.

We also tested glycine in the same experimental arrangement and found no lipolytic activity. Thus it appears that such activity is specific to lysine and histidine (and possibly to some other amino-acids) but cannot be a general property of all amino-acids.

We were impressed by the fact that the pH optima which we postulated for the lipolytic activity of lysine

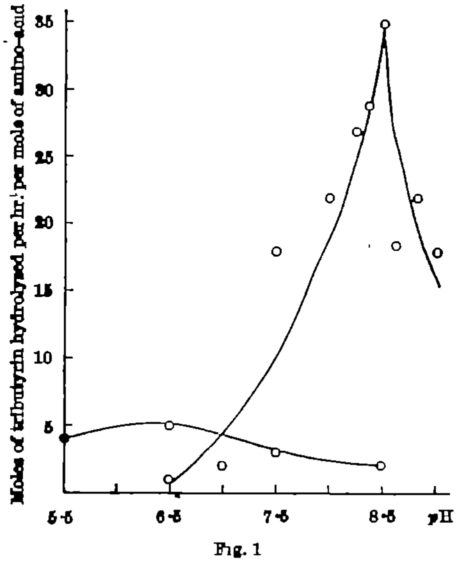


Fig. 1

and histidine, and which were confirmed by the experiment, are also the *p*H optima of the natural lipases. The question arises whether the lipolytic activity of lysine and histidine has any relevance to that of the lipases, that is, whether lysine and histidine are also lipolytic when within a polypeptide chain. (Note that the postulated lipolytic mechanism of both these amino-acids involves only one O of the carboxyl group and not at all the α-amino group.) The attractiveness of this idea lies in the circumstance that it accounts for lipolytic activity in a protein without calling on any other factors than two amino-acids ubiquitous in proteins, and that it explains the *p*H optima of the lipases. Against the hypothesis must be held the fact that not all proteins are lipases, but those that are, are much more potent catalysts of lipid hydrolysis than are lysine and histidine. However, both these amino-acids are highly hydrophilic and therefore at a disadvantage in attacking lipids. If they are to be important in the activity of those polypeptides which act as lipases, the rest of the polypeptide molecule must be equally important in providing the means—for example, van der Waals bonds—by which the catalyst attaches itself to the substrate and allows the active portion of the polypeptide to attack the ester group of the lipid.

Likewise, specific esterases could operate by means of a lysine or histidine radical attached to such other amino-acids as are optimal for attachment to the specific substrate in question.

Experiments designed to explore these possibilities are now in progress, and their results will be reported from time to time.

Anion Exchange Chromatography and Molecular Size of Deoxyribonucleic Acid

IN conjunction with investigations on deoxyribonucleic acid isolated from white blood cells of patients with leukæmia (Polli, E. E., Rosoff, M., di Mayorca, G., and Cavalieri, L. F. (unpublished) and ref. 1), an interesting correlation was found between the molecular parameters of the acid and their chromatographic profiles obtained by fractionation on columns of 'Ecteola'[2].

Specimens of deoxyribonucleic acid were prepared from the white blood cells of two patients with chronic lymphatic leukæmia who had been treated with X-rays. The acid from each patient was prepared both by a detergent method[3] and the Sevag amyl alcohol–chloroform procedure[4]. Analyses by the Sakaguchi method for possible residual protein contamination indicate less than 0·05 per cent protein in both types of preparations. Chromatography on columns of 'Ecteola' of the samples of deoxyribonucleic acid obtained from one patient gave the different patterns shown in Fig. 1. (Patterns nearly identical to these were obtained with the samples of deoxyribonucleic acid from the second patient.) The differences in the chromatographic profiles are especially evident in regions I and III.

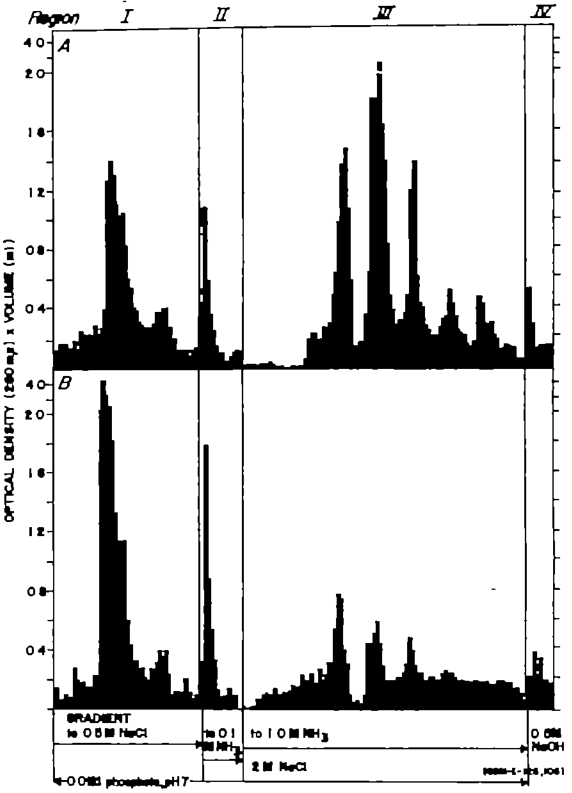

Fig. 1 Anion exchange chromatographic fractionation of 3 0 mgm. of deoxyribonucleic acid from white cells of patients with chronic lymphatic leukæmia (X-ray treated) on 0·5 gm. columns (0·6 × 5·9 cm.) of 'Ecteola' (Ecteola-SF-1, 0·51 per cent N, 0·20 meq. ionizing groups/gm., flow-rate about 6 ml./hr., 2-hr. collections). The black areas shown are directly proportional to the weight of deoxyribonucleic acid. Upper profile (*A*) is for deoxyribonucleic acid isolated by a detergent procedure (ref. 3); recovery 93 per cent. Lower profile (*B*) is for that isolated by the amyl alcohol–chloroform procedure (ref. 4); recovery 94 per cent

With the detergent procedure (Fig. 1*A*), regions I and III contained, respectively, 30 and 62 per cent of the added deoxyribonucleic acid. In contrast, regions I and III from the Sevag-treated sample contained, respectively, 67 and 18 per cent (Fig. 1*B*).

Light-scattering and viscosity data are given in Table 1.

Table 1. DEOXYRIBONUCLEIC ACID FROM THE WHITE BLOOD CELLS OF A PATIENT WITH CHRONIC LYMPHATIC LEUKÆMIA

Isolation procedure	Amyl alcohol–chloroform method (ref. 4)	Detergent method (ref. 3)
Molecular weight	$3·0 \times 10^6$	$4·0 \times 10^6$
Radius of gyration	1800 A.	2200 A.
Intrinsic viscosity, 100 ml./gm.	20	37
Sedimentation coefficient	16	25

Light-scattering was measured in a Brice–Phoenix photometer; viscosities were determined in a Couette viscometer based on Eisenberg's design[5]; weight-average sedimentation coefficients were determined in a 'Spinco' Model *E* ultracentrifuge[6].

The lower molecular weight for the alcohol–chloroform preparation is in accord with the results of Shooter and Butler[6], who showed by sedimentation analysis with deoxyribonucleic acid of calf thymus that the Sevag procedure leads to the removal of material containing the acid of high sedimentation coefficient. Additional evidence that a higher mole-

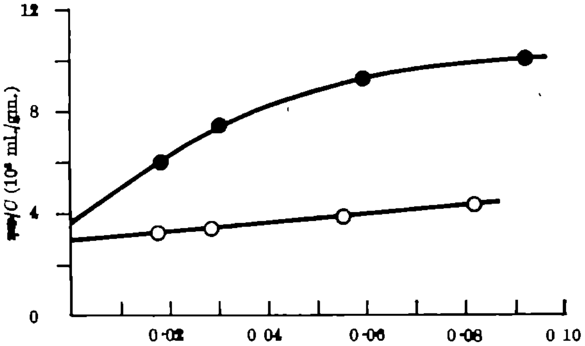

Fig. 2. Reduced viscosity of deoxyribonucleic acid from white cells of a patient with chronic lymphatic leukæmia (X-ray treated). Plotted against concentration. ●—●—●, Acid isolated by detergent method (ref. 3); ○—○—○, acid isolated by amyl alcohol–chloroform method (ref. 4)

ular weight fraction has been removed by the application of the Sevag method is provided by the smaller concentration dependence of the reduced specific viscosity (Fig. 2).

Sedimentation distribution analyses of the present samples are in essential agreement with the prior results obtained by Shooter and Polli (personal communication) on similar specimens. The results indicate that about 35 per cent of material with $S > 26$ which is present in the Dounce[3] preparation is completely lost, while another 20 per cent of material with $S = 21$–26 is partially removed by the Sevag treatment. It is suggestive to compare the 55 per cent loss, calculated from the sedimentation distribution, with the parallel loss of 44 per cent of the material from region III of the chromatogram of the Dounce preparation. It thus appears that region III represents material with sedimentation coefficients between 21 and 54, and region I those fractions with S between 8 and 21.

Since the distribution in sedimentation coefficients reflects a distribution in shape as well as molecular size, it is likely that fractions with $S > 26$ may not possess molecular weights as high as those which can be calculated if the relationship $S \propto M^{1/3}$ is assumed[7]. The small difference in the intrinsic viscosities of both samples as well as in the radii of gyration indicates that the higher sedimenting components have a more compact configuration. (The radius of gyration determined by light scattering is a z-average quantity and therefore very sensitive to the presence of small amounts of material of highly extended configuration.) Indeed, a difference of one million in the molecular weight of the two samples would correspond only to the loss of fractions with a weight average molecular weight of about five million.

It is concluded from these studies that the loss of material with higher molecular weight and relatively greater extensibility has resulted in the alterations in the chromatographic profile. This offers further support for the contention[8] that molecular size and shape are important factors in the fractionation of deoxyribonucleic acid by 'Ecteola'-chromatography.

We wish to thank Dr. G. B. Brown and Dr. E. E. Polli for helpful discussions and Mr. H. S. Rosenkranz for competent assistance. One of us (G. D. M.) holds a Damon Runyon Cancer Research Fellowship. This investigation was supported by funds from the American Cancer Society, National Cancer Institute, National Institutes of Health, Public Health Service (Grant CY–3190), and from the Atomic Energy Commission (Contract No. AT. (30–1), 910).

A Phenol-extracted Bacterial Deoxyribonucleic Acid

IN the course of extraction of highly polymerized bacterial deoxyribonucleic acid from *Brucella abortus* cells first killed with 0·5 per cent phenol and then exposed to sodium deoxycholate, it was discovered that phenol treatment alone results in the recovery of material high in content of deoxyribonucleic acid. The acid isolated by this phenol procedure proved to possess specific transforming activity. Its breakdown products exerted selective effects upon bacterial population changes[1,2]; they also reduced the $LD50$ of pneumococci for mice[3] and enhanced phagocytosis *in vitro* (Pomales-Lebrón, A., Braun, W., and Stinebring, W., unpublished results); they also stimulated the growth of lymphosarcoma cells in mice. The polymerized material produced antibodies that appear to show a specificity for the deoxyribonucleic acid molecule[4]. In view of these diverse biological effects, additional details regarding the phenol extraction procedure and some characteristics of the resulting material will be presented here.

Bacterial cells are harvested from growth on tryptose agar in ten Blake bottles (100 ml. medium per bottle). The growth from each bottle is washed off with 10 ml. of a 0·1 M sodium citrate – 0·1 M sodium chloride solution. The pooled cell suspensions (approximately 1 × 10¹¹/ml.) are then supplemented with melted crystalline phenol to yield a phenol concentration of 0·5 per cent. The phenolized suspensions (100 ml.) are shaken, gently enough to avoid foaming, for 48 hr. at 37° C. in a 1,000-ml. Erlenmeyer flask with 100 ml. of 4-mm. glass beads. (Various stages of the extraction procedure at which samples were removed for analysis will be designated A–E.) The suspensions (A) then are treated with 0·1 vol. amyl alcohol (10 ml.) and 0·3 vol. (30 ml.) of chloroform[4]. The mixture is shaken for 20 min., distributed into centrifuge tubes, and centrifuged at 1,500 r.p.m. at 5° C. for 20 min. The supernatant is decanted and set aside in the refrigerator. The sediment is then re-extracted by adding to the total sediment from the first extraction 100 ml. of citrate–saline and then amyl alcohol and chloroform as above; this is shaken for 20 min. and centrifuged at 5° C., and the resulting supernatant is pooled with the supernatant from the first extraction (B). To the pooled supernatants is added 0·3 vol. of chloroform (60 ml.) and 0·1 vol. (20 ml.) of amyl alcohol. Again, the mixture is shaken for 20 min., the layers are permitted to separate, the top layer is decanted and then recentrifuged in the cold (*C*) (chilling prior to centrifugation will ease decanting). This procedure may be repeated (*D*) as often as four to five times until, on the basis of non-cloudiness in the supernatant and absence of an intermediate ('protein') layer, deproteinization appears to be complete. However, more recent studies have indicated that such continued deproteinization is unnecessary for biological effectiveness. To the supernatant from the final 'deproteinization', 6 vol. of 95 per cent ethyl alcohol are added. The resulting fibrous precipitate is removed by winding on a glass rod, and is dissolved in approximately 150–200 ml. of saline (*E*); overnight storage at 5° C. plus shaking may be necessary to dissolve the material. The deoxyribonucleic acid–saline solution is assayed[5] and divided into aliquots equalling approximately 10 mgm. of the acid (mucoid cells of *Br. abortus*, strain 19, harvested from 10 Blake bottles yield an average of 60 mgm. deoxyribonucleic acid). The acid from each of these aliquots is then reprecipitated by addition of 6 vol. of 95 per cent ethyl alcohol; the precipitates are removed by winding on a glass rod and placed separately into vials containing 10 ml. of 95 per cent ethyl alcohol for storage at 5° C. For use, the material is removed by decanting the alcohol and dissolved in saline.

The deoxyribonucleic acid nature of the resulting material has been indicated by ultra-violet absorption, viscosity measurements, susceptibility to deoxyribonuclease action, positive Dische–Stumpf reaction and chromatography for pyrines and pyrimidines following hydrolysis. Absorption in the ultra-violet range showed a maximum at 258 mμ and minima at 234 and 290 mμ in 0·85 per cent saline, similar minima and a maximum at 260 mμ with an ϵ (*P*) of 8,900 in 0·15 *M* acetic acid. Intrinsic viscosity in 0·2 *N* sodium chloride at 35·4° C., measured with an Ostwald viscosimeter, was 16 and decreased to 50 per cent within 200 sec. following treatment with deoxyribonuclease (Worthington 1 × crystallized). Under identical conditions calf thymus deoxyribonucleic acid prepared according to Kay *et al.*[6] had an intrinsic viscosity of 19. Ribonucleic acid was found[7] to represent less than 1·5 per cent of the final material. However, a considerable amount of protein, apparently difficult to dissociate by conventional deproteinization procedures, was found to remain associated with the deoxyribonucleic acid. Biuret tests indicated approximately 25 per cent protein at stage *B*. Similarly, a high nitrogen/phosphorus ratio at this stage of purification pointed to the retention of considerable protein (Table 1). It is noteworthy that with further treatment by the Sevag procedure the nitrogen/phosphorus ratios shifted in the direction of increased nitrogen (Table 1). Similar alterations, probably indicative of a loss of deoxyribonucleic acid during the amyl alcohol–chloroform deproteinization procedure, previously have been observed by others for calf thymus nucleic acid[8]. The unusually high nitrogen/phosphorus ratios might also reflect differences between the nitrogen–phosphorus content of this bacterial deoxyribonucleic acid and values established for calf thymus deoxyribonucleic acid. The protein present was found to contain at least 15 amino-acids, on the basis of qualitative paper chromatography following hydrolysis of stage *B* material. Nitrogen/phosphorus ratios obtained for deoxyribonucleic acid isolated from smooth cells of *Br. abortus* tended to be slightly higher than those recorded here for material from mucoid cells and showed similar changes during purification. The phenol-extracted material was completely but slowly soluble in 0·85 per cent saline and could be reprecipitated almost quantitatively from the resulting viscous solution by the addition of ethyl alcohol.

Table 1. CHEMICAL ANALYSES OF TWO PREPARATIONS OF DEOXYRIBONUCLEIC ACID OBTAINED FROM MUCOID *Br. abortus* CELLS

		Extraction stages analysed (ref. 5)				
		A	*B*	*C*	*D*	*E*
Preparation 1	N/P	2·86	2·18	2·60	3·03	4·17
	DNA/N	2·48	2·95	2·59	2·12	2·20
	DNA/P	7·07	6·44	6·74	6·42	9·17
Preparation 2	N/P	2·94	2·29	2·30	3·33	5·00
	DNA/N	2·44	2·94	1·81	1·71	2·10
	DNA/P	7·18	6·68	4·34	5·67	10·50

The 0·5 per cent phenol extraction procedure has been applied successfully to the isolation of deoxyribonucleic acid from *Escherichia coli* cells, pneumococci, salmon sperm and mouse lymphosarcoma ascites cells. The use of the method with calf thymus required prior exposure of homogenized tissue to 6 *M* sodium chloride.

Although the resulting material most closely resembles deoxyribonucleic acid and has been referred to as such, and despite indications that all hitherto tested biologic and antigenic effects of the material appear to be independent of the amount of protein remaining, it is recognized that the procedure here described might actually lead to the isolation of an unusually stable nucleoprotein.

The co-operation of Drs. W. Nickerson and J. Noval in the viscosity determinations, of Dr. J. Noval in the protein tests, and of Mr. W. Firshein in ribonucleic acid assays, is gratefully acknowledged. Part of this study was supported by grants from the National Science Foundation (*G*-2184) and the U.S. Public Health Service (*E*-1137).

Action of Glucose-1-Phosphate on the Deposition of Phosphate in the Bones of Growing Diabetic Rats

IT has been shown in a previous paper[1] that the ossification process of growing diabetic rats is strongly retarded in comparison with normal animals and that the administration of insulin restores the ossification process to a normal rate. An even more pronounced effect was obtained by daily injections of 1–2 gm./kgm.

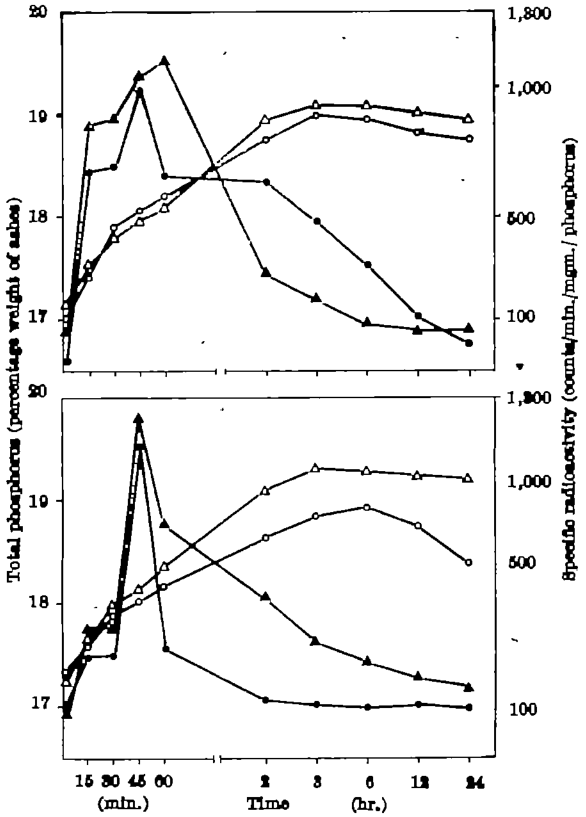

Fig. 1. Above: Normal animals; below: diabetic animals. ●, Total phosphorus after injection of 3·3 μmole/kgm. $NaH_2{}^{32}PO_4$; ▲, total phosphorus after injection of 3·3 μmole/kgm. glucose-1-^{32}phosphate; ○, specific radioactivity of phosphorus-32 after injection of 3·3 μmole/kgm. $NaH_2{}^{32}PO_4$, corresponding to a 10-μc. radioactivity; △, specific radioactivity of phosphorus-32 after injection of 3·3 μmole/kgm. glucose-1-^{32}phosphate, corresponding to a radioactivity of 10 μc. Full point represents the mean value of data obtained from five animals

of glucose-1-phosphate over a period of 10–15 days. The ready response to glucose-1-phosphate suggested that the impairment of ossification in diabetes might be attributed to a possible glucose-1-phosphate deficiency and that this ester might act as phosphate carrier or donor in phosphate deposition in the bones.

It is the object of the present communication to test this hypothesis: to this end the behaviour of the total phosphorus and of phosphorus-32 content of bones was examined at different time-intervals after the administration of glucose-1-^{32}phosphate.

Experiments were carried out on normal 2-months-old rats (approximately 80 gm. body-weight) fed on a calcium-rich diet and on rats of the same age and weight which had been made diabetic by intravenous injections of alloxan (100 mgm./kgm. body-weight). No rat was used less than two weeks after alloxan administration.

Glucose-1-phosphate-^{32}P, kindly supplied by the firm S.P.A. of Milan, was injected intraperitoneally at a dose of 1·1 gm./kgm. body-weight, corresponding to a radioactivity of 10 μc./kgm. As control, an equal number of normal and diabetic animals were injected, with equal amounts of phosphorus and of phosphorus-32 in the form of $NaH_2{}^{32}PO_4$.

At various time-intervals after the injection the rats were killed and the bones of the hind limbs quickly removed and ashed. The total phosphorus of the ash was determined by the Fiske and Subbarow procedure and the specific radioactivity using a Nuclear-Chicago Corp. counter.

The results relative to the normal and diabetic animals are respectively illustrated in Fig. 1, *A* and *B*. These results show that while in normal animals the administration of either $NaH_2{}^{32}PO_4$ or of glucose-1-phosphate-^{32}P influences the deposition of the phosphate in the bones practically at the same rate, in diabetic animals glucose-1-^{32}phosphate exhibits a more pronounced effect than $NaH_2{}^{32}PO_4$.

The possibility that the higher utilization of glucose-1-phosphate by diabetic animals might be due to a gradual release of inorganic phosphate radicals from glucose-1-phosphate should be excluded because the phenomenon is not apparent in normal animals. It seems therefore reasonable to assume that the bones of growing diabetic rats utilize the phosphorus of glucose-1-phosphate better than that of inorganic phosphates.

This research has been assisted by a grant from the Italian C.N.R.

Action of Ethylene Dibromide on Hen Gonadotrophic Hormones

Ethylene dibromide (dibromoethane) was found to remain in small amounts in fumigated grain up to six weeks after fumigation[1]. This fact, unusual for fumigants, had a harmful effect on laying hens. Diminution in size of egg, followed by cessation of laying were observed. Significant decrease in weight of egg occurred even when grain containing 15 p.p.m. of ethylene dibromide was fed to laying hens over 12 weeks[2]. The total amounts of ethylene dibromide ingested by such hens were well below those reported as harmless to various laboratory animals[3,4]. The following observations lead to the hypothesis that the action of small amounts of ethylene dibromide is very specific on pituitary gonadotrophic hormones and should be distinguished from the general poisonous action of large doses.

The general behaviour of hens fed with grain containing ethylene dibromide was normal, and no specific changes could be detected by autopsy. The ovaries of hens which stopped laying were found to contain follicles of small size similar to those of young hens before the laying season. A few eggs laid occasionally by such adult hens, several months after stopping the treatment with ethylene dibromide, weighed only 16–20 gm. The yolk of these eggs was extremely small and the relation between weights of yolk and egg white was about 1 : 4 (instead of about 1 : 2 in normal eggs). It is known that the size of eggs is conditioned mainly by the size of ovulated follicles.

From the two principal gonadotrophic hormones—the follicle-stimulating hormone and the luteinizing hormone—the former should have been primarily affected, because ethylene dibromide could be dosed so as to obtain only decrease of egg weight, without changes in their number. Ovulation apparently proceeded normally.

Furthermore, it was assumed that formation (or release) of follicle-stimulating hormone is affected by ethylene dibromide rather than the hormone itself, after it has left the pituitary. This assumption arose from an observation that hens laying small eggs after treatment with ethylene dibromide recovered only after several weeks of normal feeding.

The following experiments were performed to prove this hypothesis.

(1) 10 hens (15 months old) were fed with grain containing ethylene dibromide until they were laying eggs smaller by 30–40 per cent from the mean before the treatment. Then the hens were divided into two groups. One group received daily, during 11 days, one injection of 14 mgm. follicle-stimulating hormone preparation in 0·5 c.c. 0·9 per cent sodium chloride (7·2 mgm. purified follicle-stimulating hormone, *S* 70*A*, prepared and kindly donated by W. McShan, were equivalent to 1 gm. dry pituitary tissue). The second group remained as control group. In the group treated with the hormone an increase of 10–15 per cent in egg-weight occurred 6–7 days after beginning of hormone injections and persisted up to 4–6 days after stopping the treatment. At this time the egg returned to former smaller size. It is known that the process of follicle growth in the ovary takes about 10 days. The eggs of the control group (hens treated only with ethylene dibromide, but not with hormone) showed no increase during the experimental period.

(2) The follicle-stimulating hormone preparation mentioned above was exposed to ethylene dibromide vapours for 24 hr. and then injected in the usual way to a group of five female albino rats[5]. Another group of rats received the untreated hormone.

After total amount of 1·4 mgm. follicle-stimulating hormone per rat the average ovary-weights were:

47 ± 2 mgm. for the group receiving untreated follicle-stimulating hormone
46 ± 1 mgm. for the group receiving follicule-stimulating hormone treated by ethylene dibromide
28 ± 2 mgm. for the group control (without follicle-stimulating hormone injections)

The qualitative response to the hormone was the same in both groups treated with follicle-stimulating hormone. The observation that ethylene dibromide did not affect the follicle-stimulating hormone *in vitro* supports the assumption that ethylene dibromide does not act on follicle-stimulating hormone directly, but attacks rather the formation or release of the hormone from the pituitary.

I am indebted to Prof. W. McShan, University of Wisconsin, for his interest in the work, helpful discussion and gift of the follicle-stimulating hormone preparation.

Clearance of Injected Heparin from the Blood

HEPARIN is an extremely potent inhibitor of blood coagulation, and it is on the basis of this property that it has been widely accepted in the clinical treatment of thrombosis[1]. It is a sulphur-containing mucopolysaccharide which is naturally present in a number of animal tissues, the highest concentration being found in liver and lung[2] and very minute amounts in the blood[3]. When heparin is injected into the bloodstream, its anticoagulant activity manifests itself immediately; however, this effect is lost within a comparatively short period of time. The problem as to the fate of the administered heparin and its concentration in blood at different intervals after injection is therefore of considerable importance from a pharmacological and physiological point of view. Previous studies on the metabolism of heparin presented some difficulty, since the concentrations involved were minute and the possibility always existed of contamination by other sulphated mucopolysaccharides. The preparation in this laboratory of heparin labelled[4] with sulphur-35 opened the possibility for tracing and quantitatively determining minute amounts of heparin in various tissues. The present communication is a report on the determination of heparin in blood subsequent to its administration as the labelled product. The correlation is shown between this concentration and the clotting time.

Dogs weighing 14·5 kgm. were injected intravenously with 30 mgm. sodium heparin-^{35}S having a specific activity of 8,200 c.p.m. per mgm. Clotting times by the Lee and White method[5] were determined on blood drawn at different intervals after administration. Simultaneously, radioactivity assays were made on 4-ml. blood samples by combustion and counting as barium sulphate[4].

Fig. 1 shows the results obtained in these experiments. The initial radioactivity immediately after

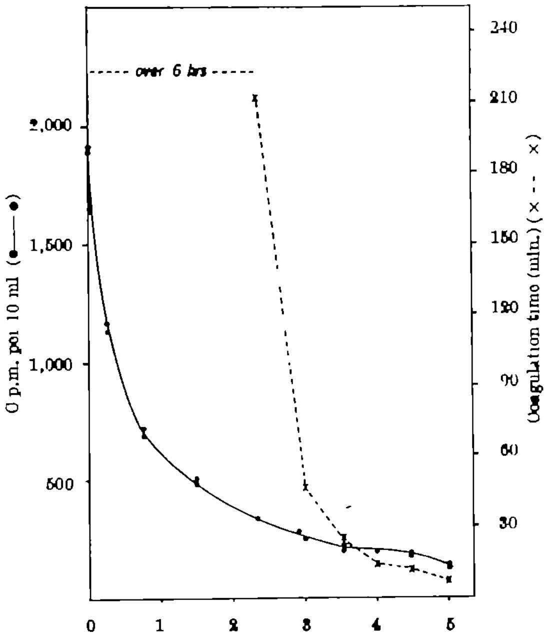

Fig. 1. Radioactivity in blood and coagulation time following injection of 30 mgm. of labelled heparin into 14 5-kgm. dogs

injection is 1,900 c.p.m. per 10 ml. of blood. This corresponds to 0·023 mgm. of heparin per ml. The clotting time of this blood was more than 24 hr. and consequently no accurate estimation could be made. During the first ½ hr. there is a sharp drop in the blood heparin concentration so that after 45 min. the radioactivity indicates that there are only 0·008 mgm. of heparin in each ml. Afterwards, the rate of removal of heparin from the blood decreased sharply so that after 3 hr. the concentration was still 0·003 mgm. per ml. The clotting time, on the other hand, became measurable only 2·7 hr. after injection and gave a normal value after 5 hr. At this time there were only traces of the injected heparin in the bloodstream.

Experiments were also conducted where 20, 40 and 50 mgm. of heparin were injected to dogs of similar weight. Although there is a prolongation in the physiological effects with increasing dosage, it was not considerable in the cases where more than 30 mgm. were administered. Radioactivity assay of the blood after different intervals indicated that the rate of elimination from the blood is greatest during the first 45 min. The rate of this ejection from the bloodstream increases as the dose administered is increased until the concentration is approximately 0·01 mgm. per ml.

These experiments also suggest that the comparatively rapid return of the bloodstream to normal is not due to any deactivation of the heparin within the bloodstream but to its rapid elimination as shown by the disappearance of radioactivity from the blood. Other studies indicate (unpublished results) also that heparin is not desulphated in the blood so that the loss of radioactivity is not due to the removal of the label from the tagged molecule. Thus the loss of the heparin effect is a result of the actual elimination of the molecule from the bloodstream.

This investigation was supported in part by grant *H*–2823 of the National Heart Institute, United States Public Health Service.

Elastin, a Metabolically Active Lipoprotein

THE protein elastin has been generally regarded as an inert substance on the basis of its solubility properties[1] and tracer studies[2] employing carbon-14. That elastic tissue demonstrates dynamic, functional properties other than that of elasticity has been suggested in part by studies on arteriosclerotics. The breakdown of the arterial elastic lamellæ is generally reported to be the initial event in the pathological changes of the arteries[3]. That the elastic lamellæ of arteries act as selective filters to tissue fluid components has been proposed[4]. The present report demonstrates that elastin, as it exists *in situ* in elastic tissue, is composed of metabolically active components.

Several reports have indicated that lipids affect the reactivity of elastin to the proteolytic enzyme, elastase, and Lansing has suggested that elastin is a lipoprotein[5-7]. In this laboratory elastin was prepared by conventional methods from beef ligamentum nuchæ and then exhaustively extracted for lipids over a period of several days. In the defatted protein a plasmalogen and unsaturated lipid were detected by means of the Schiff reaction. When defatted elastin was hydrolysed by elastase, extraction of the protein solution yielded a Schiff-positive unsaturated fatty compound the reactivity of which was blocked by bromination. Unsaturated fatty acids are known to react with Schiff's reagent, and Rapport and Franzl[8] have shown that certain aldehydes depend upon unsaturation in the molecule for their Schiff positivity. The amount of this lipid material in defatted elastin was estimated at 0·5 per cent of the dry weight.

The identification of protein-bound unsaturated fatty acid in elastin described above may well explain certain reported observations of other workers. Partridge and Davis[9] observed in elastolysates an unknown substance with an absorbance peak at 2750 A., which is in accord with the absorbance peaks due to the ethylenic bonds in unsaturated fatty acids. Balo and Banga[10] observed that a bromine-consuming substance was slowly released from a solution of elastin which was allowed to stand for several days. The bromine consumption was not due to liberated end groups, and the substance combining with bromine was dialysable. In this laboratory it was found that the unsaturated lipid in elastin was partially released during enzymatic hydrolysis. The findings of Balo and Banga may be explained upon a continued liberation of unsaturated lipid from the deteriorating soluble elastin. Elastin contains a yellow pigment, and a coloured solution results upon hydrolysis of the protein. The pigment cannot be removed either from the native sclero-protein or its soluble products. Kendall[11] observed a yellow pigment in a preparation of serum albumin which could be removed by lipid solvents only after denaturation of the protein. The substance was identified as an unsaturated fatty acid. The yellow substance in elastin is more tightly bound, since it is not extractable after the solubilized protein is boiled.

Plasmalogens have been reported to be lipid-soluble substances. That present in elastin is not extractable with fat solvents either from the insoluble scleroprotein or its soluble products, although it may be a tightly bound lipid. Partridge and Davis postulated the presence of a compound which is involved in the cross-linking of the polypeptide chains in elastin, since the known types of cross-linkages are not operative. The plasmalogen in conjunction with the protein-bound fatty acid may be concerned with this cross-linking.

That lipids are important in determining the integrity of elastic fibres is established by certain metabolic studies. Boucek and Noble[12] found that the scleroprotein of connective tissue incorporates lipid at a significant rate. Menschik[13] observed fragmentation of cardiac elastic fibres in cases of vitamin E deficiency, the condition being aggravated by feeding unsaturated fatty acid or by eliminating saturated acids from the diet. Sinclair[14] showed that the formation of the polyunsaturated, essential fatty acid, arachidonic acid, from linoleic is mediated by vitamin B_6, and Rhinhart[15] has produced arteriosclerosis in monkeys made deficient in this vitamin.

I suggest that the non-extractable plasmalogen and unsaturated lipid found in the elastic protein are concerned with the maintenance of the elastic fibre. It is proposed that breakdown of the elastin molecule occurs when a deficiency in the normal lipid constituents occurs or when the constituent lipids are displaced by other lipids as a result of some metabolic lesion. For example, a high dietary intake of saturated fatty acid may result in the replacement of elastin-bound, unsaturated fatty acid by saturated fatty acid. The saturated acid–elastin complex is unstable, resulting in the degradation of the lipoprotein molecule. The breakdown of the elastic lamellæ then leads to lipid infiltration, plaque formation, and necrosis. Peifer[16] fed individual fatty acids in high concentrations to animals and found that the more saturated the acid the more diffuse were the arteriosclerotic lesions produced.

In addition to non-extractable, protein-bound fatty acid and plasmalogen, elastin contains about 0·01 per cent phosphorus which is resistant to extraction by cold acid, fat solvents, and hot 0·1 *N* alkali and is presumed to be in phosphoprotein combination. Radioactive studies in which phosphorus-32 was employed showed that the protein-bound phosphorus turns over at a rate second only to inorganic phosphorus. The specific activity of protein phosphorus in aortic elastin ranged from 10 to 25 per cent of the values for the specific activity of aortic inorganic phosphorus; the specific activities of lipid phosphorus and alkali-soluble phosphorus in the aorta were only 1 to 10 per cent of the values for inorganic phosphorus. Johnson and Albert[17] believe that phosphoprotein is not a storage form of phosphorus, since it is present usually in small concentrations, but that it may serve an enzymic function.

Reports in the literature in which carbon-14 was employed did not indicate the metabolic activity of the protein phosphorus component or of lipids which may be physically bound to elastin. Also, the carbon-14 activity of lipids in chemical combination with elastin would be masked by the greater proportion of the relatively inert protein carbon. Elastic tissue must be regarded as a whole rather than assigning to it a metabolic role which is the sum of its components. In conjunction with lipids, the active elastic lamellæ may well possess the function of a selective filter. In this laboratory significant concentrations of cerebroside have been determined in the ligamentum nuchæ and a functional, rather than a structural, role is suggested for this lipid, since it is found in relative paucity in the body.

The hypothesis is set forth that the elastic protein is a lipoprotein and more metabolically active than heretofore regarded. It is believed that the combination of the elastic protein with other substances, as described above, possesses distinct characteristics, both chemical and physical, which none of the components demonstrates alone. It is further suggested that unsaturated fatty acid is essential for maintaining the integrity of the fibrous protein. Qualitative or quantitative alterations in body lipids, as produced by dietary or pathological states, affect the type of scleroprotein–lipid complex and hence the state of the elastic fibre. The arteriosclerotic events generally initiated by elastic-tissue degradation may well be due primarily to a biochemical lesion in lipid metabolism. Studies to test these hypotheses further are being undertaken.

Composition of Muscle in Malnourished Human Infants

ALTHOUGH protein deficiency is probably the commonest form of malnutrition throughout the world, there is no means of assessing its severity in the living subject. One approach to this problem is by tissue analysis. Measurement of the protein content of tissues by itself is of little value, since significant changes do not seem to be found[1]. If, however, protein content is related to deoxynucleic acid, an index is obtained of the amount of protein per cell. By this method we have shown that there is a very severe loss of protein from the livers of malnourished infants on a protein-deficient diet[2].

These measurements have now been extended to muscle. 7–10 days after the infants were admitted to hospital, samples of muscle weighing 50–100 mgm. were taken under local anæsthesia from m. pectoralis major in the anterior axillary fold. The biopsy was repeated on the other side 1–3 months later. The tissue was dried *in vacuo* over calcium chloride, and then digested for 48 hr. at room temperature ($\sim 30°$ C.) in 0·5 *M* lithium hydroxide. The undissolved residue was taken to be collagen. Non-collagen nitrogen was measured in the supernatant. It is important to allow for collagen, since we have found that in protein-depleted rats there is a relative increase in the collagen content of muscle; all the loss of protein occurs at the expense of the cellular fraction[3].

Another aliquot of the lithium hydroxide extract was acidified with nitric acid. Deoxynucleic acid phosphorus was measured in the precipitate, and sodium, potassium, chloride and total phosphorus in the supernatant. This supernatant phosphorus

Table 1 COMPOSITION OF MUSCLE IN EIGHTEEN MALNOURISHED INFANTS

	First biopsy	Second biopsy	Significance of difference · P
Body-weight, per cent of ideal weight	53*	68·5	
Non-collagen nitrogen, mgm. per mgm. deoxynucleic acid phosphorus	237 ± 16·5	343 ± 15·2	< 0·01
Potassium, µeq. per mgm. non-collagen nitrogen	2·43 ± 0·074	2·82 ± 0·08	< 0·01
'Supernatant' phosphorus, µgm. per mgm. non-collagen nitrogen	26·3 ± 1·57	22·3 ± 1·96	0·05
Water content, per cent	77·6 ± 0·053	75·7 ± 0·063	< 0·05 > 0·01
Sodium, µeq. per 100 mgm. dry weight	33·4 ± 1·44	27·6 ± 1·81	< 0·05 > 0·01
Sodium/chloride, µeq. per µeq. (whole muscle)	1·42 ± 0·073	1·365 ± 0·080	not significant
	Mean, ± standard error		

* Body-weight was measured after the loss of clinical oedema

fraction includes inorganic phosphate, acid-soluble phosphate esters and ribonucleotides.

The results in eighteen consecutive cases are shown in Table 1. Between the first and second biopsies, the ratio non-collagen nitrogen/deoxynucleic acid phosphorus increased by 45 per cent. On the assumption that the pectoral muscle is representative of the musculature as a whole, this figure gives a minimum estimate of the increase in muscle mass. If, as is probable, new deoxynucleic acid was formed as well as new protein, then the increase in muscle mass would be more than 45 per cent.

The increase in body-weight during this period was not so great—only 29 per cent. The discrepancy can be explained by the suggestion, often made but never proved, that during recovery the gain in tissue protein is partially masked by loss of water and of fat. Further evidence is provided by the fact, observed by us and by others, that in the early stages of recovery nitrogen balances are positive, with little or no increase in body-weight[4].

The normal ratio of potassium/nitrogen in muscle is 3; it was unexpected to find the ratio still low at the time of the first biopsy, since this was not done until treatment had been given for the acute disturbances of water and electrolyte balance that are often present when the infant first comes to hospital[5].

The reduction in 'supernatant phosphorus' was somewhat variable, but in the group as a whole was significant. Balance studies also point to a phosphorus deficiency; some infants in the early stages of recovery retain large amounts of phosphorus, and excrete practically none in the urine.

The water-content of the muscle and the sodium content were slightly increased at the time of the first biopsy, even though this was not done until clinical oedema had disappeared. It is probable that these increases were in the extracellular phase, since the ratio of sodium/chloride was not significantly different in the initial and final specimens.

We are indebted to Miss V. G. Wills, who performed the biopsies.

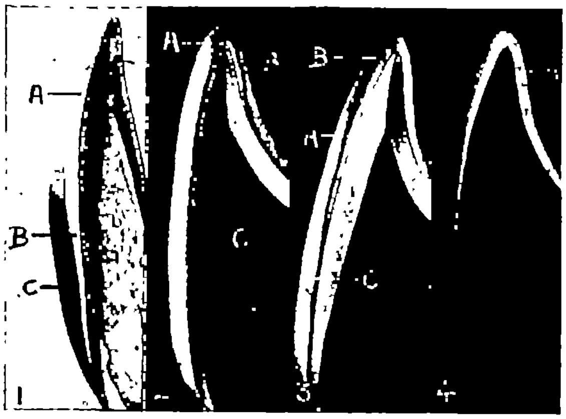
Mineralization of Human Enamel

SINCE the publication in 1940 of Diamond and Weinmann's work on amelogenesis[1], there has been, with a few exceptions[2-4], widespread support for their views on enamel mineralization. The findings of a recent investigation in this laboratory, however, show that the later stages of mineralization of the enamel do not occur as outlined in the Diamond and Weinmann theory.

In this investigation human deciduous teeth ranging in age from 26 weeks *in utero* to 18 months postnatal were examined. The appearances of routinely decalcified sections were correlated with the microradiographic and the polarized light appearances of ground sections from the same teeth. The following results, obtained with a deciduous maxillary first incisor from a two-weeks postmature infant, illustrate these findings.

The tooth was dissected from its follicle, fixed in 10 per cent formol-saline and bisected longitudinally labio-lingually. From the mesial half thus obtained a 100-µ thick ground section was prepared. Decalcified sections (using a formic and citric acid mixture) were prepared from the distal half of the same tooth.

The ground-section, when immersed in distilled water ($n = 1 \cdot 335$) and studied in plane polarized light, showed a thin zone of enamel of negative intrinsic birefringence along the incisal part of the amelodentinal junction, broadening out on its lingual side (Fig. 2). In potassium mercuric iodide ($n = 1 \cdot 47$) this area of negative birefringence had expanded



Figs. 1–4. 1, Decalcified section from distal half of a deciduous maxillary central incisor (× 8·5); *A*, Area of 'soluble' enamel matrix; *B*, artefact space; *C*, 'insoluble' enamel matrix. 2, Ground-section from medial half of same tooth as (1), in water; polarized light (× 7·5). *A*, negatively birefringent enamel; *B*, isotropic enamel; *C*, positively birefringent enamel. 3, Same section as 2, but in potassium mercuric iodide; polarized light (× 7·5). *A*, negatively birefringent enamel; *B*, isotropic enamel; *C*, positively birefringent enamel. 4, Microradiograph of same section as 2 (× 7·5). *A*, Lingual area of highest X-ray absorption

cervically along the full length of the amelo-dentinal junction, and peripherally to the enamel surface on the lingual side of the incisal region (Fig. 3). A microradiograph of the same ground section showed high absorption along the amelo-dentinal junction broadening out in the lingual incisal area (Fig. 4).

The polarized light and microradiographic observations thus showed that the later stages of enamel mineralization started at the incisal amelo-dentinal junction and expanded peripherally and cervically in a plane neither parallel nor perpendicular to the striæ of Retzius.

The decalcified sections, however, showed the line of junction between the 'soluble' and the 'insoluble' enamel organic matrix to be at right angles to the striæ of Retzius (Fig. 1).

This result, which is clearly in conflict with the X-ray and polarized light findings, indicates on the Diamond and Weinmann theory a secondary mineralization direction at right angles to the striæ of Retzius.

As the X-ray absorption under the experimental conditions used was almost entirely due to the mineral matter present, it may be assumed that the microradiograph accurately recorded the distribution of mineral matter and hence the direction of mineralization. This distribution was further confirmed by the variations in the sign and strength of birefringence shown in polarized light.

The decalcified sections, however, gave direct information concerning only the enamel organic matrix, not the mineral matter.

These results therefore suggest that the sequence of changes in 'solubility' of the enamel organic matrix does not occur in exactly the same direction as the later stages of mineralization, and is of limited value in assessing the extent and direction of the latter.

A full account of this work will be published later.

Thanks are due to Dr. J. J. Hodson, Prof. A. G. Quarrell, Dr. J. L. Emery and Mr. M. Rudland for assistance during this investigation.

Use of Logarithms to the Base 2 in recording Serological Reactions

The expression of dilution titres for serological reactions frequently requires the use of large numbers. In cases where the antibody content of an immune serum is high, the conventional means of recording the titre may be misleading; that is, the difference between a titre of 1 : 10,240 and 1 : 20,480 seemingly is greater than that between 1 : 40 and 1 : 80 but both represent only a single dilution step in the usual procedure and have the same degree of precision. Since serological procedures usually involve serial two-fold dilutions, the resulting titres are exponential functions of 2. Consequently, we suggest the simple expedient of using logarithms to the base 2 ($\log_2$) to express serological titration data.

A convenient table of logarithms to the base 2 has recently been published[1], and conversion from $\log_{10}$ values is readily made from the relationship,

$$\log_2 n = 3\cdot322 \log_{10} n$$

In a serological dilution series of 1 : 2, 1 : 4, 1 : 8, 1 : 16 . . . 1 : 2^n, the resulting $\log_2$ values follow directly as 1, 2, 3, 4 . . . n. In a series in which the initial dilution is other than 1 : 2, it is a simple matter to add to the subsequent 2^n dilution series the $\log_2$ of that initial dilution; for example, in a dilution series of 1 : 10, 1 : 20, 1 : 40, 1 : 80 . . . 1 : 10 × 2^n, the resulting $\log_2$ values are 3·32, 4·32, 5·32 . . . 3·32 + n.

Although titrations of antiserum still are commonly made by serial two-fold dilutions, greater precision may be obtained by using smaller dilution steps. This superior principle has been applied by Horsfall and Tamm[2] using a fractional dilution procedure in steps of 0·1 $\log_{10}$ unit, in which case the titres may be expressed as common logarithms.

Selectively Balanced Polymorphism at a Sex-linked Locus

A STABLE selectively balanced polymorphism dependent on a pair of autosomal genes (or chromosomal arrangements) is known to exist when the heterozygote is at a selective advantage with respect to both homozygotes. It has sometimes been assumed[1] that the same conditions apply also to a selectively balanced polymorphism at a locus in the X-chromosome and that the existence of heterosis may consequently be inferred when heterozygotes are found to be more frequent than homozygotes in the homogametic sex. However, these assumptions seem to be unwarranted.

We must take account of the relative selective values of the different genotypes in both sexes. If there are two allelomorphs A and a at a given locus in the X-chromosome, there are two genotypes in the heterogametic sex (which we shall assume to be male) one containing the gene A and the other a. Let the selective values of these two genotypes be in the ratio $t_A : 1$, where $t_A = 1 + h$, say, will be taken to be greater than one. In the homogametic sex there are three genotypes, AA, Aa and aa, and we shall suppose that their selective values are in the ratio $S_{AA} : 1 : S_{aa}$. It can be shown that the gene ratio can have a stable equilibrium value if and only if $S_{aa} < 1 + \frac{1}{2}h$ and $S_{AA} < 1 - \frac{1}{2} \cdot \frac{h}{1 + h}$. The equilibrium value of the gene ratio in the gametic output of females is then:

$$\left(\frac{p_A}{p_a}\right)_f = \frac{1 + t_A - 2S_{aa}}{1 + t_A - 2t_A . S_{AA}}$$

while in males it is:

$$\left(\frac{p_A}{p_a}\right)_m = t_A . \left(\frac{p_A}{p_a}\right)_f$$

Clearly, when t_A has any value other than unity, it is neither necessary nor sufficient for the heterozygote to be at a selective advantage with respect to both homozygotes in order that a stable balanced polymorphism may exist. Thus, for example, when $t_A = 1 \cdot 5$, and $S_{AA} = 0 \cdot 8$, $S_{aa} = 1 \cdot 1$, there is a stable equilibrium value for the gene ratio, but when $t_A = 1 \cdot 5$ and $S_{AA} = S_{aa} = 0 \cdot 9$, no equilibrium exists.

Not only is heterosis in the homogametic sex neither necessary nor sufficient for the existence of a selectively balanced polymorphism at a sex-linked locus but also the occurrence of heterozygotes with a frequency in excess of that of homozygotes is not necessarily an indication of the existence of heterosis at such a locus. As an example showing a marked excess of heterozygotes in the absence of heterosis, we may take the case where $t_A = 6$, $S_{AA} = \frac{1}{2}$ and $S_{aa} = 2$; 64 per cent of adult females in such a population will have the genotype *Aa* when equilibrium is attained.

Several examples of polymorphism at sex-linked loci are being investigated in this Laboratory with the view of comparing a range of observational data with the above results.

Induction of Translocations in Mice by Triethylenemelamine

THE findings of Jackson and Bock[1] that triethylenemelamine causes male sterility in rats instigated an investigation into the possibility that this effect is at least partially due to the production of dominant lethals through chromosome breakage. If this were true, one might expect to find that a proportion of the survivors carry translocations. In support of this idea is the work of Fahmy and Fahmy[2,3] on *Drosophila*, where it was shown that triethylenemelamine induces a high frequency of translocations as well as dominant lethals. A search for translocations in the offspring of treated male mice was therefore started.

Two groups of mice were treated, one group being composed of five males (Exp. 1) and the other group of sixteen males (Exp. 2). The method of treatment was the same in both cases: it consisted of two intraperitoneal injections of solutions of triethylenemelamine on two consecutive days. The solutions were made up with 0·9 per cent sodium chloride and the doses used were 0·8 mgm./kgm. in Exp. 1 and 0·64 mgm./kgm. in Exp. 2. The Exp. 1 males were mated to unrelated females throughout the week following treatment, but litters were only produced to matings within the first two days. Such litters as were born ranged in size from one to four; consequently only twelve F_1 animals in all were produced and could be tested. These consisted of nine females and three males. In Exp. 2, the males were each placed with five unrelated females after treatment and allowed to mate at random. Litters were only produced to matings in the first five days after the second injection; thereafter no progeny were produced until the twelfth day. Seven males and two females from the early litters and also nine males from the later litters were tested.

It has been shown that a proportion of the progeny of X-irradiated male mice produce small litters when mated to normal animals, and this defect re-occurs in about half their progeny. This condition has been called heritable semi-sterility[4,5] or heritable partial sterility[6]. Snell[7,8] has genetically proved that such animals are heterozygous for a reciprocal translocation, and this has been confirmed cytologically by Koller[9,10]. In the present experiments, suspected heterozygotes for a translocation were selected on the basis of litter size. The males were then tested cytologically by the method described by Slizynski[11,12], where it can be seen that such heterozygotes regularly show nineteen instead of twenty tetrads at diplotene, diakinesis, and metaphase of the first meiotic division. Both the genetical and cytological methods for detecting translocations give less conclusive results in females than in males; small litters may be due to physiological rather than genetical causes, and good cytological pictures are much more difficult to obtain. Females suspected of being semi-sterile were therefore tested by their sons. A female which carries a translocation will transmit this property to about half her sons; these will be semi-sterile and can be examined cytologically for the presence of a translocation.

The following results were obtained. In Exp. 1, eight out of twelve F_1 animals were normal as judged by the size of their litters. These were discarded without further tests. Two females had small litters and were shown to carry a translocation by tests on their sons. A third female was suspected of being semi-sterile, for she produced only one litter of a single offspring which died at an early age. Finally, one male was suspected of being completely sterile, for before suddenly dying of some unknown cause, he had access for two weeks to females which did not produce any litters afterwards. In Exp. 2, only one F_1 male was judged normal by the size of his litters. Of the remaining six males, two were heterozygous for a translocation, and four (two by the same treated father) were completely sterile. Both females produced small litters, and the examination of their sons showed that they were heterozygous for a translocation. The nine males from the later litters all produced normal litters except one, which was completely sterile. This male had been sired by the same treated animal which produced two sterile sons in the early litters. Cytological examination of the sterile males showed that only one carried a translocation. In all these males, spermatogenesis proceeded to pachytene or metaphase of the first meiotic division, but only one produced a very small number of spermatozoa, and these were grossly abnormal. It seems that this type of complete sterility is caused, not by multiple translocations but by a breakdown of spermatogenesis which may or may not proceed far enough to produce abnormal sperm. The ultimate cause of this phenomenon may be a dominant mutation.

When the results of Exps. 1 and 2 are combined, there are six or possibly seven semi-sterile animals out of the twenty-one tested, that is, 28·5 or 33·3 per cent. This is about the same frequency of translocations as is produced by a dose of 600 r. X-rays. At equivalent doses, the number of completely sterile animals produced by triethylenemelamine seems higher than that produced by X-rays. Russell[6] quotes a figure of 10 per cent dominant sterility for 700 r. X-rays as compared with 19 per cent produced by triethylenemelamine. The fact that a completely sterile F_1 animal, with similar defects in spermatogenesis, occurred in a later litter, might seem to indicate another difference from irradiation, which rarely leads to the production of sterile 'Spätprobanden'. However, since the early sterile period after treatment with triethylenemelamine is probably a different phenomenon from the later one caused by X-rays, such a comparison may not be valid.

Triethylenemelamine is a powerful chemical mutagen for mice, much more powerful than nitrogen mustard[12], which produced only a few translocations at doses which were highly toxic. It will be interesting to study the efficiency of triethylenemelamine in producing other types of genetical change.

I would like to thank Dr. C. Auerbach and Dr. B. M. Slizynski for most helpful advice and criticism, and also Prof. C. H. Waddington for laboratory facilities. I acknowledge a grant from the Agricultural Research Council.

Relation of Structure of 2,4-Dichlorophenoxyacetate to its Mode of Action as an Auxin

Heath and Clark[1] have proposed a possible mechanism for the mode of action of auxin which involves interference with metal ion metabolism. This conclusion was based on work involving the growth stimulation of wheat coleoptile sections. They found a particularly interesting relationship between many known chelators of various molecular structure and their ability to act as growth substances. These workers extended their findings on this relationship of chelators and growth stimulation with root-growth experiments[2].

Almost simultaneously, Johnson and Colmer[3-5] proposed a mode of action for the commonly used herbicide 2,4-dichlorophenoxyacetate to explain its inhibition of the respiration of *Azotobacter vinelandii*. Their findings related the inhibitory action of 2,4-dichlorophenoxyacetate to its ability to chelate or produce complex formation with magnesium, an element well known for its essential role in the activity of cells[6,7].

The argument should be strengthened by the fact that both pairs of workers independently, and using two completely different approaches, arrived at the same conclusion.

Plant physiologists and workers in chemical weed control have reported on many studies dealing with the specificity of the structure of 2,4-dichlorophenoxyacetate and its related compounds to their toxicity for plants. Since our work with 2,4-dichlorophenoxyacetate related its toxicity to its ability to deny magnesium to the cell, it was thought to be of interest to study the interaction of some related compounds on the magnesium content of the environment of the test bacterium.

The organism used was *A. vinelandii* strain *O*. The nitrogen-free mineral salts solution of Burk[8] with 1 per cent mannitol was the growth medium. The organisms were grown in 300 ml. of medium in a 1,000 ml. flask on a rotary-type shaker at 30 C.° for 16–18 hr.

At the end of the growth period the cells were centrifuged from the medium at 3,000 r.p.m. for 10 min. at 4° C. The cells were washed and centrifuged once with 10 ml. amounts of 0·2 per cent potassium chloride solution, *p*H 6·9. They were suspended in 0·2 per cent potassium chloride and filtered through Reeve Angel filter paper No. 202, and were then adjusted to an optical density of 1·0 with a B. and L. Spectronic 20 spectrophotometer at 420 mμ.

The usual Warburg procedures were employed[9]. Each flask had in the reaction chamber the following materials expressed as final molar concentrations in a total volume of 2·5 ml.: cells, 0·5 ml.; phosphate buffer *p*H 6·9–7·0, 0·08 *M*; magnesium sulphate, and the test compounds as indicated. The side-arms of the flasks had 0·1 ml. of a 0·1 *M* solution of mannitol which when tipped gave a final concentration of 0·003 *M*. The centre well had 0·1 ml. of 10 per cent potassium hydroxide and a fluted filter paper strip. All vessels were made to volume with triple-distilled water.

The gas phase was air and the temperature was 31° C. The vessels were allowed to equilibrate for 5 min. and then the substrate was tipped in from the side-arms. Oxygen uptake was measured for 60 min. The 2,4-dichlorophenoxyacetate used was obtained from the Dow Chemical Co. and was labelled 'pure'. All the other compounds were purchased from the Eastman Kodak Co.

Table 1 shows that phenoxyacetate, lacking chlorine atoms, is much less toxic to *A. vinelandii* than 2,4-dichlorophenoxyacetate. Phenylpropionate lacking both chlorine atoms and the oxygen of phenoxy-

Table 1. RELATIONSHIP OF STRUCTURE OF 2,4-DICHLOROPHENOXYACETATE AND RELATED COMPOUNDS TO THEIR INHIBITION OF RESPIRATION OF *A. vinelandii*

Agents	Concentration for complete inhibition of respiration of *A. vinelandii*	Molar ratio of magnesium to agent for complete protection from this inhibition
2,4-Dichlorophenoxyacetate	8×10^{-3} *M*	1 : 1
Phenoxyacetate	2×10^{-3} *M*	1 : 1
Phenylpropionate	2×10^{-3} *M*	2 : 1
ortho-Chlorophenoxyacetate	2×10^{-3} *M*	2 : 1
para-Chlorophenoxyacetate	1×10^{-3} *M*	1 : 1

acetate but having the same side-chain length also was less toxic than 2,4-dichlorophenoxyacetate. The position of the chlorine atom on the ring structure of the test compound altered the toxicity of it as shown when the *ortho* or *para* configuration was used. It was only when 2,4-dichlorophenoxyacetate with its specific configuration was used, however, that the greatest toxicity was demonstrated. These findings concerning molecular structure and activity agree with those of Zimmerman and Hitchcock[10] in their work with higher plants.

Table 1 also shows that in all cases the inhibiting action of the test agents was abolished by the addition of low molar ratios of magnesium to the agents. These low ratios are of particular interest in light of the findings of Soncin[11]. In his tests with certain tetracyclines and *Escherichia coli* a molar ratio of 50,000 : 1 magnesium to the test agent was needed to prevent inhibition.

The work reported here with the synthetic auxin 2,4-dichlorophenoxyacetate and its relation to the essential element magnesium in the respiration of the test bacterium lends emphasis to the explanation of Heath and Clark that a possible mode of action of auxin is the chelation or complexation of metal ions.

This work was made possible in part by a grant from the Southern Fellowships Fund to one of us (E. J. J.).

Starch-gel Electrophoresis of Animal Sera

USING a starch-gel electrophoresis technique[1], Ashton[2] investigated the serum protein patterns of the cow, dog, horse and pig. We have been using this technique for studying vitamin B_{12} binding by serum proteins. For comparative purposes, we have also examined the sera of various animal species. In this way we have obtained the starch-gel electrophoresis patterns which are shown in Fig. 1.

The differences between the species are well illustrated. In common with Ashton we have not actually identified the protein bands in different species. We have, however, run human and various animal sera concurrently on the same gel. A typical picture of such a gel with dog serum can be seen in Fig. 2. This illustrates the fact that there is remarkably little correspondence in the relative intensity of the various bands of the two species. Also, there is not always correspondence in position of the bands. In the human the most intensely staining narrow bands are the fast alpha 2 ($F\alpha_2$), the beta and the slow alpha 2 ($S\alpha_2$). In the dog the only really intensely staining narrow band appears just in front of a fainter band travelling with the same electrophoretic mobility as human fast alpha 2.

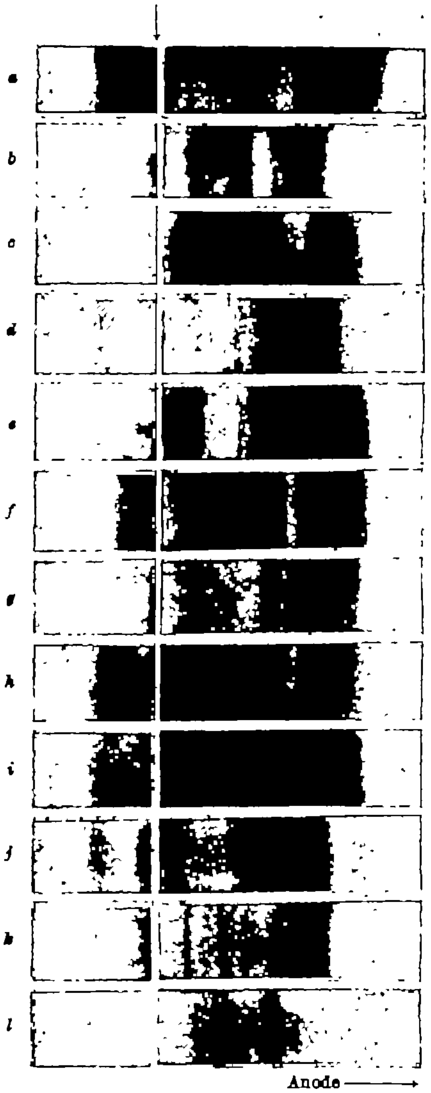

Fig. 1. Results of starch-gel electrophoresis of the sera of various animals: *a*, human; *b*, rat; *c*, mouse; *d*, guinea pig; *e*, rabbit; *f*, cat; *g*, dog; *h*, horse; *i*, cow; *j*, sheep; *k*, pig; *l*, cod. The top arrow indicates the position of the serum sample slot

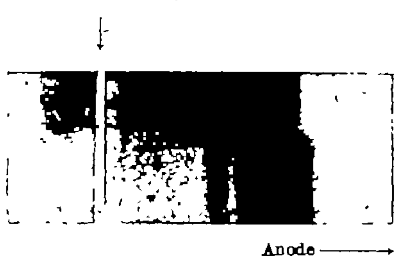

Fig. 2. Results obtained with human and dog sera run side by side on the same gel. The human serum is the upper

It will be seen that a number of the bands do correspond in position, and for the time being for purposes of identification we propose to give similar designation as for the human to those bands with corresponding mobilities in animal sera.

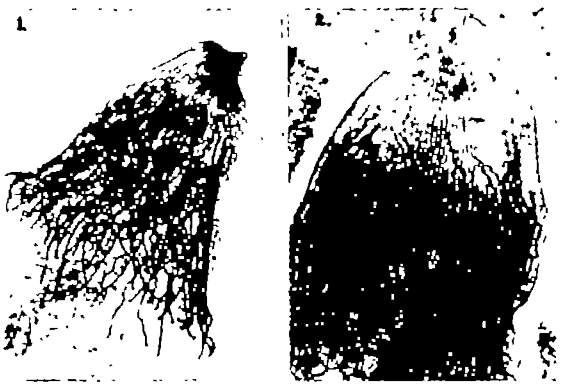
Cytochemical Localization of Acid Phosphatase in *Trichonympha turkestanica* Bernstein (Trichonymphina, Trichonymphidae)

H. W. Dean and E. W. Dempsey[1] found prominent deposits of acid phosphatase in the Golgi region of the duodenal epithelium in the rat, mouse, deer mouse, hamster, cat and monkey. They also recorded the presence of well-defined concentrations of acid phosphatase in the Golgi zone of the uterine epithelium of the pregnant cat and sow. These two authors also observed granular deposits of the same enzyme in the Golgi region and in the apical cytoplasm of cells from the liver and kidney of sundry species.

Bourne[2] mentioned that the acid phosphatase of the intestinal mucosa occurs in the cytoplasm of the cells, particularly in the region occupied by the Golgi element.

In his work on the spermatogenesis of guinea pig, R. B. Sharma (unpublished work) pointed out that the acid phosphatase granules seem to follow, in a way, the fate of the Golgi apparatus. From the spermatogonia to the final formation of the sperm, the Golgi apparatus can be seen in the acid phosphatase preparations by the phase-contrast microscope. In the spermatogonia, the negative image of the Golgi apparatus was seen along the site of localization of the enzyme granules. Similarly, the negative image of the Golgi apparatus was visible in the spermatocytes and spermatids. He also added that the Golgi apparatus might secrete this enzyme, but he had no proof.

In the present work, I was able to demonstrate that the only organelle which shows any reaction to the acid phosphatase Gomori technique[3] in the protozoan *Trichonympha turkestanica* Bernstein is the parabasal apparatus (Figs. 1 and 2). *Trichonympha turkestanica* Bernstein is a symbiotic zooflagellate living in the lumen of the hind gut of the termite *Anacanthotermes ochraceus* (Burm.). This protozoan has a characteristic parabasal apparatus in the form of about fifty irregularly twisted cords that are relatively large. Each parabasal cord has a diameter of about 3 microns. Some of these cords may attain a length of about 100 microns. Pierre Grassé and Nina Carasso[4] showed by electron microscope studies that the parabasal apparatus of zoöflagellates (*Trichonympha*, *Spirotrichonympha*, *Trimitus*, *Foaina*, *Joenia*), the dictyosomes of somatic and germinal cells, and the Golgi 'cords' of secretory cells have the same composition and are strictly homologous elements.



Figs. 1 and 2. Cytochemical reaction of acid phosphatase (Gomori's method) in *Trichonympha turkestanica* Bernstein. The incubation period is 1 hr. in Fig. 1 and 18 hr. in Fig. 2

The protozoan under investigation, with its conspicuous and characteristic Golgi apparatus (parabasal apparatus), is excellent material for showing the close relationship between the Golgi apparatus and the sites of localization of the acid phosphatase enzyme.

I thank Prof. J. Brontë Gatenby for suggesting and supervising this work.

Infection of Native *Solanum* Species by the Potato Blight Fungus

SINCE the discovery of *Phytophthora infestans* (Mont.) de Bary on the New Zealand shrub *Solanum aviculare* Forst.[1] in native bush near Auckland by Miss J. M. Dingley, many other infected plants of this species have been found in both the North and South Islands (Brien, R. M., personal communication).

A sample of fungus from *S. aviculare* received in June 1956 was inoculated to leaves and tubers of a number of commercial potato varieties, to leaves of a series of differential hybrids, and to leaves of *S. aviculare* and the related species *S. laciniatum* Ait[2]. Susceptible varieties and the two native species were readily infected, but no hybrid carrying one or more immunity genes was infected, suggesting the presence[3] of the common race *O*. Blight spores were taken from *S. laciniatum* and inoculated to a further series of plants as above with the same result.

In May 1957 blight races 0, 1, 4, 1–3, 2–4, were isolated from samples collected throughout New Zealand. Both species were susceptible to all races. In June 1957 blight was found on plants of *S. laciniatum* growing in the Lincoln township, and tests indicate the presence of race *O*.

In the past, diseased tubers have been considered to be the sole means for carrying on the fungus from year to year. In New Zealand it would appear that these two shrubs could well act as overwintering hosts. Both species are common, *S. aviculare* mainly in the north and *S. laciniatum* in the south[2]. In view of the small foci needed to start an epidemic[4], and the distance spores can travel[5], even a small amount of infection from this source could be important in determining the first appearance of blight each year.

Overwintering hosts may occur also in Australia, for blight has been collected from the Australian species, *S. simile* Muell., growing in the Dunedin Botanic Gardens by Dr. G. T. S. Baylis of the University of Otago (Brien, R. M., personal communication).

Water Absorption by Submerged Leaves

DIXON[1,2] and van der Paauw[3,4] have both recorded the uptake of water by the cut ends of submerged shoots of land plants; but there is divergence in their findings concerning the factors which affect the rate of absorption. Dixon found that factors which favoured rapid photosynthesis caused an increased rate of absorption. Van der Paauw found that in illuminated shoots the rate of water uptake was reduced to zero or that water was even exuded from the cut end, but darkness favoured absorption. Other workers[5] were unable to confirm Dixon's early results.

Recent work in this laboratory, on single cut leaves of *Bignonia grandiflora*, indicates that the pre-treatment of the material may have an important bearing on its subsequent experimental behaviour. In our experiments the leaves were severed under water and the cut ends were always supplied with water. They were then held in a saturated atmosphere and subjected to various periods of light and darkness. After this treatment they were immediately submerged in aerated, distilled water and strongly illuminated. Uptake of water by the cut ends was measured by means of a sensitive potometer.

In one experiment the leaves were stored in the dark for 15 hr. and absorption was not observed during a subsequent period of 9 hr. under conditions of complete submergence and strong illumination. Similarly, absorption was not observed when the above pre-treatment was followed by 12 hr. illumination and then by 3 hr. in the dark again.

Absorption did occur, however, when the leaves were stored for 15 hr. in the dark and then illuminated for a further 12 hr. The total uptake of one leaf during a period of 330 min. was 29·5 mm.^{3} and when the experiment was concluded absorption was still occurring at a rate of 2·4 mm.^{3} per hour. Under these conditions the magnitude of the force causing the water to enter is considerable. A single leaf raised a column of mercury to a height of 49 mm. during a period of 490 min.

Other experiments have been performed to determine the effect of varying the environmental factors during the actual observation period. Leaves cut at 5.0 p.m. and stored in the dark for 15 hr., did not absorb when submerged afterwards in aerated, distilled water and strongly illuminated, but did so when the carbon dioxide concentration of the water was raised. Bubbles of gas were rapidly evolved from the leaf, and starch accumulated.

Leaves pre-treated in the dark for 15 hr. also absorbed when submerged in aerated, distilled water in the dark, but the flow was invariably reversed after about 20 min. During this time the intercellular spaces of about one-third of the leaf area became injected with water. Complete injection occurred after a maximum period of 12 hr. submersion. Injection of the spaces has never been observed in submerged, illuminated leaves.

The absorption of water by the cut ends of submerged, illuminated leaves can therefore be related to the pre-treatment in the first instance. After cutting, illumination in a saturated atmosphere after a period of darkness will cause absorption to occur when the leaf is afterwards submerged and strongly illuminated. The effect of the light pre-treatment on the water uptake disappears if followed by a 3-hr. period in the dark. Absorption does not occur under the same conditions if the pre-treatment is carried out in a dark, saturated atmosphere, but does occur if the carbon dioxide concentration of the water is raised. Under these latter conditions rapid photosynthesis occurs.

It is possible that these findings may explain in part the divergent results of the earlier workers. Further experiments are now in progress to try to elucidate the mechanism causing the absorption.

Responses of *Cerianthus* to Stimulation

THE neuromuscular activities of the Anthozoa have been studied extensively as examples of the working of the 'elementary nervous system'[1,2]. Most of the information in this field comes from the sea anemones, the order Actinaria, sessile animals which exhibit basic patterns of slow periodic activity together with certain quick protective responses. The latter are facilitated responses in which single electrical stimuli are ineffective; responses occur only to the second and subsequent stimuli of a series within a limited frequency-range[3].

Such studies influence our ideas about the evolution of the nervous system, and it is important, therefore, to extend them to as many groups of the Anthozoa as possible. In this connexion, the Ceriantharia are an obvious choice for investigation. They are a small and isolated order of tube-living anthozoans, found in North Atlantic and Mediterranean coastal waters. The musculature of the cerianthids differs greatly from that of other Anthozoa. It consists in the main of a thick and compact core of longitudinal muscle lying between the ectoderm and the mesogloea. The contractions of this muscle pull the animal back into its tube by a series of sharp jerks whenever it is disturbed unduly by external stimuli.

This communication describes the results of some stimulation experiments on the species of *Cerianthus* found at Naples, *C. membranaceus* and *C. viridis*[4].

In my experience individual *Cerianthus* do not readily give closing responses to tactile stimuli. It is possible to handle the animal, even to pick it up in its tube, flick its tentacles or prod it sharply with a glass rod, without eliciting the powerful withdrawal movement. In this respect, *Cerianthus* differs markedly from anemones like *Calliactis* and *Metridium* which close down in response to quite gentle tactile stimulation. Since the latter do not respond to single electrical stimuli, it was surprising, therefore, to discover that the relatively insensitive *Cerianthus* always responds to any single supra-threshold stimulus, and shows no sign of facilitation in the response to a series of stimuli. Moreover, with the electrodes placed anywhere on the surface of the animal, even at the very tip of a single tentacle, one gets this powerful but apparently invariable withdrawal movement to the first and all subsequent stimuli at frequencies down to 0·25 sec.

Fig. 1*a* shows the response to a single stimulus (condenser discharge) with the electrodes brought up to the tip of a single tentacle. Fig. 1*b* shows the response to five stimuli at a frequency of 0·85 sec. with the electrodes near the base. The tracings, taken with a spring lever, show a uniform rise in tension with each stimulus, and at the end of this series the shortening of the animal was virtually complete. It is noteworthy that the tension was maintained for some time after the contraction and up to 1 min. almost no relaxation took place. The response follows the stimulus with a latent period of 0·05–0·10 sec. in different animals, and no marked differences in latency were detected when the electrodes were applied to various places on the surface of the animal.

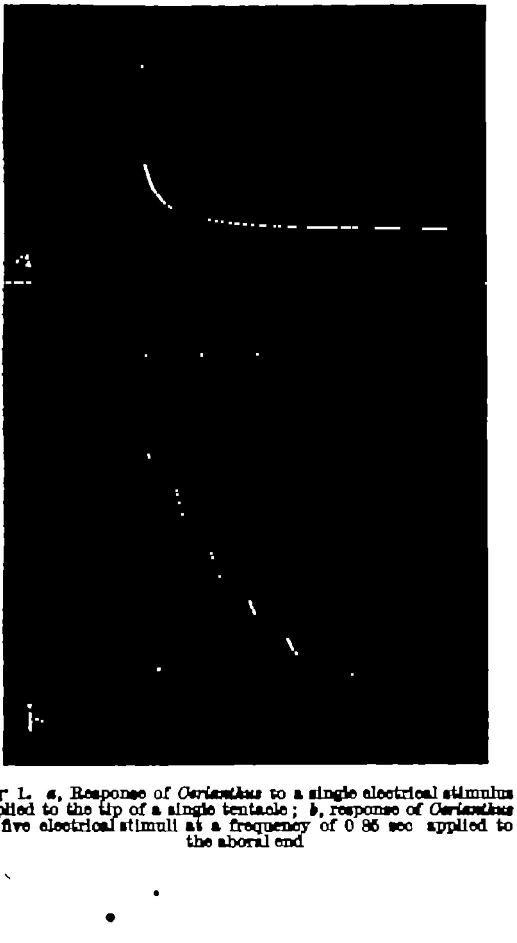

Fig. 1. *a*, Response of *Cerianthus* to a single electrical stimulus applied to the tip of a single tentacle; *b*, response of *Cerianthus* to five electrical stimuli at a frequency of 0·85 sec applied to the aboral end

Both in responses to stimulation and in general behaviour, *Cerianthus* seems to be extraordinarily limited in its activities. No definite slow movements were recorded in animals attached to levers for several hours, and no slow movements were ever seen as distinguishable components in the responses to electrical stimuli. Yet the animal is certainly sensitive to light and to various chemical and food stimuli, but the nature of the response to such stimuli remains to be analysed.

These observations have a bearing on certain functional and phylogenetic problems. The neuromuscular equipment of *Cerianthus* is clearly a rapidly conducting, open-junction system. It resembles a giant-fibre/striped-muscle situation more than the nerve-net/slow-muscle system generally regarded as typical of the Anthozoa. Yet the all-or-none response of *Cerianthus* to single stimuli would be most unsuited to animals like *Calliactis* and *Metridium*, the neurosensory apparatus of which seems to be so much more easily excited. For these animals, facilitation acts as a safeguard against unnecessary closure; perhaps it should be regarded as an adaptation to that situation.

These results with *Cerianthus* make it clear that, even in the Anthozoa, the 'elementary nervous system' has to supply a complete range of effector types, from slow to fast, from rhythmically active to quiescent, and it must therefore display a corresponding range of nervous adaptations. The real value of the Anthozoa for studies in comparative neurophysiology is not that they are primitive in the phylogenetic sense, but that being mostly non-locomotory, their simple activities may be analysed with a fair measure of completeness[3].

I wish to thank the Director and Staff of the Stazione Zoologica, Naples, for their help and hospitality during my stay there, and the Council of the Royal Society for a grant from the Browne Fund, which made my visit possible.

Cerianthus responds to a single condenser shock by a rapid contraction of tentacles and column. The response is symmetrical no matter where the shock is applied, from aboral end to tentacle tips, is propagated with a velocity of 1–2 m.sec., and is independent of the strength of the stimulus above threshold. The response is followed by an absolute refractory period of 60–70 m.sec. at 22–23° C. and a relative refractory period up to 200 m.sec. after the stimulus. For stimulation of either tentacles or column a threshold at twice the rheobase was obtained by discharge of a 0·05 μF. condenser through a total electrode-plus-preparation resistance of 3,000 ohms, thus giving a capacitance-resistance value of 0·15 m.sec. and chronaxie of 0·05 m.sec. Non-polarizable zinc–sulphate–zinc–agar glass tube electrodes of 0·5 mm. orifice diameter were used. With the same apparatus the chronaxie of the column through-conducting system of Naples specimens of *Calliactis* was 1·0 m.sec. Hill's[1] equation for the excitation of nerve fits the strength-duration curve for *Calliactis* but does not approximate closely to that for *Cerianthus*. Complete curves of the strength-duration relation and the relative refractory period will be published elsewhere.

For a maximally facilitated contraction, the optimum interval between two effective shocks is 90–100 m.sec., and no facilitation is detectable with intervals greater than 1 sec. Except for the much shorter chronaxie, the excitable properties of the *Cerianthus* through-conducting system are therefore similar to those of the mesenteric system of *Calliactis*[2], but in *Cerianthus* there is as yet no evidence of co-ordination by nerves. The physiological observations indicate a nerve net of large fibres with rapid conduction and short chronaxie, but the histological picture does not fulfil these expectations. Ganglion cells and a nerve net of the usual type are reported to be absent in the expected positions[3]. In these circumstances the facilitation of contraction cannot be assumed to be neuromuscular. The relevant muscle fibres of tentacles and column are ectodermal.

A characteristic feature of *Cerianthus* is explained by the short chronaxie. The animal is remarkably tolerant to mechanical stimulation and rough handling. Histological studies show a great density of superficial primary sense cells, an anatomical picture which looks as if it would be very sensitive. The short chronaxie of the through-conducting system means that local excitation of it, such as electrotonic changes, decays very rapidly. Therefore the input from the sense cells to the through-conducting system is a differentiating filter with a short time-constant and high signal-to-noise ratio. It could allow only excitation of high frequency or from many sense cells in synchrony to pass. This is a crucial point for the natural excitation of the through-conducting system, which is thereby isolated from insignificant stimulation.

In addition to the rapid symmetrical response of the through-conducting system there is another set of co-ordinated slower responses of tentacles, disk and column which may be elicited by light, gravity, mechanical, chemical or sub-threshold electrical stimulation without causing an accompanying quick contraction. Electrical stimulation may arouse the faster and slower contractions simultaneously. A mechanically stimulated tentacle contracts and bends towards the mouth, and following stronger mechanical stimulation the neighbouring tentacles bend towards the mouth while the edge of the disk is raised. A slow bending of the column is produced by touch, by a series of sub-threshold shocks or by illumination. The time-scale of these slower responses is such that contractions may take 5 min., and relaxations are usually complete in 15–30 min. An animal resting in a glass tube makes continual local movements, particularly of the column end. A strip of column muscle left on the kymograph shows irregular slow movements for many hours, probably in part stimulated by the fixing pins. Following a quick twitch, a slower contraction may appear as a delay of the relaxation, which can then occupy 15–30 min., whereas a normal quick twitch has relaxed after 2 min. under a load of about 10 gm. The slower components of contractions are propagated along the muscle strip but less readily around the column. Two longitudinal strips, connected by a transverse bridge, give similar quick twitches but only the stimulated strip also gives the slower component.

The quick response to a single shock is clearly co-ordinated by a single all-or-nothing impulse which spreads over the whole ectoderm. Therefore any series of such impulses must be followed by a quick contraction. Therefore excitation which co-ordinates other activities cannot be transmitted by impulses in the same pathway. Previous histological work[3] and new methylene blue preparations as yet show the existence of only primary sensory cells, but no cell bodies or fibres of co-ordination neurones. A plexus of very thin fibres within the ectodermal layer has been described, but Torelli[3] does not consider these to be nervous elements.

If this histological picture be accepted, *Cerianthus* must have the simplest metazoan large-scale contraction mechanism, with two types of transmission and the muscle as the only component. But a preferable conclusion is that the exact locations of the co-ordination pathways remain obscure. Physiological properties so far available are alone not sufficient to allow a decision as to the presence or absence of a nerve net.

A Growth Inhibitor of *L. bulgaricus* 09

While assaying skim-milk powder samples for orotic acid using *L. bulgaricus* 09, by the method of Wright *et al.*[1], the presence of a substance inhibitory to the growth of this organism was detected in samples which had been stored at 60° C. for six months.

This inhibitor was also formed when skim-milk powder was heated at 100° C. for 5 hr. or autoclaved at 15 lb. pressure for 30 min. Further, autoclaving lactose with any of the proteins, casein, edestin, fibrin, hæmoglobin, or with tryptone or with any of the following amino-acids, leucine, *iso*leucine, valine, methionine and glycine, led to the formation of the inhibitor. Concentrates of the inhibitor have been prepared from samples of skim-milk powder stored at 60° C. for six months, by extraction with acetate buffer at *p*H 4·6, followed by extraction with ether and from autoclaved mixtures of casein and lactose by extraction with benzene. The growth-inhibitory activity of these preparations for *L. bulgaricus* 09 was determined, and they were found to cause complete inhibition of growth at levels between 200 and 400γ per ml. of medium.

This growth inhibitor was soluble in water and in a number of solvents such as ether, benzene, alcohol and butanol. It was adsorbed on charcoal at *p*H 4·6. Hydrolysis with acid or alkali was found to inactivate it. By employing the ascending-paper chromatographic technique, using Whatman No. 1 filter paper and the solvent system butanol/acetic acid/water (4 : 1 : 5), it was found that the inhibitor concentrate gave a spot ($R_F = 0·89$) which answered the benzidine test for reducing substances and the Rydon and

Smith test[2] for peptides but was negative to ninhydrin. However, when the inhibitor concentrate was hydrolysed with 2 *N* hydrochloric acid at 100° C. for 20 hr. and chromatographed similarly, 4–5 ninhydrin-positive spots were obtained, depending upon the source from which the inhibitor had been extracted.

These properties, together with the fact that the inhibitor is formed on autoclaving lactose with a number of proteins, tryptone and amino-acids, indicate that it is peptide in nature.

Further studies on the exact composition of this inhibitor and its mode of action are in progress and will be reported elsewhere.

We are indebted to Dr. L. D. Wright, Cornell University, for the culture of *L. bulgaricus* 09 and to the Madras State Research Committee for financial assistance during the course of this study.

Pigments and Pterins in the Skin of the Green Mamba, *Dendroaspis viridis*

IT has previously been reported that the skins of the green snakes *Philothamnus semivariegatus* and *Dispholidus typus* contain riboflavin, *iso*xanthopterin and 2-amino-4-hydroxpteridine-6-carboxylic acid[1,2]. *D. typus* also contains 2-amino-4-hydroxypteridine[2] and an unknown yellow pigment[1].

After this investigation had been completed, a single male specimen of the green mamba, *Dendroaspis viridis*, became available to us. The anterior and middle portions were leaf green, and the posterior portion dull yellow.

The animal was skinned and the skin cut into the green and yellow portions.

The yellow skin was extracted with 50 ml. portions of boiling 80 per cent aqueous ethanol, in the dark, until the extract was colourless. The combined extracts were evaporated to dryness, the residue dissolved in 50 ml. of *N*/4 aqueous ammonia and the solution filtered from insoluble material. Analysis of this solution by paper chromatography showed the presence of a yellow non-fluorescent pigment; and, on viewing in 365 mμ light, an additional yellow fluorescent substance, a purple fluorescent substance, a bright blue fluorescent substance and a blue fluorescent substance.

The yellow fluorescent substance was identified as riboflavin by its similar behaviour to an authentic sample in three solvent systems; pyridine/propanol/water (3 : 1 : 1 by vol.); tert-butanol/pyridine/water (50 : 15 : 35 by vol.); and tert-butanol/pyridine/water (60 : 15 : 25 by vol.).

The purple fluorescent substance was identified as *iso*xanthopterin, the bright blue fluorescent substance as 2-amino-4-hydroxypteridine-6-carboxylic acid, and the blue fluorescent substance as 2-amino-4-hydroxpteridine. This was done by comparing their behaviour with that of authentic samples in the three previous solvent systems and in butanol/acetic acid/water (4 : 1 : 5 by vol.); 5 per cent aqueous acetic acid (by vol.); and 3 per cent aqueous ammonium chloride.

The yellow non-fluorescent substance could not be identified. Its chromatographic behaviour in butanol/acetic acid/water (4 : 1 : 5 by vol.) was similar to that of the unknown yellow pigment in *D. typus*[1].

The green portion of the skin was extracted with 50 ml. portions of boiling 80 per cent aqueous ethanol until the extract was colourless. The extracts were combined, and the presence of riboflavin and *iso*xanthopterin was shown by paper chromatography, as before. No attempt was made to identify 2-amino-4-hydroxypteridine-6-carboxylic acid nor 2-amino-4-hydroxypteridine in the ethanolic extract. The yellow non-fluorescent substance was present.

I am grateful to Mr. A. H. Booth of the Zoology Department of this College for supplying the specimen of *D. viridis*; and to the Chemical Society for a grant in aid of this investigation.

Onset and Cessation of Hibernation under Constant Temperature and Light in the Golden-mantled Ground Squirrel (*Citellus lateralis*)

TOWARDS the end of the summer of 1955 we received, through the kindness of Dr. J. E. Moore (University of Alberta), a number of golden mantled ground squirrels (*Citellus lateralis*). These animals had been trapped during August–September in the Turner Valley, Alberta, and were shipped to Toronto by express. Our stock was further replenished in the same manner during the summer of 1956.

One of the experiments we have undertaken involved placing a squirrel in a cold room with a mean temperature of about 35° F. (min., 30° F.; max., 42° F.) and leaving it there indefinitely. At the present time (July 1957) one animal has been there for nearly two years, and during this time has had ample bedding, food and water *ad lib.*, and has been subject to an artificial 12-hr. day throughout. Or to put it another way, the animal has been removed from all known seasonal fluctuations in temperature, light and availability of food. Notwithstanding this, it seems remarkable that the squirrel has hibernated only at 'the right time of year', that is, autumn–winter (October–May) and has been active only at the 'right time of year', that is, spring–summer (June–September).

Thus far only one animal has been under these constant conditions for this length of time. However, from data on eight other animals (3 males, 5 females) which have been in our possession for the same length of time, but which have been subject to varying conditions of temperature, light, food and access to exercise wheels, all show a tendency to hibernate over the winter months and to be active in the summer months regardless of the temperature and the length of the artificial day. During June–September denial of food, which is accompanied by a large drop in weight, will after several days force the animal to hibernate; but it cannot survive this for long, whereas during the normal winter hibernating period, practically no food is consumed for seven or eight months.

Of thirteen additional animals which have been in our possession now for ten months, nine (4 males, 5 females) have been kept in constant cold from October 1, 1956, to the present (July 1957), and all but one of these hibernated over the winter months, and again with the exception of one, all became active in the spring. It should be noted here that a gradually decreasing length of the artificial day in the autumn, down to 7 hr., did not induce hibernation earlier than those in a constant 12-hr. day. Furthermore, in March, prior to the animals becoming active, the length of the day in three cases was reduced to 4 hr. and in two cases increased to 20 hr., but even this caused no significant difference in the time at which the animals became active and continued in that state. It seems, however, that access to an exercise wheel in the autumn tends to delay the onset of hibernation for about a month, but once the animal enters hibernation it continues in this state until approximately the same time as those which are denied an exercise wheel.

It is still conceivable that the organisms we have studied have received clues concerning the seasons from some other variations such as noise level, from barometric pressure changes or from variations of the water content of the air. None of these factors seems likely to us to be of appreciable significance however. Instead, it seems necessary to conclude that the species in question possesses some form of 'internal seasonal clock' which determines the periods of hibernation and activity, and which is independent of the normal seasonal fluctuations of temperature and light, and is not governed by the food supply.

The Columbian ground squirrel (*Citellus columbianus*) and the thirteen-lined ground squirrel (*Citellus tridecemlineatus*) also seem to show the same type of phenomenon, though our results from these animals is as yet rather scanty.

This work is being supported by the National Research Council of Canada and through the Ontario Research Foundation.

Susceptibility of the Hedgehog (*Erinaceus europaeus*) to Infection with *Leptospira pomona*

Leptospira pomona is widely distributed in New Zealand, and outbreaks of leptospirosis among farm animals cause considerable economic loss to the livestock industry. While it is generally accepted that the domestic pig is the normal reservoir of infection it is rarely possible to inculpate the pig directly in ovine outbreaks of leptospirosis, and many outbreaks also occur on dairy farms on which no pigs are kept.

In view of its feeding habits, the hedgehog, which was introduced into New Zealand some sixty years ago and has now become extremely numerous in most districts, suggested itself as a possible alternative reservoir of infection.

I have recently caught some thirty hedgehogs in a suburban garden area and inoculated them with a culture of *L. pomona* which has been maintained in this laboratory since its isolation from an ovine outbreak of the disease in 1953. Every hedgehog contracted a clinical leptospirosis, and the disease appears to run a remarkably characteristic course in this species.

Small young and half grown individuals almost invariably die with some or all of the signs of classical Weil's disease (l. icterohaemorrhagiae), that is, recurrent febrile peaks with sub-normal intermissions, icterus, meningitis, 'butterfly' lungs, and typical degenerative lesions in spleen, liver and kidneys. Those surviving long enough commence urinary excretion of the organisms around the 10th–18th day.

Adults usually survive the challenge infection but excrete the organisms in their urine over a period and develop high agglutination-lysis titres to *L. pomona* antigen. Pregnant females may abort.

Guinea pigs inoculated with emulsified liver and kidney substance obtained from infected hedgehogs at post mortem and also with the stomach content of aborted fœtuses gave a typical response and the organisms were recovered from them.

By the time these experiments were completed winter had set in and most hedgehogs were in hibernation; but I have just examined two individuals found after a careful search on a dairy farm on which a severe outbreak of leptospirosis had recently occurred. Both these adult hedgehogs revealed typical leptospiral lesions on post-mortem examination; the organisms were present in the urine of one, and the blood serum of both had agglutination-lysis titres in excess of 1/3,000 against *L. pomona* antigen.

The hedgehog has thus proved highly susceptible to experimental infection with the strain of *L. pomona* used here and it has also been established that natural infection may occur in the field. As soon as these animals become active again in the coming spring it is intended to carry out a survey to determine the extent of natural infection.

Hitherto the hedgehog has only found a very limited use as a laboratory animal in virology research, but in the light of the results here reported it may prove a useful tool in leptospiral research in general.

The Sheep Lungworm *Protostrongylus brevispiculum* in Great Britain

During the past year observations have been made to assess the seasonal pattern of lungworm infection in a flock of sheep grazing on the Wiltshire Downs. In the course of the examination of fæcal samples from some of these animals first stage lungworm larvæ of an unusual type were encountered. A description of such larvæ could not be found in the literature. A search for the adults was, therefore, made. This proved to be more complex than had been anticipated as a number of lungworm species new to us were found. One of these has been identified as *Protostrongylus brevispiculum*, and the present record is thought to be the first of the occurrence of this lungworm in sheep in Great Britain.

The only records and descriptions of this lungworm are those of Mikačić[1], who found specimens in sheep

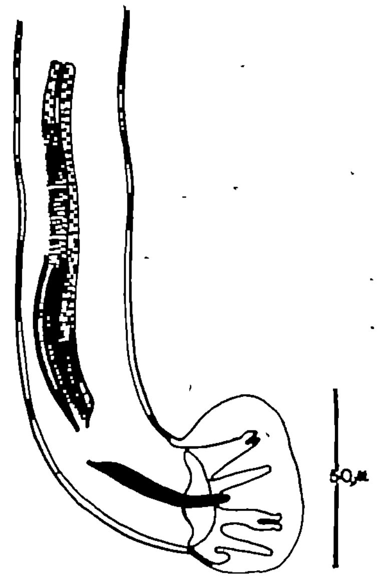

Fig. 1. Lateral view of hind end of male *Protostrongylus brevispiculum*

in Yugoslavia. He named the worm *Protostrongylus rupicaprae* (Gebauer, 1932) *brevispiculum*; this is amended to *P. brevispiculum* by Dougherty and Goble[2] in their classification of the subfamily Protostrongylinae.

Mikačić's original descriptions are somewhat incomplete, being based mainly on a detailed study of the hind end of the male worm, and it is mainly from this description that our specimens have been identified as *P. brevispiculum*.

The worms are similar in general appearance to *Muellerius capillaris*, being small and hair-like. An intact male measured 5 mm. long by 0·033 mm. wide. The bursa of the male is, however, of the typical protostrongylin type (Fig. 1). The dorsal ray is small and rounded, the externo-dorsals are elongate. The postero- and medio-laterals are fused along most of their length, while the antero-laterals are separated from them. The ventro and latero-ventral rays are united along the greater part of their length, forming a very distinctive conical base. The spicules, between 110–130μ long, the crura of the gubernaculum 30–33μ long, and the telamon are all clearly visible.

This worm is found within the lung tissues in lesions which on superficial examination are identical with those resulting from infection with *M. capillaris*. In most of the lungs examined both species of lungworm were frequently recovered from one and the same lesion. Although only a limited number of lungs have been examined and as yet there are insufficient data to assess the incidence of this lungworm in the flock, the indications are that it is by no means rare.

Detection of the Substrate of Enzymic Browning in Cacao by a Post-chromatographic Enzymatic Technique

The polyphenols of the cacao bean have been described by Forsyth[1], who has demonstrated the presence of four catechins, three leucocyanidins and two anthocyanins. It is evident from his observations and my own (unpublished) that other phenolic materials remain to be identified.

In view of the importance of enzymic browning in the commercial drying of cacao, experiments have been undertaken to determine the relative importance of the polyphenols of the bean in the browning process. To this end, a post-chromatographic enzymatic technique was developed which was designed not only to assess the contribution of each of the known polyphenols to the browning process but also to detect the presence of any hitherto undetected phenolic compounds, which might give rise to browning under the influence of polyphenol oxidase.

Freshly harvested cacao beans were macerated in methanol in a Waring blendor for three minutes. The suspension was then filtered and the residue exhaustively washed with methanol until the washings were colourless and no longer reacted with a 1 per cent solution of ferric chloride. The residue was white in colour, and although it exhibited a high polyphenol oxidase activity in aqueous solution on the addition of substrate no browning of the aqueous suspension occurred in the absence of added substrate. It was therefore concluded that all of the naturally occurring substrate of enzymic browning was removed from the residue of the bean by exhaustive methanolic washing. That a non-browning leucocyanidin material was however present in the residue was shown by the production of cyanidin on digestion of the residue with 2 *N* aqueous hydrochloric acid[2].

Methanolic extracts of both Forastero and Criollo type beans were then applied to a chromatogram, which was formed into a cylinder and developed with butanol–acetic acid–water (40 : 10 : 50) for 16 hr. The chromatogram was then dried at room temperature and heavily sprayed with a filtered aqueous solution of the methanol-washed residue which had been shown to possess a high polyphenol oxidase activity. The chromatogram, still in cylindrical form, was then placed on a wire gauze platform over a shallow layer of water contained in a glass tank. The lid was sealed into position with lanolin and the tank incubated at 40° C. By means of this apparatus, it is possible to maintain the chromatogram in a moist and highly aerobic condition in a humid atmosphere and at the optimum temperature of the phenoloxidase for an indefinite period. Under these conditions the oxidative enzymic reactions go to completion and brown colorations develop on the chromatograms in the position of the original phenolic substrates. By comparison of such chromatograms with similar chromatograms sprayed with phenolic reagents, namely, ferric chloride/potassium ferricyanide[3] or diazotized *p*-nitro-aniline[4], the identification of the major polyphenols concerned in enzymic browning may be effected.

Examination of the enzymatically treated chromatograms of extracts of Forastero and Criollo type beans indicated that in both cases the major substrate of enzymic browning was (−)-epi-catechin, a large and intense region of browning being found in a position corresponding to an R_F of 0·65. The formation of brown pigmentation occurred only in traces elsewhere on these chromatograms, although the presence of large amounts of phenolic material of low R_F value was detected by the diazotized *p*-nitro-aniline reagent on the control chromatograms. Similar results were obtained when a 1 per cent aqueous hydrochloric acid extract of the beans was examined by this technique.

In a further series of experiments, in which two-dimensional chromatograms, developed first with water and secondly with butanol–acetic acid–water, were submitted to the enzymatic treatment, although essentially the same phenomena were observed, the greater degree of resolution of the polyphenols revealed slight browning in the position of the faster moving leucocyanidin (L_1 leucocyanidin of Forsyth, 1955). Prolonged incubation did not result in any increase in the intensity of the spot, which remained weak. These observations indicate that the leucocyanidins are not an important substrate of browning in the cacao bean.

The two anthocyanins, which appeared on the untreated chromatograms as purple spots of R_F 0·33 and 0·41, were observed on incubation of the enzymatically treated chromatograms to become slowly colourless and afterwards to give rise to faint brown colorations.

Since it appeared possible that further phenolic material might be rendered susceptible to polyphenol oxidase action in the course of the commercial fermentation process, to which the beans are subjected prior to drying, methanolic extracts of fermented beans were prepared and examined by the above technique. No additional substrates were, however, detected in fermented material and the only difference noted was a reduction in the amount of brown pigmentation in the epi-catechin position. This was however expected as Forsyth[1] has reported a loss of epi-catechin by exudation from the bean during fermentation.

It would thus appear that in the cacao bean (–)-epi-catechin is the major substrate of polyphenol oxidase and accordingly that the (–)-epi-catechin content of the cacao bean at the end of fermentation is a major factor in the subsequent enzymic browning of the bean. It is, moreover, evident that the leucocyanidins, which are present in the cacao bean in quantities comparable to those of the catechins (Forsyth, 1955), contribute to a very limited extent to the enzymic browning of the bean.

Sporendonema

MY attention has been directed to a letter published in *Nature* of February 9, 1957, by F. C. Wood on *Sporendonema*, in which it is stated that the fungus known to mushroom growers as 'red *Geotrichum*' and 'lipstick mould' is invariably referred to as *Geotrichum* sp. The letter proceeds to report its identification by Mason and Hughes as *Sporendonema purpurascens*.

In fact this fungus was referred to in the report of the Mushroom Research Association, 1946–48, as 'Red Geotrichum', and in the report for 1949 as *Sporendonema* sp. (Red Geotrichum), as a result of studies by my former colleagues in the Association, Dr. C. J. La Touche and Miss C. W. Duncan.

The fungus is referred to as *Sporendonema* sp. (Red Geotrichum) in the 1950 and 1956 editions of "Mushroom Growing Today", by F. C. Atkins, and also in the Ministry of Agriculture Bulletin 34, "Mushroom Growing".

Galileo on the Ptolemaic and Copernican Systems

IN my review of the Salusbury translation of Galileo's "Dialogue", revised by Giorgio de Santillana, in *Nature* of September 7, I wrote that this was the first modern edition of the work in the English language. Mr. J. B. Mack, librarian of Lehigh University, Bethlehem, Pennsylvania, has, however, directed my attention to an earlier English translation, which was published in 1953[1]. I hasten to repair the injustice involuntarily done to the author of the latter work.

Having been struck some two decades ago by the strange fact that a work ranking so high among the classics of science was not available in English, Mr. Stillman Drake, of Puerto Rico, undertook the task of repairing this breach in the literature of the history of science and fulfilled it after ten years strenuous labour, during which time he became a possibly unparalleled connoisseur of Galileo's life and work in general. He made his translation from the original text as published in Vol. 7 of the Edizione Nazionale, and, as a comparison will readily show, bestowed the utmost care on it.

This does not mean that he felt obliged to give a strictly literal rendering of the text. He rightly believed that the translation should make as easy and fascinating reading to a non-specialist of our times as the original must have made for cultivated and interested Italians of the seventeenth century. In this, I believe, he succeeded remarkably well. His work will certainly contribute in making a most important and influential classic accessible to the modern reader.

The value of the translation is enhanced by giving (between square brackets) the additions which Galileo made to the work after the first edition of 1632. It is a good thing also that his marginal notes, which often are omitted in modern editions, have been retained.

Only one critical remark should be made. The title of the "Dialogue" is reproduced in this translation in a convenient but highly abbreviated form. No objection can be made to this, but one regrets that the exact and complete rendering of its wording is nowhere to be found.

FORTHCOMING EVENTS

*(Meeting marked with an asterisk * is open to the public)*

Monday, December 16

Institution of Electrical Engineers, Radio and Telecommunication Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Informal evening on "Electronics and Automation—Electronics in the Textile Industry". Talk by Mr. K. J. Butler.

British Computer Society (at the Northampton College of Advanced Technology, St. John Street, London, E.C.1), at 6.15 p.m.—Dr. S. Gill: "Parallel Programming—a Study of a New Technique in Digital Computer Programming".

Tuesday, December 17

Royal Statistical Society (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.15 p.m.—Mr. J. S. Cramer. "The Depreciation and Mortality of Motor Cars".

Institution of Electrical Engineers (joint meeting with the Institutions of Civil and of Mechanical Engineers, at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 5.30 p.m.—Sir Ewart Smith: "The Engineer and Management" (Fourth Graham Clark Lecture).

Institution of Electrical Engineers, Measurement and Control Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. J. Lamb: Informal lecture on "Recent Uses of Ultrasonics in Investigating the Characteristics of Materials".

Plastics Institute, London and District Section (at the Wellcome Building, 183–193 Euston Road, London, N.W.1), at 6.30 p.m.—Mr. C. W. Welch: "The Plastics Institute, Press and Industry" (Chairman's Lecture).

Wednesday, December 18

Society of Chemical Industry, Corrosion Group (at 14 Belgrave Square, London, S.W.1), at 2.30 p.m.—Discussion on "Teaching Corrosion Science". "Existing Facilities for Training in Corrosion Science" opened by Mr. L. W. Stubbs; "Future Requirements" opened by Dr. T. P. Hoar.

Royal Meteorological Society (at 49 Cromwell Road, South Kensington, London, S.W.7), at 5 p.m.—Mr. J. L. Monteith: "Dew"; Mr. N. H. Rider: "Water Losses from Various Land Surfaces".

Royal Statistical Society (at University College, Gower Street, London, W.C.1). at 5.15 p.m.—Prof. J. Neyman and Prof. Elizabeth Scott: "Statistical Approach to Cosmology".

British Institution of Radio Engineers (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6.30 p.m.—Mr. H. Garthwaite, M.B.E., and Mr. A. G. Wray: "Recent Developments in Electronic Instrument Design".

Society for Analytical Chemistry, Biological Methods Group (at "The Feathers", Tudor Street, London, E.C.4), at 6.30 p.m.—Annual General Meeting, followed by a Joint Meeting with the Microchemistry Group. Discussion on "The Weighing and Measurement of Small Quantities", opened by Dr. G. F. Hodsman and Mr. R. Goulden.

Oil and Colour Chemists' Association (at the Royal Society of Tropical Medicine and Hygiene, Manson House, 26 Portland Place, London, W.1), at 7 p.m.—Dr. L. A. O'Neill: "Polyvinyl Acetate Emulsion Paints: Solved and Unsolved Problems".

Society of Cosmetic Chemists of Great Britain (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 7.30 p.m.—Dr. R. H. Marriott. "Penetration of Skin—Dead or Alive".

Thursday, December 19

Institution of Mining and Metallurgy (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—General Meeting.

London Mathematical Society (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. N Aronszajn. "Finite Dimensional Perturbation and Spectral Problems".

Institute of Fuel (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 5.30 p.m.—Dr. W. Idris Jones, C.B.E.: "Russian Coal Mining and Fuel Technology".*

Society of Chemical Industry, Road and Building Materials Group (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Mr. D. C. Soul and Mr. R. R. Davidson: "The Whiting–Oil Relationship in Glazing Putty"; Dr. J. Bowler-Reed: "The Examination of Building Mastics and Similar Compositions".

Thursday, December 19—Friday, December 20

Physical Society (at Imperial College, London, S.W.7)—Conference on "The Band Theory of Metals and Experimental Investigations into the Structure of the Fermi Surface".

Friday, December 20

Institute of Navigation (at the Royal Geographical Society, 1 Kensington Gore, London, S.W.7), at 5.15 p.m.—Rear-Admiral K. St. B. Collins, O.B.E., D.S.C.: "Admiral Francis Beaufort, His Contribution to Hydrography and Navigation".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer in Bacteriology—The Secretary, North of Scotland College of Agriculture, 41½ Union Street, Aberdeen (December 20).

Research Scholar (honours graduate in chemistry or physics) in the Physicochemical Laboratories, to carry out research work on the flow properties of polymers and coal—The Registrar, The Manchester College of Science and Technology, Manchester 1 (December 20).

Senior Lecturer (with a degree in psychology, preferably with biology, mathematics or physics) in Psychology in the Department of Management and Production Engineering—The Principal, Brunel College of Technology, Woodlands Avenue, London, W.3 (December 21).

Assistant in Entomology in the Department of Zoology—The Secretary, The University, Edinburgh (December 28).

Botanical Assistant, for duties which include teaching elementary botany and the identification and labelling of plants—The Director, The Royal Horticultural Society's Gardens, Wisley, Ripley, Surrey (December 28).

Demonstrators (2) (male graduates) in each of the following subjects: Physics, Chemistry, Civil or Mechanical Engineering, at the Royal Military College of Science, Shrivenham, Berkshire—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.30/7A (December 30).

Lecturer (preferably with a knowledge of nuclear engineering, heat transfer or mechanical design) in Engineering (Mechanical)—The Registrar, The University, Manchester (December 31).

Senior Lecturer in Applied Mathematics at the University College of Ghana—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (January 3).

Biometrician in the Ministry of Agriculture, Federation of Rhodesia and Nyasaland, for duties which include the design of experiments in all phases of agriculture and animal husbandry research and analysis of data and related statistical practice—The Secretary (R), Rhodesia House, 429 Strand, London, W.C.2 (January 4).

Chair of Engineering Structures tenable at the Imperial College of Science and Technology—The Academic Registrar, University of London, Senate House, London, W.C.1 (January 6).

Reader in Extraction Metallurgy at the Imperial College of Science and Technology—The Academic Registrar, University of London, Senate House, London, W.C.1 (January 13).

Statistician, Scientific Officer or Senior Scientific Officer grade (with a good honours degree and preferably postgraduate experience)—The Secretary, East Malling Research Station, near Maidstone, Kent (January 17).

Lecturer in Electrical Engineering—The Registrar, University College, Singleton Park, Swansea (January 18).

Chair of Zoology tenable at Queen Elizabeth College—The Academic Registrar, University of London, Senate House, London, W.C.1 (January 21).

Senior Lecturer or Lecturer in Zoology at the University of Otago, Dunedin, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand, January 30).

Assistant Lecturer (man or woman graduate) in Mathematics, preferably Applied—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (January 31).

Chair of Botany—The Registrar, University College of Wales, Aberystwyth (January 31).

Curator (with a university degree in one of the natural history subjects, or an equivalent qualification, and experience in museum administration, and preferably with the Diploma of the Museums Association) of the Hancock Museum—The Hon. Secretaries, Natural History Society of Northumberland, Durham and Newcastle-upon-Tyne, The Hancock Museum, Newcastle-upon-Tyne 2 (January 31).

Lecturer in Physics at the University of Cape Town, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Cape Town, January 31).

Lecturer or Assistant Lecturer in Mathematics at Makerere College, University College of East Africa—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (January 31).

Lecturer or Assistant Lecturer in Physics at the University College of the West Indies—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (February 15).

Professor (with a university degree in science or in agriculture, and special qualifications and experience in teaching or research) of Plant Science (Agricultural Botany) at Canterbury Agricultural College (University of New Zealand)—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand, February 15).

Readers (2) in Mathematics, one in the field of pure mathematics and the other in the field of applied mathematics, at the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, February 28).

Senior Lecturer in Pure or Applied Mathematics at the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, February 28).

Director of the Institute of Biological Control, Ottawa, Canada; Assistant Director of the Institute of Entomology, London; and Assistant Director of the Bureau of Dairy Science and Technology, Shinfield, near Reading, Berks—The Secretary, Commonwealth Agricultural Bureaux, Farnham House, Farnham Royal, Bucks (March 31).

Analysts, Experimental Officer grade (not under 26 years of age, with at least G.C.E. in five subjects including English language

(Ordinary) and chemistry and one other scientific or mathematical subject (Advanced) or equivalent qualifications), for the examination of radioactive materials—The Senior Recruitment Officer, Atomic Weapons Research Establishment, Aldermaston, Berkshire, quoting Ref. 1641/34

ASSISTANT (preferably with electronics experience) to help in biophysical research—The Medical Research Council, Biophysics Research Unit, King's College, Strand, London, W.C.2.

BIOCHEMIST, Senior or Basic grade (with a B.Sc. degree with honours in chemistry or biochemistry, or equivalent qualification)—The Group Secretary, Royal Hospital, Wolverhampton.

CHEMIST (aged 23–26, with a good B.A. or B.Sc. honours degree, and interested in organic and physical chemistry), to join a small team carrying out fundamental research—The Assistant Secretary, Ref. D.47, The British Coal Utilization Research Association, Randalls Road, Leatherhead, Surrey.

CHEMISTS, Scientific Officer or Senior Scientific Officer grade (with a first- or second-class honours degree in chemistry or equivalent), at the Road Research Laboratory (D.S.I.R.), Harmondsworth, Middlesex, for research on the use and performance of bituminous road materials and on problems arising from the presence of organic matter in soils—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting F.647/7A.

LECTURER (with teaching and research experience, preferably in applied entomology or soil zoology) IN AGRICULTURAL ZOOLOGY—The Registrar, The University, Nottingham.

PHYSICIST (Basic grade), for work connected with the medical applications of radioactive isotopes and general dosimetry of X-radiation—The Group Secretary, Nottingham General Hospital, Nottingham

PHYSIOLOGICAL RESEARCH ASSISTANT (university graduate, with experience of experimental methods and of neuro-physiology) IN THE OTOLOGICAL INVESTIGATION UNIT, for work which includes investigation of the physiological reaction of the two parts of the internal ear in the human subject and also experimental research in the physiology and neurophysiology of the acoustic and vesicular system—The Secretary, Institute of Laryngology and Otology (University of London), 330/332 Gray's Inn Road, London, W.C.1.

RESEARCH ASSISTANT (with a science degree) IN THE DEPARTMENT OF PHYSIOLOGY AND BIOCHEMISTRY—The Head of the Physiology and Biochemistry Department, The University, Southampton.

NATURALLY OCCURRING QUINONES

By R. H. THOMPSON, D.Sc., Ph D., F.R.I.C.
University of Aberdeen

This book presents, for the first time, a comprehensive account of the quinone pigments which form the largest group of natural colouring matters.

The quinones are considered mainly from a chemical stand-point with emphasis on their reactions and constitution, and with biologists in mind, the data on natural sources have been carefully compiled. The literature is completely covered up to the end of 1956, and there are many references to papers published in 1957

QUANTITATIVE PLANT ECOLOGY

By P. GREIG-SMITH, M.A.
University College of North Wales, Bangor

The growing awareness among ecologists of the need to place their science on a more exact basis is changing the emphasis from extensive work on vegetation to intensive work on selected aspects and, consequently, more precise methods of examination are necessary

The need for improved techniques is made more urgent by the rapid depletion of natural vegetation and the realisation that advances in many branches of agriculture and forestry depend upon answers to ecological questions

The author makes an assessment of the practical potentialities of various methods and techniques, and provides guidance on the most profitable means of handling data as well as a broad survey of the quantitative approach to plant ecology.

Price 30*s*

CONTROL OF THE PLANT ENVIRONMENT

Edited by J. P. HUDSON, M.B.E., G M.
University of Nottingham

Control of various factors of the plant environment offers a powerful new research tool for the study of growth and yield. This approach offers attractive opportunities in fields of research ranging from fundamental aspects of plant physiology and genetics to applications of immediate importance in plant breeding, agriculture and horticulture.

The Fourth Easter School in Agricultural Science, held at the University of Nottingham School of Agriculture in April, 1957, was devoted to the "Use of Controlled Environments in Crop Experimentation"

LECTURES AND COURSES

CHELSEA COLLEGE OF SCIENCE AND TECHNOLOGY

APPROVED COURSES FOR THE DIPLOMA IN TECHNOLOGY IN PHARMACOLOGY AND IN BIOCHEMISTRY

Two full-time courses for this Diploma, one in Pharmacology, the other in Biochemistry, begin in September, 1958. Each course is of four years' duration. The first, second, and fourth years are spent in College. The third year is one of Industrial Apprenticeship Requirements for admission are successes at the advanced level of the General Certificate of Education examination in Chemistry and Physics, and at ordinary level in three subjects, including Mathematics and English.

Full information about these courses can be obtained from the Secretary, Chelsea College of Science and Technology, Manresa Road, London, S.W.3.

THE POLYTECHNIC

REGENT STREET, W.1

DEPARTMENT OF MATHEMATICS AND PHYSICS

The following course of 14 lectures will be held on Tuesdays from 7 to 8 30 p.m., commencon January. 7, 1958.

SEMICONDUCTOR CIRCUIT ELEMENTS

Application for prospectuses and enrolment forms should be made to the Director of Education as soon as possible.

OFFICIAL APPOINTMENTS

TEA RESEARCH INSTITUTE OF CEYLON

SENIOR PATHOLOGIST

Applications are invited from suitably qualified persons for the post of Senior Pathologist in the Institute. Applicants must possess a first- or second-class honours degree, and should preferably have a postgraduate degree as well. They must also have had satisfactory postgraduate training and research experience in the application of pathology to agriculture. The selected officer will conduct research on problems of practical importance to the tea growing industry, and will be expected to plan and supervise field experiments, and to give technical advice to the growers. Experience with tea or a similar plantation crop would be an advantage. If a non-Ceylonese citizen from overseas is appointed, the inclusive salary will depend on qualifications and experience, and will normally be between £2,000 and £3,000 per annum, paid in local currency. A higher salary might be considered, commensurate with outstanding experience. The appointment will be for four years, in the first instance, followed by six months' home leave. If the officer should have had a minimum of ten years' tropical service, the period of contract will be three years with six months' leave. On appointment, and when travelling on home leave, first-class sea passages will be paid for the officer, his wife, and up to two children. The officer will be required to contribute 10 to 15 per cent of his salary to an approved Provident Fund, and the Institute will contribute an additional 15 per cent. Certain medical benefits are available. A free, hard-furnished, house will be provided on St. Coombs, which is situated at 4,500 ft. in the centre of the island, and which enjoys an equable and very healthy climate. Furing experience, qualifications and age. Post is

Applications should be sent under registered cover, giving full details of qualifications, research experience, and quoting names of referees, and should reach the undersigned not later than December 21, 1957.

ACTING DIRECTOR,
Tea Research Institute,
Talawakelle, Ceylon.

BRITISH IRON AND STEEL RESEARCH ASSOCIATION

Chemist or Metallurgist (male) required by the Association in the Physical Chemistry Section of the Chemistry Department in Battersea (London) Laboratories for research work on the physical chemistry of ferrous metallurgical processes Applicants should have an honours degree or equivalent qualification Future prospects are good for a man with initiative and research ability. Starting salary from £800 to £900 per annum, depending on experience, qualifications and age. Post is superannuated under the F.S S U Five-day week.

Written applications only, quoting "C P 9." to the Personnel Officer, B.I.S R A., 11 Park Lane, London, W 1.

MILK MARKETING BOARD FOR NORTHERN IRELAND

SENIOR POST OF CHEMIST

Applications are invited from suitably qualified men for the post of Chemist at the Board's Central Laboratory. This laboratory is at present temporarily located at Ballymure, Co. Antrim, but it is the intention of the Board that the Central Laboratory will be situated in Belfast within the next two to three years. This post, which offers scope for the exercise of initiative, is a senior one on the technical staff of the Board who are responsible for the marketing of over one hundred million gallons of milk per annum. The successful candidate will be responsible under the Board's Technical Officer for the supervision of the Board's laboratory services and for work relating to the quality control of milk and milk products. The salary scale is £1,160 per annum rising by five annual increments to a maximum of £1,370 per annum and the commencing salary will be determined by reference to qualifications and experience. The conditions of employment are attractive and there is a contributory superannuation scheme in force which the successful candidate will be required to join Applicants must possess a good honours degree in chemistry, food technology or related subjects and have had at least three years' suitable experience. Preference will be given to suitably qualified ex-Service candidates.

Applications should be made, in writing, giving full details of education, experience, qualifications, stating date of birth, present post and salary and the names and addresses of two referees, to the Acting Secretary-Manager, Milk Marketing Board for Northern Ireland, Castlehill Road, Belfast. The closing date for the receipt of applications is Saturday January 4, 1958

NORTHERN POLYTECHNIC

HOLLOWAY, N.7

The Governing Body invite immediate applications for appointment as part-time Lecturers in Mathematics for day-time and evening classes for G C E. Ordinary and Advanced Levels and for standards up to the B.Sc. (General) Degree.

Apply, in writing, giving full particulars of age, qualifications, experience, etc., to the Secretary.

SENIOR SCIENTIFIC OFFICERS · SCIENTIFIC Officers. The Civil Service Commissioners invite applications for pensionable appointments covering a wide range of scientific research and development in most of the major fields of fundamental and applied science. In biological subjects the number of vacancies is small. Individual vacancies exist in the Natural History Museum for candidates who have special knowledge of or who are interested in, taxonomic entomology. palaeontology. The Royal Naval Scientific Service require a Scientific Officer (male) for the National Institute of Oceanography to work on oceanic Cephalopoda; and a vacancy for a Metallurgist (Scientific Officer) has arisen in the Royal Mint. Candidates must have obtained a university degree with first- or second-class honours in an appropriate scientific subject (including engineering) or in mathematics, or an equivalent qualification, or be otherwise qualified by high professional attainments. Candidates for Senior Scientific Officer posts must also have had at least three years' postgraduate or other approved experience. Age limits: Senior Scientific Officers between 26 and 31, but specially suitable candidates under 26 may be admitted; for Scientific Officers between 21 and 28 during 1957 (up to 31 for permanent members of the Experimental Officer class). Salary (London) Senior Scientific Officers: minimum £1,190 (women £1,098). Men's scale maximum £1,410. Scientific Officers: minimum £635. Men's scale maximum £1,110 Women's pay above £635 slightly lower but being raised to reach equality with men's in 1961 Somewhat lower rates in the provinces. Five-day week, generally.—Further particulars, from Civil Service Commission, Scientific Branch, 30 Old Burlington Street, London, W.1, quoting No S.53/57 for Senior Scientific Officers and S.52/57 for Scientific Officers. Application forms should be returned by December 31, 1957.

AGRICULTURAL RESEARCH COUNCIL Unit of Experimental Agronomy requires Abstracter/Indexer to assist in the production of "Weed Abstracts" Appointments, to start January 1, in the Assistant Librarian, Grade II, salary £485 by £25 to £685. University pension's scheme and holidays (six weeks per annum).—Apply, in writing, with the names of two referees, to The Secretary, Department of Agriculture, Parks Road, Oxford

COMMONWEALTH of AUSTRALIA

DEPARTMENT OF SUPPLY

AUSTRALIAN DEFENCE SCIENTIFIC SERVICE

The Weapons Research Establishment, Salisbury, Adelaide, Defence Standards Laboratories, Maribyrnong, Melbourne, Alexandria, Sydney; and Finsbury, Adelaide, invite applications for positions of Scientific Officer, Grades 1 and 3, at the above Laboratories from honours graduates and experienced research workers. Salary: Scientific Officer, Grade 1, £A.1,313 to £A.1,628; Scientific Officer, Grade 3, £A 1,718 to £A.1,938. Duties: defence research in one of the fields of aerodynamics, chemistry, electronics, mathematics, metallurgy, optics, physics, and mechanical or electrical engineering. Qualifications: Scientific Officer, Grade 1, appropriate honours degree. Some relevant research experience would be an advantage. Scientific Officer, Grade 3, appropriate honours degree or other academic qualifications considered equivalent together with research experience, desirable Location: Maribyrnong, Alexandria, and Finsbury are within the suburban areas of Melbourne, Sydney, and Adelaide respectively. Salisbury is situated approximately 16 miles north of Adelaide While the positions are on a temporary basis, the tenure of employment is not limited First-class boat fare for the appointees, their wives, and dependent children will be paid by the Commonwealth of Australia

Application forms, together with a descriptive leaflet, are available from the Senior Representative, Department of Supply, Australia House, Strand, London, W.C.2, with whom applications should be lodged by December 19, 1957, quoting Ref AP.89

GOVERNMENT OF NORTHERN RHODESIA

DEPARTMENT OF WATER DEVELOPMENT AND IRRIGATION

GEOLOGIST OR GEOPHYSICIST

Qualifications. First- or good second-class honours degree in geology Experience in pre-Cambrian terrain an advantage Duties: Geologist. General field geology as applied to water supply. Geophysicist. Geophysical surveys for the location of underground water by the electrical resistivity method. Terms of appointment. On probation to the pensionable establishment with emoluments in the scale £990 to £1,950 per annum. Outfit allowance. Free passages. Quarters provided if available at rental Free medical attention. Generous leave. Taxation at low local rates

Apply to Director of Recruitment, Colonial Office, London, S.W.1. State age, qualifications and experience. Quote BCD.140/3/04

METEOROLOGICAL OFFICE, SCIENTIFIC Officers. The Civil Service Commissioners invite applications for permanent posts. The duties include research in atmospheric physics, covering the study of cloud structure, synoptic and dynamical meteorology, large and small scale diffusion and turbulence, climatology, and development of instruments. There is a limited number of posts for forecasting work at the more important centres. Successful candidates will be given a course in meteorology before being assigned to a research or forecasting establishment for further training and experience. In some instances candidates with national service obligations can be commissioned in the R.A.F. for forecasting duties at R.A.F. stations. Further information may be obtained from the Secretary, Meteorological Office, Air Ministry, Kingsway, London, W.C 2. Candidates must be between 21 and 28 during 1957 They must have a first- or second-class honours degree preferably in physics or mathematics, or an equivalent qualification. Salaries (London rates) £635 to £1,110. Women's pay above £635 slightly lower but being raised to reach equality with men's in 1961. Somewhat lower rates in provinces. Opportunities for promotion to Senior Scientific Officer (£1,190 to £1,410), and higher posts.—Particulars from Civil Service Commission, Scientific Branch, 30 Old Burlington Street, London, W.1, quoting No. S52/57 (Met). Application forms should be returned by December 31, 1957.

POLLARDS WOOD RESEARCH STATION. Institute of Cancer Research, Chalfont, St. Giles, Bucks. Technician (female) required to assist in biological research at the above Research Station. The post is permanent and superannuable, and salary is in accordance with age, qualifications and experience.—Applications, marked "MJF." should be sent to the Secretary, Chester Beatty Research Institute, Fulham Road, London, S.W.3, within a week of the appearance of this advertisement.

THE EXPLORATION OF SPACE BY RADIO

by

R. Hanbury Brown and **A. C. B. Lovell**

D.I.C., A.M.I.E.E., F.R.A.S.
Reader in Radio Astronomy, University of Manchester

O.B.E., F.R.S.
Professor of Radio Astronomy, University of Manchester

Professor Lovell, Director of the Jodrell Bank Experimental Station, and his colleagues on the Station, here describe some of the results and possibilities of the investigation of the universe by radio methods. Both authors were "in at the birth" of this new science and have led the field of research and practical application ever since.

A TREATISE ON LIMNOLOGY

Volume I—Geography, Physics, and Chemistry

by

G. Evelyn Hutchinson

Department of Zoology, Yale University

The first of a two-volume work which, when finished, will give as complete an account as possible of the events characteristically occurring in lakes. The comprehensive treatment of the subject provides an invaluable reference work not only for workers in limnology, but for biologists, geologists and oceanographers.

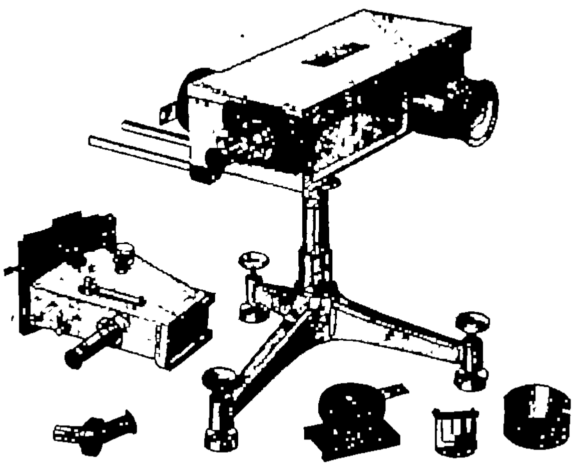
PRECISION B S INSTRUMENTS

Direct Reading Wavelength Spectrometer



for use in the visible spectrum and also, when required, in the ultra violet and infra red. Reading in wavelengths directly.

A camera attachment can be supplied giving the following length of spectrograms :

With quartz prism, wavelength 10,000 A. to 2,200 A., 70 mm.

With glass prism, wavelength 10,000 A. to 3,600 A., 125 mm.

A large range of accessories can be supplied with this spectrometer, making it a really universal instrument, and our staff will at all times be pleased to recommend the equipment most likely to meet special requirements.

PUBLIC CONFIDENCE AND SCIENTIFIC DEVELOPMENT

"THE important thing for this country to-day is that people should come to realize first, that science is not latter-day witchcraft but simply a process of disciplined thought and experiment; and second, that technology is neither a mystery nor beneath contempt but simply the translation of knowledge into practical advantages in everyday life." Those words from the conclusion of the Duke of Edinburgh's speech on opening the new extensions of the Manchester College of Science and Technology on November 22 should be borne in mind in considering the recent accident at the Windscale factory of the Atomic Energy Authority. If Britain is to enjoy the full advantages of the developments made possible by the work of her scientists and technologists, those developments must be broadly understood by the people at large, who must have a general appreciation of the price to be paid.

It was argued quite reasonably by Mr. D. Renton, replying for the Minister of Power in the House of Commons on November 11, that if public confidence was shaken at all by what happened at Windscale, so far as Calder Hall and the Electricity Authority's nuclear power stations are concerned, confidence should be completely restored by what is set forth in the White Paper (see *Nature*, November 23, p. 1093) and by the Prime Minister's statement of November 8. Nevertheless, the question of public confidence in regard to technological development generally is the over-riding issue raised by the whole incident, and it was well brought out in the debate in the House of Lords on November 21. Lord Lawson, on whose motion the debate was opened, commented on the sense of responsibility which he observed in the whole bearing of those who worked at Windscale, and said that work such as is being done at Windscale and Calder Hall could not continue in an area where people harbour any feeling of grievance against those who are operating the factories concerned.

Lord Lawson recognized that the three committees appointed to evaluate the technical observations derived from the accident and to recommend any necessary measures to remedy defects in organization—in relation to the operation of reactors in the Atomic Energy Authority's Research Group, in the control of health and safety generally, or to the controlled release of Wigner energy in particular—are likely to lead to arrangements which will ensure that repetition of such an accident is improbable, and that the choice of Sir Alexander Fleck as chairman should guarantee that there is no undue delay. Nevertheless, he was somewhat critical of the Authority's safety organization, though his main point was that staff of the appropriate calibre and insight could do much to engender the general confidence which he stressed as so important.

It is here, of course, that security considerations make it difficult to remove all misgivings, as the publication of the full report might have done. There can be little doubt that the Prime Minister is right to withhold publication on security grounds, but the technical character of the report does not affect the consideration that secrecy is always a stumbling-block to establishing public confidence and understanding. To ensure confidence, prudence requires that the limits of secrecy should be kept under continuous scrutiny and revised from time to time. The fullest possible publicity is the surest way of securing public understanding and goodwill in such enterprises, and public confidence rests rather on the positive achievements of the scientists and technologists and others responsible than on negative measures or concepts.

This much was implied in Viscount Stonehaven's view that wide publicity should be given to the fact that future nuclear power plants are being built on a totally different principle, and that this kind of accident could not occur in the closed cycle, carbon dioxide cooling system now being used. Lord Rea also urged that the Minister and the Government should take the public more into their confidence, while Lord Glyn, who referred to the utmost importance of a sense of proportion in regard to the accident, said that the real danger is that it might affect public opinion throughout the country. It would be a disaster if people got the idea that there is a danger wherever a new establishment is erected. It should be emphasized that there is no reason for believing that the new establishments being set up by the Atomic Energy Authority, with outside organizations, are a source of danger to the public.

The debate in the House of Lords went far to provide the reassurance which Lord Glyn suggested should be provided whenever this question is discussed. Lord Glyn himself paid a tribute to those who had carried out all this development without serious accident, and Lord Mills amplified it; and both the Prime Minister and Mr. Gaitskell in the House of Commons gave generous acknowledgment to the courage, energy and resourcefulness of those at the installation after the accident, Mr. Macmillan agreeing with Mr. Woodburn that heroism on the part of some scientists had averted real disaster. Although the accident may have been due to human error, the vigour with which it was dealt with, and the standards of responsibility and the skill and judgment which have made possible Britain's ambitious nuclear power programme, and enabled it to operate until the accident at Windscale without a single serious accident, constitute a firm basis for continuing public confidence. Even after this serious accident, the Atomic Energy Authority can still say that all this has been done without anyone being hurt, let alone killed, by radiation from one of its plants. This background of swift progress, safety and success must not be forgotten, and it provides the right perspective when we are seeking to determine just where the fault lay, how it can be remedied and what can be learned from the accident. Nevertheless, the public may well ask whether the Authority may be too complacent in future about other unsuspected dangers as great and as insidious.

Here the frankness of the White Paper is reassuring, though it is still possible to wonder whether secrecy might have been relaxed a little further in the effort to dispel public anxiety. Lord Mills was no less frank in his reply to the debate on November 21, and although he added nothing technically substantial to what was in the White Paper, he indicated that Sir Alexander Fleck's three committees were already at work. He agreed to consider suggestions that more should be done to inform and advise the local population, but pointed out that this was not overlooked by those in charge at Windscale even at the height of the incident. The Atomic Energy Authority is not satisfied, however, that the arrangements for local liaison are entirely satisfactory, although relations between the Windscale management and all local organizations in Cumberland are excellent. The Authority has now decided to put relations between all its works and local interests on a more comprehensive basis, and liaison committees are now being formed, on which the steps to be taken in an emergency will be fully studied with all the local interests which might be concerned.

Lord Mills added that the Agricultural Research Council and the Ministry of Agriculture have been conducting very intensive research into the effect of radioactive fall-out on grass and crops, and he was sure that they will have full regard to points as to strontium-90 and marketing arrangements made by Lord Alexander of Hillsborough. Under the Atomic Energy Act, 1954, the Authority has an absolute duty to ensure that no ionizing radiations from anything on any premises occupied by it causes any hurt to any person or any damage to any property, and it has announced that it will consider claims from persons who can produce evidence that they have suffered harm.

As Minister of Power, Lord Mills is closely concerned that nothing should prejudice the continued success of the nuclear power programme of Britain; but in conclusion he claimed that the debate had shown that confidence in the country's nuclear future is fully justified. He repeated the conclusion of the White Paper that the accident at Windscale could not happen with the Calder Hall reactors, or with the reactors being built for the electricity authorities. He claimed that there is nothing in the Windscale accident which need make our policy for siting nuclear power stations more restrictive, and he repeated that proper arrangements for any emergency would be available for all such stations. The lessons to be learnt from the Windscale incident, he said, will be carefully applied to the nuclear power stations to be erected and operated by the Electricity Authority.

Until Sir Alexander Fleck's committees report, it is improbable that anything further can be added to the White Paper and what has already been said in Parliament. Meanwhile, however, three points already noted there should be kept in mind. First, there is the desirability of keeping secrecy to a minimum. Secondly, a considered policy in relation to the siting of nuclear power plants and other nuclear energy establishments, particularly when a threat to Nature reserves, national parks or other amenities is involved, would go far to avert public suspicion and opposition. Neither Mr. Renton nor Lord Mills seemed sufficiently to appreciate the importance of this point, that no Authority should be judge in its own interest, or the bearing of this principle on public confidence. Thirdly, the vital importance of staff of the highest calibre, not merely technically competent but also alive to the human and other issues involved, cannot be over-emphasized. To obtain, and retain, such staff, it is essential not merely that conditions of service, including salaries, as Lord Rea emphasized, should be satisfactory, but also that the educational system should be providing a supply of technologists such as the Duke of Edinburgh urged—well educated and not simply specialists—and that they should enjoy the respect and understanding of the community as a whole.

PRE-FAMINE IRELAND

Pre-Famine Ireland

A Study in Historical Geography. By T. W. Freeman. Pp. viii+352. (Manchester: Manchester University Press, 1957.) 35s. net.

MUCH has been written by historians on the social and economic conditions in Ireland during the middle of the nineteenth century, when the disastrous famine of 1845–52 permanently changed the face of the countryside and started the decline in population which has continued to the present day. T. W. Freeman, however, is the first geographer to make a detailed study of the period, and in this book he gives a lively factual account of life and landscape in the country just before the onset of the famine. He is fortunate in having abundant material upon which to draw. 1842 saw the completion for Ireland of the first set of Ordnance Survey maps to cover any country on a scale of six inches to one mile; the population census of 1841 was the most reliable yet taken for the country and was much more than just a simple enumeration of people; while the reports of numerous commissions, notably that under the chairmanship of Lord Devon, gave accurate and sympathetic reviews of social and agricultural conditions throughout the country. Mr. Freeman has handled this material with skill, and, where possible, has plotted his data to produce interesting distribution maps of such diverse matters as population density, house types and illiteracy.

The book is divided into two sections. Part 1 deals systematically with population, emigration, agriculture, trade, communications and social problems. The picture which emerges is a grim one. By 1841 the population exceeded 8 million, and of these, three-quarters were tenant farmers attempting to gain a living from the land. Long-continued subdivision of the farms had reduced many of the holdings to such a size that they could no longer support a family, even taking into account the high yield of the potato, which was the basic item of diet. Many lived in extreme poverty, especially those who were landless, for there was little prospect of employment and the alternatives were starvation or emigration. Thousands of emigrants found their way into the growing industrial towns of Great Britain and the United States of America.

The chapter on agriculture in this section is relatively short and might have been expanded with profit. That on trade is more exhaustive and includes a full discussion on mineral resources and industry; while the chapter on communications is a model of its kind.

Part 2 is a detailed regional analysis of the country. There are maps to show the distribution of demesne land and rough pasture; and also population density. The latter are of special interest for they indicate that practically all the habitable part of the western seaboard had a density of population exceeding 400 per square mile. These regional studies are useful to anyone interested in specific parts of the country; but they also serve to show the wide difference that existed between, for example, the Provinces of Connaught and Leinster, and between the industrialized north-east and the remainder of the country where industry, though widely distributed, was of very little real significance.

The arrangement of this book gives rise, inevitably, to some repetition, and a few of the maps have suffered from over-reduction, but these are relatively minor points which do not obscure the fact that Mr. Freeman has made a substantial and lasting contribution to the historical geography of Ireland.

J. P. HAUGHTON

ECONOMICS AND COMMON SENSE

Economic Analysis

By Prof. Edmund Whittaker. Pp. xiii+460. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1956.) 52s. net.

PROF. E. WHITTAKER starts his consideration from the choices before individuals, farmers, businesses, voluntary groups and organs of government. This enables him to raise in his readers' minds the economic questions which may legitimately be asked. He sets out the quantities by which decisions should be guided and only introduces, as the argument proceeds, the terminology of the economist. He explains why, for example, a textile mill might be sold up while still a going concern; and points out that a proper policy for conservation is not always that one which guards the interest of the future by preventing too rapid an exploitation of natural resources in the present. It was perhaps not necessary to provide for the incompetence of the farmer who sows his seed so thickly that the crop does not ripen (pp. 224 and 225); and the reviewer, for one, would have liked to learn more of the reasons why, on p. 195, a family was supposed to value at 80 dollars the exhilarating experience of watching "the telly" for a month. But these objections are by the way. Prof. Whittaker asks questions and gives answers acceptable to most social scientists. His illustrations, however, are so peculiarly North American and drawn so often from farming that their significance may be lost on readers not well acquainted with the customs and constitution of the United States of America nor familiar with the techniques of agriculture. Surely, too, some more elegant way could have been found of expressing what was meant than by those inversions designed to avoid prepositions which so irritated at least one English reader. "Favorable purchase opportunities" on p. 203 is one example, and the reviewer would have been quite mystified by the "adjustment of land-labor proportionality called for by altered production and market conditions" on p. 218 had he not already known about the enclosures of common land in England during the eighteenth century.

An impressive mass of material is collected by departments of government in the United States, by agricultural stations, firms, universities and other research institutions. (The American economist is far better served in this than his British counterpart.) The hopes of the scientist for economics will be raised by this wealth of data. But they will certainly be dashed by the dependence of economic analysis (which the author does not attempt to disguise) upon the vulgar prejudices of common sense.

The book is designed, as the author tells us in his preface, to serve as a text for undergraduates taking the economic analysis and theory offered in American colleges after an introductory course. Prof. Whittaker insists that economic problems involve the interaction of more than those two variables to which most academic economists, faced with a class and a blackboard, have been content to confine themselves. But scientists will not gain much from the graphical representation of a three-variable analysis nor will they find in Prof. Whittaker's pages any detailed treatment of those fascinating issues upon which, without assistance from electronic computers and multi-channel analogue machines, six economists have so comfortably maintained their seven opinions. All these must be sought in the works which Prof. Whittaker has included in the bibliographies appended to his chapters.

GILBERT WALKER

MIDDLE-EASTERN APHIDOIDEA

The Aphidoidea of the Middle East

By F. S. Bodenheimer and E. Swirski. Pp. iv+378. (Jerusalem: The Weizmann Science Press of Israel, 1957.) n.p.

THE importance of aphids as economic pests and as virus vectors has led to a considerable amount of research on this group in recent years and to a corresponding increase in the already large volume of aphid literature. This, however, is mostly in the form of specialist papers in a variety of journals, and up-to-date comprehensive works are comparatively few. A careful and well-documented study of the biology and systematics of the aphids of a geographical region such as the Middle East, which Prof. Bodenheimer and Dr. Swirski have produced, is therefore to be welcomed, particularly as the aphids of this area have never been studied intensively before.

The authors state at the outset that their aims are to help the taxonomist and the agricultural entomologist to identify aphids, and to suggest further lines of research into aphid ecology. The first half of the book deals with life-history studies, the problems of migration and host-finding, nutrition, climatic influences, and the relationships of aphids with ants and with predators, together with a brief chapter on aphid damage and control. In most of their ecological studies, carried out in Israel, Prof. Bodenheimer's team of workers have applied methods worked out by European aphidologists, whose work is freely quoted and discussed, and the chief interest of the book lies in the new light it throws on the behaviour of aphids in an arid, subtropical climate.

Most aphids are best suited to life in a temperate climate, and in those that occur in the tropics it is usual to find that the sexual phase of the life-cycle, with the laying of over-wintering diapause eggs, has been suppressed. In order to survive, such anholocyclic species must have a continuous supply of suitable food. In arid zones such as Israel, nearly all suitable aphid host plants are dry and dead during the summer and autumn, and for long it was unknown how aphids, which regularly infest plants in the spring growing period, survive the dry season. The authors find that this is effected for the most part either by a few individuals which chance to find sheltered conditions favourable to survival, or, in the case of root feeders, by refuge in ants' nests at considerable depths below the soil surface. In either case, the mortality of such species at the onset of the dry season is enormous. In some groups, however, notably the Fordinae, which migrate between *Pistacia* species and the roots of grasses, there is a true holocycle, complete with sexual phase and the laying of diapause eggs, which is adapted to withstand conditions of this sort. The cycle lasts for two years, one of which is passed as diapause eggs. For the remainder, the developing colonies live either in enclosed leaf-galls, which offer protection against predators and prevent evaporation, besides providing suitable food at times when normal foliage does not, or below ground on grass roots. The critical changeover from primary to secondary host takes place in the autumn, when the winged migrants leave the *Pistacia* galls and deposit their young on the soil or under stones, where they remain quiescent and unfed for some weeks until the grass seeds germinate with the coming of the first rains.

The second half of the book comprises keys for the identification of Middle Eastern aphids and a systematic list of the two hundred species so far recorded from the region, with notes on the synonymy, bibliography, hosts, distribution and life-histories of each. The system of nomenclature follows that of Borner, and is in line with that adopted by most European aphidologists. The keys appear to be soundly constructed, but are, of course, valid only for the limited number of species they cover. It is unfortunate, though probably unavoidable, that in the Pemphiginae and some of the Fordinae, the keys run down to genera but no further. A separate key to the galls of these species, however, makes good this deficiency to some extent. The section ends with a host plant list and a good bibliography.

The book is printed in good, clear type, but the paper does less than justice to the illustrations, especially those in half-tone. Some of the graphs and diagrams are insufficiently explained, and the index is confined to specific names of aphids only, omitting references to subjects or authors dealt with in the text.

Nevertheless, the authors succeed in achieving considerably more than their modest aims suggest, and by presenting the results of original research together with a résumé of much recent work by European specialists, they make a contribution of real value to entomology as a whole.

J. P. Doncaster

TRIBAL GOVERNMENT

Government and Politics in Tribal Societies

By Prof. I. Schapera. (Josiah Mason Lectures delivered at the University of Birmingham.) Pp. viii + 238. (London: C. A. Watts and Co., Ltd., 1956.) 21*s*. net.

THE present volume, based on the Josiah Mason Lectures delivered by Prof. I. Schapera at the University of Birmingham in 1950, sets out to compare the traditional forms of government that had been developed among the indigenous peoples of South Africa—the Bantu, Hottentots, Bergdama and Bushmen—in pre-colonial times. Each of these peoples had its own distinctive mode of life, ranging from the food-gathering economy and nomadic existence of the Bushmen to that of the agricultural and more sedentary Bantu; there were also important differences between the 'communities' in terms of population size and distribution as well as in forms of local grouping. However, Prof. Schapera finds a unit of comparison in the concept of the 'political community'. The 'political community' is defined by reference to exclusive rights to a given territory, the members sharing other rights and obligations that do not extend to outsiders; but the distinctive criterion is that the 'political community' manages its own affairs independently of external control. On this basis, the author has been able to examine for each of his major divisions in turn what leaders there are, the qualifications for and requirements of office, the activities and functions of the governors, their privileges and powers and the limitations on the exercise of these powers, and a number of other related questions. His summary of the data suggests, in a number of propositions, the relationship between forms of political behaviour and increasing social and economic differentiation.

In the original lectures the illustrations were selected from a wide range of peoples in many different parts of the world. Here Prof. Schapera has chosen deliberately to confine himself to a more limited field—one, moreover, in which his authority is undisputed. This has enabled him to bring together in a readily accessible and valuable form a rich array of ethnographical material on political organization for the whole area. His emphasis on the importance of historical factors, which arises directly from his wide knowledge of the literature of the region, provides a valuable corrective to the more purely structural analyses of tribal government.

But "Government and Politics in Tribal Societies" is not a mere compilation; it is an essay in the comparative method. Initially, in outlining his own mode of approach, the writer argues that the concept of the 'political community' justifies him in treating as like units the Bergdama band and the Sotho 'nation', despite their great difference in size, territorial extent, social composition and complexity of organization. Thus by contrasting Bushman hunters and collectors with Bantu pastoralists he is able to deduce some of the 'apparent trends' in tribal government. For example, as one moves from one extreme of the continuum to the other, the community tends to become much larger and more heterogeneous; the functions of the government become more numerous and varied, and specifically 'political' institutions develop. This in turn is associated with greater specialization, and the emergence of a hierarchy of authorities, often on a regional basis, and so on. These conclusions are valuable and interesting in themselves, but they also point out some of the limitations of the method Prof. Schapera has followed in the present volume. Since the conclusions that emerge from his comparison are couched in terms of a theory of 'development', it would seem that the units of comparison do not in fact belong to the same order of social organization. Prof. Schapera indicates the areas of social life into which one must inquire in studying political organization. It is to be hoped that he will follow this up with a comparative study of the Southern Bantu alone, to whom the bulk of the material presented is in fact devoted, where one is dealing with units of the same order of social organization.

A. L. EPSTEIN

TRAVELS IN SOUTH AMERICA

Highway of the Sun

By Victor W. von Hagen. Pp. 264+21 plates. (London: Victor Gollancz, Ltd., 1956.) 18s. net.

Tupari

By Dr. Franz Caspar. (Translated by Eric Northcott.) Pp. viii+224+16 plates. (London: G. Bell and Sons, Ltd., 1956.) 18s. 6d. net.

THESE two books have one characteristic in common, namely, that both are popular accounts of their authors' travels in South America, but that they do not set out to describe any scientific discoveries their expeditions may have made.

Mr. von Hagen's object was to follow and record the Inca roads in Peru. The general lines of the road system were already known, but the expedition has doubtless filled in details, verified the physical remains of the roads and plotted them on maps. They tested the pace of local relay runners at an altitude of about 14,000 ft., finding that it would have been possible, as the chroniclers said, to cover the distance from Cuzco to Quito in twenty-four hours, and this is perhaps the most interesting piece of information in the book. For part of the journey on the coast there were archæologists in the party, but their chief concern was not with the roads and their results are for publication elsewhere. Had they been consulted they could have saved the author from publishing a picture of a tapestry of much later date as a mummy wrapping from Paracas Cavernas (p. 192), and a double whistling jar of Coast Inca type as Mochica, which is much older (p. 224).

No one will claim that travel off the beaten track in Peru is comfortable, and the discomforts and dangers of the journey lose nothing in the telling. The expedition had one eye on the *New York Times*, to which it sent frequent cables, and the style in which the book is written is sufficiently indicated by the sub-title, which describes the roads as "fabulous high-roads".

Dr. Caspar, who was returning from Bolivia to Europe, wished to visit and study some forest Indians who had not been changed by acculturation. He succeeded in joining a small group of about two hundred people in the Brazilian forests, who called themselves Tupari, although they turned out to be an agglomeration of the remnants of various tribes. He lived among them for about six months, gained their confidence, worked and hunted with them, and took part in some of their ceremonies; in fact, he seems to have done almost everything except respond to the advances of the wife they offered to him. The story is told in a straightforward and interesting manner, and it gives a good general idea of the way the Indians lived. It mentions some of the clues which the author obtained about their beliefs. The book does not give any details about how they built their houses or made their pots, the material of their arrowheads, the form of their stone tools or the exact nature of their musical instruments. There is no map, apart from a sketch map of a small area which serves no useful purpose, and there is no index. The author made extensive ethnological collections and could doubtless publish details about them elsewhere, but so far as I am aware he has done little in this way.

There is a sad postscript describing briefly a subsequent visit six years later, in 1955. Two-thirds of the group had died of measles, caught from rubber gatherers. The remainder had adopted European dress, and fallen, as the author says, victims to civilization.

G. H. S. BUSHNELL

TRANSMISSION-LINE THEORY

Transmission-Line Theory

By Prof. Ronald W. P. King. Pp. xii+509. (London: McGraw-Hill Publishing Company, Ltd., 1955.) 90s.

THIS book gives what is probably the most comprehensive treatment of the radio-frequency transmission line which has been published. The basic theoretical treatment is applicable to all frequencies, of course, but effects which are negligible except at high radio-frequencies are dealt with at length.

The first chapter deals with the infinitely long line by both the distributed-circuit and the electromagnetic-field methods and discusses thoroughly the limitations of the former. Parallel-wire lines (two, three or four wires, screened or unscreened), coaxial lines and strip lines are all discussed.

The terminated line is then treated, including the conducting pistons and disks used as terminations at very high frequencies. A consideration of the impedance and admittance of lines follows, including stub and other methods of modifying impedances, balanced to unbalanced transformations and hybrid junctions. Matrix methods of solution are used here. It seems a pity that anyone, having thought out an elegant arrangement for dealing with balanced to unbalanced lines (p. 207), should call it an 'unbalance squelcher', but for this Prof. King cannot be held responsible.

The distribution of current and voltage along a line, the measurement of standing-wave ratio and Q-factor from the current distribution, are topics which are thoroughly discussed. Many different forms of discontinuity are treated.

This book would overwhelm any reader who was just commencing the study of lines, because the author insists on a rigorous treatment, without introducing approximations until a late stage in the discussion. It should, however, prove a useful and stimulating book for any reader who has already a fairly good knowledge of the subject, and it will also be very useful to the radio engineer who needs the theoretical treatment of some specific line problem such as, for example, the effect of a bend in a parallel-wire line.

The book is well produced, the mathematics being well set out and the numerous graphs and diagrams adequate in size. Rationalized M.K.S. units are used.

C. R. STONER

NATURAL GAS IN SCOTLAND

By T. S. RICKETTS and D. C. ELGIN
Chief Engineer Technical Officer
The Scottish Gas Board

NATURAL gas is now being used for town gas supply in the Midlothian town of Musselburgh and at several smaller places nearby, including Cockenzie, Port Seton, Prestonpans and Tranent. This is the first example in Great Britain of natural gas being distributed for use as a commercial fuel.

The natural gas occurs in an anticline centred on a crest of agricultural land about 550 ft. above sea-level close to the small village of Cousland; Cousland is approximately four miles south-east of Musselburgh and three miles east of Dalkeith. The existence of the anticline was discovered by the former D'Arcy Exploration Co., Ltd. (now known as B.P. Exploration Company, Ltd.), in 1938, and most of the present knowledge of its extent and character has been obtained from two major boreholes, one sunk in the immediate pre-War period as part of an oil exploration, and the other sunk in 1954 as part of the nation-wide search for natural gas sponsored by the Gas Council. The anticline is thought to run in an east–west direction and the natural gas occurs in porous calciferous sandstone series at two main levels, 1,582–1,632 ft. and 1,720–1,735 ft. (depths measured at the site of the original deep bore). Smaller shows of gas have been discovered in deeper strata, for example, at 1,760–1,806 ft., and very small traces of oil have been detected in several of the oil-shale strata located by the drillings.

The calciferous sandstone in which the gas is trapped has an average porosity of 15 per cent; it occurs in the form of a dome which is sealed by water at a depth of about 1,700 ft. The mean diameter of the gas-bearing sandstones above water-level is estimated to be about 2,500 ft.; the pores in the gas-bearing sandstone above water-level contain, on the average, about 40 per cent of moisture and about 60 per cent of gas. The sandstone is covered by a continuous upper layer of impervious rock which has prevented the natural gas from escaping from the anticline by diffusion upwards and has thus preserved the deposit. The gas is contained in the sandstone layers at a pressure of 620 lb./sq. in. (gauge pressure). Although tests were carried out to ascertain the potential gas production-rates from the sandstone strata at various levels, it was found that only those series at levels higher than 1,700 ft. could yield gas without giving rise to difficulties due to water production. The productive well at Cousland is therefore blocked by a cement plug at 1,663 ft. and the concrete lining is pierced at levels corresponding to the sandstone strata at 1,582–1,632 ft.; the piercing was carried out by means of shaped explosive charges which, under the conditions prevailing at Cousland, give a more positive and controlled connexion between the productive strata and the well than could have been obtained using copper shot.

The gas reserves which are now in communication with the productive well at Cousland have been subjected to gas production tests at rates up to the equivalent of four million cubic feet a day. During these tests the 'draw' of gas from the strata at high offtake rates resulted in the reduction of well-bottom pressures down to 415 lb./sq. in. It is of great interest, however, that at the conclusion of the test runs at high rates of flow, the gas pressure within the well returned to within 20 lb./sq. in. of the normal standing pressure over a period of ten minutes following discontinuation of gas production; the final standing pressure was regained within one hour.

Although this rapid and invariable recovery of gas pressure supports the belief that substantial quantities of natural gas may be trapped within the sandstone strata which are in communication with the Cousland anticline, it has not yet been found possible to obtain an accurate estimate of the total magnitude of the gas reserve. The disturbed nature of the geological structure and the conflicting local evidence have made it difficult to arrive at a firm figure, and estimates have varied from 200 million to 3,000 million cubic feet of gas. It is now believed generally, however, that at least 1,000 million cubic feet are likely to be available from the borehole which is now in operation. The gas obtained from this borehole has a calorific value of between 930 and 960 British Thermal Units per cubic foot. It is principally methane, but in addition to about 90 per cent of this gas there are small quantities of other paraffinic hydrocarbon gases, in particular, about 3 per cent of ethane and about 1 per cent of propane; the remaining 6 per cent is mainly nitrogen with small traces of other inert gases. The natural gas is entirely free of sulphur.

In view of the great importance placed at national level on saving coal by utilizing every other possible indigenous source of fuel, the Scottish Gas Board worked out a scheme for utilizing the Cousland natural gas reserve, and this scheme was brought into full operation when Sir Harold Smith, chairman of the Gas Council, opened the principal valve on the Cousland well-head on October 28.

The well which was thus brought into production comprises a tubular steel outer casing with an outside diameter of 8¼ in. The casing surrounds a 2-in. diameter central tube which acts as the main gas uptake. The annular space between the central tube and the casing extends down to the bottom of the well and the static gas pressure within it reflects pressure conditions in the lower gas-bearing strata. In order to give full and precise control of the well, the 2-in. diameter central pipe is fitted with an arrangement of valves known, in accordance with oil-field practice, as a 'Christmas tree'. The 'Christmas tree' is surmounted by a pressure gauge which enables a careful watch to be kept on well-head conditions. There are two main branches from the 2-in. diameter central tube at the well-head, each controlled by an independent valve. One of these branches, known as the 'burning line', is of a temporary nature and is used for carrying out special production tests on the well; the gas produced during such trials is burned in the form of a flare. The other branch is the main gas supply line. This conveys gas at well-head pressure to a cylindrical water-separator designed to remove mist or droplets which might be evolved under abnormal conditions. The gas line then enters a small building housing a series of three pressure regulators which enable the pressure of the gas to be reduced in three convenient stages, from more than 600 lb./sq. in. to about 3 lb./sq. in. This fairly rapid reduction in gas pressure is accompanied by sudden cooling of the gas, and the staging of the pressure reduction through the three regulators has to be balanced very carefully to avoid blockage of the system by the separation of frozen solids from the gas stream; these solids may be in the form of ice due to the freezing of condensed water vapour, or methane hydrates, the latter being crystalline solids formed by the loose combination of methane and water vapour at low temperatures. In order to prevent formation of these solids, the governor system is to be wrapped with a special electrical resistance heater in the form of flexible tapes, enabling the temperature of the gas to be maintained at a safe level despite rapid reduction of pressure.

As the natural gas does not have a characteristic odour, arrangements have been made for small quantities of a special odorizing agent to be vaporized into the gas before it leaves Cousland. The odorizing agent chosen was tetrahydrothiophene (C_4H_8S), known generally as T.H.T. The level of odorosity is kept within carefully controlled limits, the aim being to achieve a smell resembling, as closely as possible, the characteristic odour of town gas.

The natural gas is conveyed from Cousland to Musselburgh in a 4-in. diameter main which was laid specially for this purpose. At Musselburgh the pressure of the gas is reduced by an orthodox gas governor to a few inches water-gauge and, after being metered, is mixed with coal gas manufactured in standard continuous vertical retorts at Musselburgh gasworks. The calorific value of the coal gas made and the proportion of natural gas added to it are so balanced that the calorific value of the mixture produced is 450 B.Th.U. per cubic foot, which is the declared, or statutory, calorific value for Musselburgh. The calorific values of the natural gas, of the coal gas, and of the mixed gas are measured by special continuous recording instruments, and this enables a very fine control to be kept on the calorific value of the mixture prepared for the local gas consumers. Another type of recorder has also been provided to allow the specific gravity of the gas to be measured, and it is well known that if the relationship—calorific value/square root of specific gravity (known as the Wobbe index) is kept fairly constant, the gas will burn satisfactorily at consumers' appliances.

After mixing the natural gas and the coal gas, the final product is passed to an orthodox water-sealed gasholder for storage prior to distribution as required by consumers. A careful check has been kept on the behaviour of consumers' appliances since natural gas has been included in the town gas supply; as expected, appliance performance has been normal and no special adjustments have been required.

It is estimated that for every 7,000 cubic feet of natural gas used for this purpose, about one ton of high-grade deep-mined coal will be saved. The average quantity of natural gas included daily in the gas supply from Musselburgh is approximately 60,000 cubic feet, which represents about 9·4 per cent by volume of the town gas distributed.

While gas is being removed from the Cousland reserve, the well-head pressure is kept under careful observation. So far, the original reservoir pressure has been maintained. Any diminution in pressure which may occur will be carefully followed up with the view of ascertaining whether the sustained removal of natural gas is having any permanent effect on the reserve pressure. From time to time production tests will be carried out to ascertain whether the quantity of gas removed through the borehole represents a significant reduction in the quantity of gas in the reserve. It is thus hoped to determine, as soon as possible, the total extent of the Cousland gas field. If the field is proved to be a fairly large one, arrangements would be made to utilize the gas on a much larger scale.

Apart from the obvious commercial value of the gas which is being obtained from the Cousland anticline, and the contribution to the national fuel economy which it represents, the Scottish Gas Board is also interested in the structure from quite a different point of view. It is considered that after the pressure in the gas-bearing sandstone has been removed by the use of the greater proportion of the natural gas, the structure can be used as a very large underground gas-holder; this possibility is being examined.

It has been possible at Cousland to harness an extremely old natural resource in a very modern way, and to set in motion a commercial enterprise which is at the same time in the nature of a scientific exploration. The use of the gas reserve there may reveal a great deal of important information about the geological structure of the neighbourhood and lead to further valuable discoveries.

THE TECHNISCHE HOCHSCHULEN OF WESTERN GERMANY

By Dr. J. HORNE
University of Birmingham

THIS brief survey of the German Technische Hochschulen (technical high schools) presents a short history of their development and scientific achievements, and concludes with an account of their provisions for broad non-vocational courses under the name of the Studium Generale. It is based upon personal visits over many years, and in particular upon a recent extensive study tour through many of the technical high schools.

The German technical high schools enjoy equal status among themselves and in public esteem despite their considerable differences in student numbers, ranging from 3,164 in the smallest to 5,716 in the largest (summer 1956). More significant and striking is their undoubted parity in standing with the older universities in Germany. Indeed, the latter's initial opposition to the applied sciences was overcome by three main features which have characterized the whole development of the technical high schools from their early humble origins to the present day. These features may be summed up as follows: (1) The high standard set for entry, equal to that required by the universities, and the inclusion of general subjects in the science and engineering curricula; (2) the technical high schools' reputation for excellent teaching; and (3) their achievements in scientific and technical research.

The schools were able, at a very early stage, to meet the charge that they may well produce competent engineers but not truly educated university men (Akademiker).

The insistence upon a broadly based approach to the studies of scientific disciplines had its roots in the new modern schools (*Realschulen*) which sprang up in Germany during the eighteenth century, in response to the demands of a new experimental and industrial age. These schools offered a challenge to the older type of grammar schools (*Gymnasium*) which until then had been regarded as the only source of a true education and the sole preparation for the universities and a professional career. Now these new schools replaced the classics by more mathematics, physics and chemistry, practical laboratory work, and courses in modern languages. A little later a compromise type, the *Realgymnasium*, developed which retained Latin at the expense of one foreign language. Against widespread prejudice, these new schools soon built up a solid name for themselves by attracting enthusiastic science teachers from the universities and from industry. Moreover, the *Realschulen* took over, unchanged, the whole range of general subjects such as literature, history, music, etc., which were offered at the grammar schools, and the examinations, too, were fixed at the same high level. In this way the modern school ensured the same opportunities for its pupils when entering a university. Since the boys (and later also girls) usually elected to read scientific subjects, their lack of classical languages was no obstacle. Some faculties demanded that they should take a course in Latin during their first year.

Simultaneously with these modern schools, and prompted by the same new outlook in science and industry, there developed the early trade or technical schools in many German cities, notably in Berlin. These served, in the first place, the needs of special skills and industries, but soon expanded to include other 'useful' subjects of commercial and also general nature. These technical schools drew, from industry and the Civil Service in each German State, enthusiastic and progressively minded teachers, and they received generous endowments from civic or noble patrons. Within a short time they were raised in status and changed their names to academies, in tune with their function and importance. This elevation brought about the fixture of a later age at entry (seventeen years) and a higher scale of examination requirements, both for diplomas and trade certificates.

Barely fifty years later, these widely expanded and developed institutions received their foundation charters and became university centres of science and technology—the technical high schools of to-day.

Braunschweig, although an older ducal foundation (1745), shared the same development with the other institutions of its kind, such as Karlsruhe (1825), Munich (1827), Dresden (1828), Stuttgart (1829) and Darmstadt (1836). Aachen, the largest to-day, was the first technical high school to be created as a university directly, in 1870.

The most powerful stimulus in all these foundations was given by the example of two Austrian imperial institutes—the Polytechnic of Prague (1806)* and the Polytechnical Institute of Vienna (1815), which became the Technische Hochschule soon afterwards. The immediate success of the latter, in particular, found ready imitators in the German centres, and this eager emulation explains the very rapid succession of the academies or polytechnics in Germany. The Austrian institutes had been created on the pattern of the famous École Polytechnique of Paris, a former military training college, then the leading school of technology in Europe.

The Austrian polytechnics were from the start distinguished by certain rights and privileges usually granted only to universities: the freedom of teaching and learning, the right to confer degrees, and generous endowments for research and expansion. Prague and Vienna opened with courses leading to high-level engineering diplomas and degrees. The school in Vienna had a very strong influence on the trends in Germany, and Hanover even appointed a professor from Vienna as its first principal, and he took from his own institution the broad teaching aims, "to promote industrial skills by the application of scientifically based instruction". The full extent of this impact can best be gathered from the pattern of the four-year courses in Hanover which in many ways resemble the undergraduate courses in science, especially engineering, at British universities. We can discern a broadly introductory year, while the second, still chiefly devoted to principal subjects, also includes courses in economic geography, management and modern languages, all "being useful to the engineer". The last two years of the course show a gradual approach to higher specialization, markedly in the applied sciences.

The fame and success of the new foundation at Hanover may be gathered from the fact that when it was raised to a technical high school (1879–80), the enrolment of students from Great Britain alone was 2 per cent of the total number, and higher from other countries. Comparable international standing was soon gained by the other German academies or polytechnics, and along with their fame as centres of teaching grew their reputation for their research achievements.

This is particularly true for the first years after their elevation to university rank, and this in turn helped to attract eminent scientists to their staffs. The granting of charters was in all cases merely an outward recognition of those which had, in fact, already become full university centres, working as yet without the academic titles and offices. The scientific contribution of the technical high schools may perhaps be illustrated by a reference to the German share in the Nobel Prizes for physics and chemistry, above all the latter, in which German scientists, among them many professors at technical high schools, gained the greatest numbers of the award (twenty), compared with Britain's eleven (total awards, forty-nine). These figures are the more impressive if we remember that under Hitler scientists were forbidden to accept the Nobel Prize and that the Prize is not awarded for work in applied fields, the very disciplines in which the contribution of technologists in technical high schools (or trained in them) has been outstanding.

---

* Some five hundred years earlier, also at Prague and on the pattern of Paris, the first German university had been founded.

During the first chaotic years after the Second World War the schools lost a good deal of ground, but the past five years have seen a remarkable recovery in all fields of research, as the premises and physical conditions permitted the resumption of normal work.

The high standards of work and research led at a very early stage to a close link with local industries. The professors and assistants act as consultants in their special fields, and this close contact with industry has been a direct boon and incentive to the students of each department. The technical high schools have also for years conducted industrial apprentice schemes for vacation work and employment after graduation, and often arrange for engineering students to acquire practical experience for a minimum of six months, before commencing their studies.

The success of the technical high schools, while they were still academies, was so evident and rapid that similar colleges were set up on the same lines, serving higher education in commerce, economics, journalism, etc. Like the technical high schools, these new colleges added whole faculties of humanities which became organic members of the life in a technical high school. These faculties had developed from small departments in the academies and technical schools. In the course of the educational reforms in German universities (1948–51), the faculties of humanities assumed the responsibility for the programmes of the Studium Generale, thus carrying out their original function under a newly revived name.

In the Studium Generale, the faculties of humanities or, as they are sometimes called, of general subjects, offer annually a choice of lecture courses or individual lectures and discussion groups on a wide range of subjects. Artistic and musical activities and pursuits, which in Britain one may expect to find within a guild of undergraduates, are also part of the Studium Generale, and may be subsidized by the special funds set aside by the Ministries of Education for these broader education schemes in universities and technical high schools. Every week or month, a special Dies Academicus is reserved for major lectures on principal university themes. They are usually opened by the Rektor, a dean or a prominent visitor from outside. The discussion groups take up and develop in smaller circles under informal conditions the subjects touched on in the main speeches. The Dies Academicus usually concludes with dramatic or musical performances by the appropriate group, and prizes are given for the best presentations.

One of the most important results of the Studium Generale especially noticeable in the technical high schools is a new and close contact between students and teachers, particularly the younger lecturers. The fact that a selected set of lectures and other events are compulsory for the first year or two years has not appreciably affected the growth of this contact. Both sides greatly enjoy smaller informal gatherings. The gradual creation of more and more residential facilities enhances this development, especially where the warden is an enthusiastic professor or lecturer, as I found in the students' houses at Karlsruhe and the International Students' Village at Aachen, both attached to the technical high schools in those cities. Other forms of residence are large blocks of flats at Munich or Stuttgart. The small students' discussion groups or informal gatherings often take place in the common rooms at late hours. Residence is greatly coveted by all students and the facilities, still rather limited, are divided in equal parts between German and foreign students. Although these students' halls have done much to bring about personal contacts between students and staffs, the old tradition of aloofness has not quite died out. The residents of one hostel complained that their open invitation to Sunday coffee and cake (dinner in hall is not a social focus in German residences) had not been accepted by a single professor or his family ever since the hostel was opened two years before.

On the other hand, the personal concern of the teachers in the technical high schools and their friendship with the rank and file of the students were clearly in evidence everywhere, even, too, where I heard the complaint. In general, students' reactions to the provisions of liberal education in the Studium Generale were extremely favourable and nobody ever criticized the level of the lectures as too high or the element of compulsion.

One grievance voiced in several technical high schools was that there is a tendency to place Studium Generale events in the later afternoons and evenings, mainly 5–7, that is, after a full day's lectures and laboratory hours. This unfavourable time must be chiefly responsible for the small average attendance of 35 per cent, while the Dies Academicus invariably shows more than 75 per cent of the students attending. The considerable number of fully employed students (*Werkstudenten*), however, make up a good proportion of the 35 per cent mentioned above and of any discussion groups, where attendances are very much higher. Where these are held in a residence, they are open also to students from outside, and many *Werkstudenten* come to them.

The Dies Academicus owes its success largely to the fact that all departmental lectures are cancelled on this day. Civic and 'Land' theatres and opera houses have always been in the habit of admitting students at very low charge, and the organizers of the Studium Generale, linking on to this old tradition, encourage and arrange visits and introductory lectures for any events of an artistic nature in the city concerned. Also excursions to nearby centres, galleries or theatre and music festivals are provided under the Studium Generale and subsidized by its special funds.

Modern language courses have always been provided in the technical institutions and are open to all students, and study groups sometimes wish to go abroad with their tutors. The latter, however, are only part-time members of the technical high school staffs and cannot organize such tours as, for example, are held every spring for science students and others at Birmingham. The German students, especially of engineering, make use of every opportunity of visiting countries abroad for practical and language experience, and eagerly enlist for exchange or harvest schemes, etc.

In conclusion, it can be said that the technical high schools in Germany are to-day as active as ever, expanding their premises and programmes and making up successfully for the long eclipse in their history, the years under Hitler and immediately after the War. They certainly make striking provisions for the non-vocational education of their alumni and are concerned with their students' welfare to an extent formerly unknown.

However much a technical high school may reflect the local special demands of the regional industries, such as the Ruhr industries at Aachen or the chemical firms at the Rhineland schools or at Hanover, the technical high schools have never permitted, it seems, the wider aspects of their educational function to be forgotten. In their programmes of broader education they give prominence to-day to social and civic issues, particularly with reference to the scientist's and engineer's responsibility in society. Despite signs of reactionary students' clubs of the old type re-emerging, it must be said that the forms taken over from British university systems are all steps in the direction of closer personal contact with the students. The relevant features in this respect are to-day comprehensive students' guilds, in place of the old politically orientated corporations; the encouragement of small tutorials and informal discussions; and the gradual creation of residential facilities.

LUBRICATION AND WEAR

TWENTY years ago the Institution of Mechanical Engineers convened, under the chairmanship of the late Dr. H. J. Gough, an international discussion on "Lubrication and Lubricants" at which more than a hundred papers were contributed from leading authorities throughout the world. The Conference itself and its proceedings, published in two volumes in 1937, marked the first serious recognition of lubrication as a field of both practical and theoretical importance. As a result of the great success of these discussions, the Institution—in conjunction with its American sister organization and other bodies—decided to hold a similar conference on lubrication with the emphasis on wear. An organizing committee was set up under Dr. D. Clayton in 1955, and the results of its efforts were shown in the Conference on Lubrication and Wear held in London during October 1–3. More than one hundred papers were again contributed and delegates from sixteen foreign countries ranging—alphabetically—from Australia to Yugoslavia were present. It was a particularly pleasant opportunity to renew acquaintance with American workers in the field and to make contact with the large and representative Russian delegation. Unfortunately some of their papers did not arrive in time for publication, but they were given ample opportunity to describe their work in the discussion periods. Most of the sessions were held in the magnificent circular conference room at Church House and a pastel October sun, sustained throughout the Conference, brought out the grace and dignity of the surrounding buildings. Across the bend in the river the glittering dome of St. Paul's looked no less impressive than it did to Wordsworth.

The Conference proceedings were very much down to earth and were extremely efficiently—if somewhat severely—organized. Each section was preceded by a review of the main papers and there was widespread admiration for the effective way in which this was done.

Hydrodynamic lubrication. Perhaps the most striking impression of the papers covered in this field is the extent to which new work often containing important innovations continues to emerge. Even in the subject of journal bearings where, as Prof. D. G. Christopherson (Imperial College of Science and Technology, London) pointed out in his review article, one would have thought that after seventy years the subject would have been fully explored, the papers at the Conference provided ample evidence that this was not so. Many of the new problems have arisen or become more discernible as a result of the increasing tendency to impose higher speeds and loads on bearings: or if they were hinted at briefly in the discussion in 1937, they have received fuller and more critical analysis. Thus it is now clear that the earlier classical theories of hydrodynamic lubrication are no longer strictly valid, as is shown by some recent studies of cavitation in the hydrodynamic film in the regions of low pressure. To some extent the detailed behaviour may also be complicated by the wettability of the surfaces by the lubricant. For example, it has been found that the friction on a bearing operating in the fully hydrodynamic region may be reduced by 20 per cent by coating the surface with an oleophobic layer. Again, the temperature developed in the oil film has now been explored and it seems, surprisingly, as if the temperature around the circumference is almost uniform. This is often aided by turbulent flow in the film at very high speeds. Thus the bearing may be considered to behave as a 'mixer' containing a heat-source to which a stream of cool oil is being added and from which an equal stream of oil at the mixer temperature is being withdrawn. This provides a useful empirical simplification which facilitates bearing design: here a new feature has emerged since 1937, namely, the use of electronic computers. So far as general design is concerned it is interesting to see the general change in bearing dimensions that have become accepted in high-speed operations. The short axial length of modern bearings is a new development that has many practical advantages. Another development of increasing importance is the use of air as a lubricant in high-speed hydrodynamic bearings.

A serious practical problem dealt with in a review article by B. L. Newkirk of Schenectady is that of journal-bearing instability, such as shaft-whipping and oil-whirl. Here a beneficial modification in the structure of the main moving elements is not always possible and in many cases the troubles may be overcome by some special feature of the bearing design. It is possible that more use might be made in future of the quasi-elastic and damping capacity of the oil film itself. This leads to one of the more important ideas that has emerged in the past twenty years of hydrodynamic studies. Twenty years ago it seemed fairly safe to say that under certain extreme conditions hydrodynamic lubrication was not possible, and that only boundary sliding or even that metal/metal contact must occur. It now seems that the hydrodynamic region extends very much further than was then considered likely. As Prof. H. Blok pointed out in his review paper, this type of 'marginal' hydrodynamic lubrication is largely due to the elastic deformation occurring at and around the contact regions. This makes it possible for hydrodynamic conditions to be carried over into a region where the lubricant film is extremely thin. Coupled with this new approach is the realization that it is no longer possible to treat the lubricant oil—even when it consists of a relatively pure single constituent—as a simple Newtonian fluid. The viscosity of the lubricant is affected by the temperature, by the rate of shear and by the pressure itself. These changes are not instantaneous, and the effect of pressure, for example, on viscosity and on density involves a relaxation time that may be of importance in high-speed sliding mechanisms. More basic work in this field is required and no doubt will be forthcoming in the near future. It would certainly seem that the next few years are likely to see further applications involving very thin-film 'marginal' hydrodynamic lubrication.

Friction and boundary lubrication. In this session it was apparent that great advances have been made since the discussion in 1937, not only in fundamental ideas but also in experimental techniques. In particular, as Dr. F. P. Bowden pointed out in his review paper on the friction of solids, electron microscopy has made it possible to examine the surface damage produced during sliding in very great detail, and recent experiments by Menter and others have even revealed the molecular array and dislocations present in crystalline solids. Whereas in 1937 there was little detailed understanding of the nature of contact between rubbing surfaces, it is now generally accepted that the real area of contact is usually a very minute fraction of the apparent geometrical area and that it is the detailed behaviour at these regions that determines the overall frictional properties of the solids. There is now a large body of evidence to suggest that the friction of metals is due in large measure to local adhesions. In addition, there may be appreciable ploughing of grooves in one surface by the other, so that there will be an additional ploughing term which must be considered. For unlubricated surfaces this is generally small and the main part of the friction arises from the shearing of the adhering junctions. A similar mechanism holds for non-metals, although in this case the deformation or ploughing term may be more important. This is particularly marked in the presence of surface films which can reduce the adhesion term, so that the work of deforming the surfaces may dominate the frictional behaviour. With elastic materials such as rubber the friction during lubricated sliding is largely due to elastic hysteresis losses in the rubber itself. Indeed, one of the new points that has recently emerged is the more general importance of elastic hysteresis losses in the friction and fatigue of sliding and rolling solids. Perhaps the most surprising feature is the extent to which a relatively simple physical picture can explain the frictional behaviour of solids as diverse as metals, diamond, rubber and wood.

Papers in this session included a number of detailed studies of the formation, deformation and subsequent breaking of the contact regions, their number, size and distribution, the extent of the adhesion at the interface, the effect of tangential displacements before macroscopic sliding occurs and the factors determining the occurrence of intermittent or 'stick-slip' motion. Experiments with large-scale model friction-junctions were described which suggested how wear fragments might be produced during sliding. A new point of considerable interest was raised in a paper dealing with friction at extremely high sliding speeds—up to 2,000 ft./sec. The friction falls to a very low value due to melting of the surface layers by frictional heating. With some metals at very high speeds there is not sufficient time for plastic deformation to be propagated through the asperities. They behave in a brittle fashion and surface disintegration occurs. It would seem that the mechanism of friction and wear may be greatly modified at these extremely high speeds.

Boundary lubrication was not dealt with specifically in 1937 and in the present Conference most of the papers in this section dealt with the frictional behaviour of lamellar solids such as graphite, molybdenum disulphide and boron nitride. The gap was well bridged by Dr. C. B. Davies's review paper. He showed that the primary purpose of a boundary film is to reduce the amount of metallic welding across the sliding interface. To be most effective the film should be a solid of low shear strength and high resistance to penetration: and it should not be readily fluxed away by frictional heating because of melting, desorption, decomposition or oxidation. Fatty acids are most effective because of their ability to form metallic soaps at the surface, but these are melted or desorbed at temperatures above about 200° C. Sodium soaps (or, in special applications, the addition of fillers) may extend the temperature-range, but in general for extreme temperatures other types of lubricant films must be used. The most common are the metal sulphides or chlorides formed by adding to the lubricant small quantities of compounds containing labile sulphur or chlorine. For still more extreme conditions films of lamellar solids are now being used, though here the basic technological difficulty appears to be that of obtaining good bonding to the surface. There is evidence that in some cases the metal oxide film is an important partner in the action of these and other boundary materials.

Bearings, ball bearings, and internal combustion engines. There were forty papers covering a rather wide range of miscellaneous problems on lubrication and wear, and these were dealt with in three sessions. Mr. P. P. Love reviewed papers dealing mainly with bearing materials, and pointed out that for medium-duty purposes no bearing alloy has been developed that is significantly better than the Babbitt metal patented in 1839. However, our understanding of the action of these and similar bearing materials has considerably advanced. Important factors are a relatively low melting point and a relatively low shear strength as well as resistance to corrosion and fatigue. It is also desirable that there should be an intrinsic anti-weld tendency between the bearing and the shaft, and here mutual solubility may play an important part. In recent years new bearing materials have been developed partly as a result of special bearing problems in the field of nuclear energy. Many of these can operate in the absence of liquid lubricants. They include bronzes and other hard materials impregnated with graphite, molybdenum disulphide and polytetrafluoroethylene; and plastics containing a variety of fillers. Surface treatments may be very effective either in the running-in process or even over more extended periods. The most widely discussed were surface treatments involving the use of lamellar solids. There was no paper dealing with the 'Sulf-Inuz' process for which astonishing claims have been made, but an interesting account was given of the action of phosphate coatings, which apparently function by enabling the high-spots to be removed safely during running in.

In the field of ball and roller bearings it was depressing to note how little fundamental research had been published by the bearing manufacturers themselves. As Mr. L. F. Hall pointed out in his review, most of the work has been carried out by national research organizations and by the larger engineering companies. The detailed behaviour of rolling elements in practice is still the subject of discussion: it is clear that at high speeds and low loads in the presence of oil lubricants they often operate under hydrodynamic conditions. In the presence of greases there is evidence that only a very small quantity adheres to the surface and that the bulk of the grease collects outside the the running parts in a state of complete immobility. This conclusion runs counter to the generally accepted view of grease lubrication. On the other hand there is now a better understanding of the factors involved in low-speed rolling, and for the first time there appears to be a sound analytical and experimental study available of the rolling and slipping of balls under elastic stresses. The mechanism of fatigue failure and pitting is still not fully understood and it seems that there is no single cause to which it can be attributed. Interesting problems arise in the lubrication of ball and roller bearings at very high temperatures in gas turbines. Many of these are concerned with corrosion and fatigue produced by the hot oxidizing atmosphere. It is a pity that no reference was made in this session to the promising results obtained by Cattaneo and his collaborators in the United States; they found that small quantities of sulphur in a reducing atmosphere can provide very effective high-temperature lubrication in the bearings of a running turbine.

Gear lubrication attracted attention from only a small number of contributors working directly with gears or with simulating mechanisms. This is a field in which there is still some difference of opinion as to whether hydrodynamic or boundary conditions prevail. This subject and the mechanisms of scuffing both merit further study.

A parallel session discussed the lubrication of internal combustion engines, the use of additives and other miscellaneous applications. It is now generally agreed that reducing the oil viscosity improves the performance of internal combustion engines, but there is clearly a limit to this. When corrosive wear in an engine is important, it may be markedly reduced by increasing the alkalinity of the oil above a certain critical value. A development that could not have been envisaged in 1937 is the effect of nuclear radiation on lubricants. Apart from the danger of developing radioactivity if the oil contains sulphur additives, there is the general chemical deterioration which occurs. In his review Mr. J. G. Withers observed that although aromatics appear to be more stable to irradiation than other types of lubricants, this is not true of their thermal stability. Consequently, in assessing the viability of a lubricant the effect of both temperature and irradiation must be considered and more work in this field is required. Another contemporary problem is the lubrication of nuclear reactors in which liquid sodium is used as a heat-transfer medium. Surfaces which rub under such a medium often suffer excessive wear or fatigue, and little is known in detail of the way in which this occurs or how it can be overcome.

A novel observation in machining investigations is that an electrical potential which opposes the thermal electromotive force developed during machining can increase the life of a tool two- or three-fold, an effect which is attributed to a suppression of the oxidation process. However, this is very recent work and more detailed study is needed.

Wear. A full day was devoted to a discussion of wear, and almost forty papers were summarized in a comprehensive review by Dr. F. T. Barwell. Here again there are new techniques available which shed considerable light on a number of aspects of wear that were obscure twenty years ago. These methods include oblique or taper sections for examining subsurface damage and metallurgical changes, high-resolution interferometry for studying surface contours, micro-hardness tests for studying work hardening and phase transformations, electron microscopy for examining surface deformation on a fine scale, electron diffraction for studying surface structures and, in particular, radioactive isotopes which provide a beautiful means of studying the transfer and back-transfer processes that occur during wear.

The wear process is, of course, complex and many factors are involved. In some cases it may be purely mechanical, as in cavitation or impact, where failure probably occurs by cracking or by fatigue. It may be largely chemical as in corrosion, or a mixture of abrasive and chemical as in fretting. Probably the most common type of wear is that due to abrasion; the surfaces pluck fragments from one another as a result of strong adhesion at minute local regions of real contact, or hard fragments in one surface scrape or wipe away material from the other. Clearly in both mechanisms surface films can play an enormous part and it is generally true that lubricants are, in fact, used primarily to reduce wear and only secondarily to diminish friction. However, even if the adhesion and abrasion processes are reduced or entirely eliminated, there is another effect due to the continued stressing of subsurface elements during repeated sliding. In some cases this may lead to fatigue and failure even though the surface itself is unworn.

Our understanding of the adhesion and abrasion processes themselves is now much more satisfactory than it was twenty years ago. Radioactive studies show that in some cases the plucked fragments are first oxidized and then wiped away, or they may coalesce and become larger fragments which are fatigued by repeated sliding and then peeled off the surface. Even in the presence of lubricants the basic mechanism is not greatly modified. Unfortunately the gap between such studies and real wear problems is a large and very real one. It consists of three parts. First, in a real machine there are multiple factors which may interact in a manner not foreseen from simple laboratory experiments which can only deal with one or two variables at a time. There appears to be no short-term solution to this. Secondly, there is often a dominant factor in the practical problem which a theoretical study may completely overlook. A typical case is the wear of automobile crankshafts, which is generally caused by metal particles or dirt particles embedded in the bearing material itself. Here the basic frictional properties of the bearing-shaft/lubricant combination are less important than the way in which these alien fragments are trapped and held in the bearing metal. Again, in the lubrication of cutting tools it is often the accessibility of the work to the lubricant that is at least as important as the intrinsic lubricating properties of the machining fluid. Here it would seem that the main onus lies on the technologist who studies the wear as it occurs in practice. The basic research worker can make a direct contribution to practice only if the practical man can indicate with some precision the main causes of failure. Thirdly, there is the general difficulty of assessing in the laboratory the severity of conditions to which a machine may, in practical operation, be subjected. In the discussion at this session it was pointed out, perhaps with some exaggeration, that in everyday affairs those who handle machinery occasionally behave more like gorillas than human beings: and it is during these simian interludes that the crucial damage is usually caused.

The gap between basic studies and practice is thus a large one which is still unbridged. The basic approach has provided many stimulating ideas, and the men of practical affairs have shown a high level of critical perception. What appears to be needed, apart from further efforts in both fields, is closer co-operation between these groups of workers. The Conference on Lubrication and Wear, which brought together engineers, chemists, physicists and metallurgists, should serve as a valuable guide in this direction. All those involved must be grateful to the organizing committee and to the administrative staff of the Institution of Mechanical Engineers for the vast amount of work and organizational skill that went into making the Conference a success.

D. TABOR

NEWS and VIEWS

Sydney Young (1857–1937)

THE youngest son of a prosperous Liverpool merchant, Sydney Young was born at Farnworth, near Widnes, in Lancashire, a century ago on December 29, 1857. He was educated at the Liverpool Royal Institution, at Owens College, Manchester, where he was a student of Sir Henry Roscoe and of Carl Schorlemmer, and at Strasbourg, where he studied under Rudolf Fittig with his life-long friends, Arthur Smithells and J. B. Cohen. He graduated at the University of London in 1880 and in 1882 became lecturer in chemistry under (Sir) William Ramsay at University College, Bristol. The next five years were the most productive in Young's career, for they witnessed his researches with Ramsay into the vapour pressures of solids and liquids and their thermodynamic relations which have become chemical classics. Their work on the critical constants convinced Young of the need for dealing with exceptionally pure substances. In Germany he had become an expert glass-blower, and with the aid of a most efficient 'bubbling still-head' he studied the nature of the lower-boiling fractions of American petroleum. In 1887 he succeeded Ramsay in the chair at Bristol, and in 1903 he became professor of chemistry at Trinity College, Dublin, where, however, his administrative and teaching duties seriously interfered with his experimental work. His most important books were "Fractional Distillation" (1903); "Stoichiometry" (1908, 2nd ed. 1918); and "Distillation, Principles and Processes", written in collaboration with six industrial specialists (1922). His scientific honours included fellowship of the Royal Society in 1893, the presidency of the chemistry section of the British Association in 1904, the vice-presidency of the Chemical Society during 1917–20, and the presidency of the Royal Irish Academy during 1921–26. Young retired in 1928 and died in Bristol after a short illness on April 8, 1937, aged seventy-nine.

Controlled Thermonuclear Reactions

IN the House of Commons on December 10, the Prime Minister said that the progress of work on controlled thermonuclear reactions remained as explained by the Paymaster-General on November 11. Promising results had been obtained with the experimental apparatus ZETA at Harwell, but the interpretation of these would take time. One aspect of the collaboration between Great Britain and the United States in research in this field was the adoption of common rules for the classification of information. If the proposals of a joint United States/United Kingdom Committee for the declassification of certain categories of information now under consideration were accepted, it would be possible to make public more details about work now proceeding in both countries.

Availability of Russian Scientific Literature

THE Parliamentary Secretary to the Ministry of Works, as representing the Lord President of the Council, was again questioned on December 10 regarding the translation of Russian scientific and technical literature, and said that many individual scientists with a knowledge of Russian are employed part-time on this work, and a small number, part-time, in Government scientific and technical research establishments. Government departments also use, on a contract basis, panels of translators outside the Government services. It is hoped to improve the availability of English translations of Russian literature. Mr. Nicholls then added a somewhat surprising remark to the effect that the aim should be to encourage more scientists to learn to read Russian. While no doubt a working knowledge of Russian, such as most scientists have of French and German, would be useful, this would not enable them to dispense with the services of specialist translators. Asked about the appointment of a scientist of scientific standing as scientific attaché in Moscow, who in his own right would have access to Russian scientists, thus reducing the delay in making available the latest information about Russian developments, Mr. Nicholls questioned whether any such appointment from Britain would be welcome without voluntary co-operation in the U.S.S.R. Earlier, Mr. Nicholls had stated that the appointment of a scientific attaché in Moscow is again being considered, and that he recognized the importance and urgency of the matter; he added that it is not quite correct to say that the Russians have a scientific attaché in Britain.

International Palæontological Union

THE International Palæontological Union has hitherto functioned as a department of the International Geological Congresses, but at the 1956 Congress in Mexico it was decided to extend its activities, and it is now proposed to publish a directory to the palæontologists of the world. The expanding interests of the Union have necessitated arranging a meeting previous to the next Geological Congress, planned for 1960 in Copenhagen, and the president of the Union (Dr. Maldonado-Koerdell, Mexico City) has decided to call a meeting to coincide with the fifteenth International Congress of Zoology, and the preceding Colloquium on Zoological Nomenclature, to be held in London during July 9–23, 1958. During this session the Union will discuss and adopt a revised constitution, as modified from that first put forward in 1956 at Mexico. All interested palæontologists should write to the secretary for further particulars: Dr. Jean Roger, Service d'Information géologique, B.R.G.G.M., 74 rue de la Fédération, Paris XVe.

Physics in American Schools

THE American Institute of Physics, in collaboration with the American Association of Physics Teachers and the American Physical Society, with the support of the Fund for the Advancement of Education and the National Science Foundation, is embarking on a programme to help improve the quality and quantity of physics taught in American high schools and colleges. This educational plan, which has important implications for the teaching of science in America, has the following objectives: (1) to make a basic course of physics obligatory for every secondary school student; (2) to encourage young qualified people to seek careers in physics; (3) to investigate the possibility of teaching physics to large numbers of students by the use of television and colour films in spite of the great shortage of science teachers; (4) to assess the increasing need for physicists in a technological society and to strengthen physics instruction in high schools and colleges for those not specializing in science. To assist with this work, the American Institute of Physics has added to its staff two visiting professors, namely, Prof. G. O. Gale, on leave from the Physics Department of Grinnell College, Iowa, who is working on the use of television and films in education, and Prof. W. C. Kelly, on leave from the Physics Department of the University of Pittsburgh, who administers a scheme whereby distinguished physicists visit colleges other than their own as guest lecturers.

Journal of Ultra-structure Research

THE *Journal of Ultra-Structure Research* has been introduced as a medium for the publication of work dealing with the organization of biological materials as analysed by means of the electron microscope, X-ray diffraction techniques, X-ray microscopy and polarization, optical and infra-red analyses, etc. Papers dealing with techniques and instruments which are of importance in this field are also accepted. The field covered by the *Journal* extends from the structure of molecules of biological interest to the level of cell and tissue organization at the limit of the range of the optical microscope. Its editors are Fritiof S. Sjöstrand (editor-in-chief) and Arne Engstrom of Stockholm, but in accordance with the present practice of international journals it has a number of eminent scientists on its editorial board, and papers are accepted in French, German or English. This should ensure a high standard of published work. The first issue of the *Journal* contains two articles in French and five in English, describing work with a preponderance of electron microscope studies. Each paper has a summary in the language of the main article: probably such summaries would be of greater value if they were given in three languages. The title *Ultra-Structure Research* is adequate provided one is aware that the problems discussed are biological, but it is a question whether a title indicating the biological character of the papers might not have been an advantage. The editorial office, to which manuscripts should be sent, is in the Department of Anatomy, Karolinska Institute, Stockholm 60, Sweden. The *Journal* (subscription rate for the first volume of four issues is 15 dollars, current first issue, November 1957) is published by the Academic Press, Inc., 111 Fifth Avenue, New York, 3.

Bernice P. Bishop Museum, Honolulu

ANNUAL reports of museums are increasingly departing from the formal types of even a decade ago, and the title "No Ivory Tower" is that adopted by the Bernice P. Bishop Museum for its annual statement for 1956 (Honolulu: Bernice P. Bishop Museum, 1957). An attractive cover in bold colour introduces a report written in a lively and entertaining style. The title emphasizes the present position of museums, for if an ivory tower implies an institution isolated from the community, then Bishop Museum is the direct negation of such an edifice. The very existence of this and other museums depends not on divorcing themselves from the life of our time, but on effective participation in community and world affairs. The goal of the Bishop Museum is to make a continuous contribution to knowledge by its studies of man and Nature in the fields of science and history. The whole report amplifies this basic idea in the realms of exhibition, guide service, relationship with other educational institutions, research, public relations and reserve collections. An eminently worth-while activity is the circulation to neighbouring centres of cases under the general title of "Museums in Miniature". The report is well illustrated, and soaring attendance figures—doubled since 1952—are a measure of the vitality of this well-known museum.

The Cave of Niah, Borneo

FROM the prehistorian's point of view there is nearly everything to learn about south-east Asia. Of course, the work of Dubois and of Movius must not be forgotten, nor must that undertaken by the authorities of the Raffles Museum. But even so, our knowledge is woefully slight, especially as regards cave sites. I. Evans collected a few stone tools from a cave, and recently the Sievekings have explored a possibly mesolithic cave site near Penang; but otherwise all is still a blank, particularly so as regards Borneo before the time when the island apparently became a factory for certain types of beads, some of which seem to have reached even the shores of eastern Africa. The illustrated article by Tom Harrisson which appears in *Man* of November 1957 will therefore be very welcome. The site, some 800 ft. wide and 200 ft. high, is truly magnificent. But it was only on excavation that industries were discovered. These seem to be of two sorts, those normally found in habitation sites and those occurring in cemeteries. Flaked stone tools and polished axes have been unearthed as well as pottery. According to carbon-14 dating, it would seem that the earlier levels must go back in time into the palæolithic period. But this method of dating is only reliable when all the relevant factors are known. As we are dealing with a new region, it might be wiser to wait until a number of levels at various sites have been tested. Tom Harrisson's explorations will doubtless be continued, and it is probable that very important discoveries will be made.

Cleansing of Oil-polluted Birds

The Royal Society for the Prevention of Cruelty to Animals has published a most useful pamphlet to help those who wish to help in the cleansing of oil-polluted birds. Whereas, for several decades, many thousands of birds yearly have been victims to oil-polluted sea-water, the oiled swan is a more recent problem. Fortunately, this is a problem which appears to be much more readily soluble than that of the oil-polluted sea-bird. The principal and most harmful primary effects of oiling-up are heat loss due to loss of the heat-retaining air 'jacket' normally enmeshed in the swan's feathers. The pamphlet shows that products with strong irritant solvents like paraffin oil are lethal to birds and must never be used. Correct methods for catching and degreasing are described, as is the way in which the bird can be quickly and humanely killed when the pollution is too severe for recovery. The information in this pamphlet should be widely known. It may be obtained from the R.S.P.C.A., 105 Jermyn Street, London, S.W.1. Price 6*d*.

Leaf Shape, Nutrition and Temperature

E. Njoku has described experiments in which plants of *Ipomoea* were grown at high night temperature and at higher nutrient-levels, with observation of leaf shape and rate of formation (*New Phytol.*, 56, 154; 1957). On a node-by-node comparison, the treated plants yielded less deeply lobed leaves than did the controls. Of the three mineral elements tested, nitrogen had the greatest main effect, while phosphorus and potassium had smaller but significant effects. The potassium–phosphorus interaction was unique in increasing rather than decreasing leaf lobing. In all the experiments, changes in leaf shape were highly correlated negatively with changes in the rate of leaf production ($r = -0{\cdot}994$). It is suggested that the effects of high night temperature and mineral nutrition on leaf shape are exerted through their effects on the rate of leaf production. The results are discussed with reference to theories which have been put forward to explain heteroblastic development.

Geochemical Prospecting for Ores

In recent years much attention has been given to the development of geochemical methods of prospecting for mineral deposits, since in country covered by surface detritus these techniques sometimes provide a means of discovering ore occurrences that are otherwise masked from view. Although the literature on this topic is extensive, text-books (other than in Russian) have hitherto been lacking. This need has now been met by a publication entitled "The Principles of Geochemical Prospecting" (Bull. U.S. Geol. Surv., 1957. No. 1000-*F*. Pp. 130. 40 cents), in which Dr. H. E. Hawkes summarizes the results and conclusions of world-wide researches conducted up to March 1954. Geochemical prospecting most commonly comprises the systematic chemical analysis of rock, soil, gossan, glacial drift, vegetation and water, with the view of discovering an 'anomaly' which reflects the presence of ore; and it is rapidly becoming essential for the economic geologist to have an understanding of the principles governing the evolution and distribution of such anomalies. Students will find that Dr. Hawkes's text deals with the fundamental concepts of this subject in a clear and comprehensive manner, with the bare minimum of technical jargon. A companion work is "Geochemical Abstracts" (Bull. U.S. Geol. Surv., 1953–7. No. 1000 *A* and *G*), of which the first part (151 abstracts) covers the period to June 1952 and the second (117 abstracts) from June 1952 to December 1954. It seems likely that this compilation will develop into an annual publication.

Zoological Nomenclature

The International Commission on Zoological Nomenclature gives notice that, as from June 30, 1958, it will start voting on the following cases involving the possible use of its plenary powers for the purpose specified against each entry. Full details of these cases will be published on December 30 in the *Bulletin of Zoological Nomenclature* (13, Double-Part 10/11, and 16, Part 1): (1) *Selene* Lacépède, 1803; *rostrata* Lesueur, 1817 (*Muraena*); *latipinna* Lesueur, 1821 (*Mollienesia*); *fuscus* Storer, 1839 (*Syngnathus*): establishment of precedence of, over other names published in the same work and on the same date (Cl. Pisces); (2) *Monograptus fimbriatus* var. *similis* Elles (G. L.) and Wood (E. M. R.), 1913; *Monograptus triangulatus* var. *major* Elles and Wood, 1913; *Monograptus communis* var. *rostratus* Elles and Wood, 1913: designation of lectotypes for (Cl. Graptolithina); (3) *Calandra* (*Calandra*) Clairville and Schellenberg, 1798, suppression of, in favour of *Sphenophorus* and *Sitophilus*, both of Schoenherr, 1838, respectively, in interests of universality of nomenclature; *abbreviatus* Fabricius, 1787 (*Curculio*) and *oryzae*, emendation to of *oryza* Linnæus, 1763 (*Curculio*), validation of (Cl. Insecta, Order Coleoptera). Comments should be sent as soon as possible in duplicate to Francis Hemming, Secretary to the Commission, 28 Park Village East, Regent's Park, London, N.W.1.

Whitworth Foundation Awards

The following Whitworth Foundation Awards for engineers are to be offered for competition in 1958: (*a*) Whitworth Fellowships, not exceeding three in number, normally tenable for two years, and valued at £500 a year, which may be supplemented by dependants' allowances and allowances for travelling; (*b*) up to six prizes of £50 each to unsuccessful competitors whose work deserves recognition, to be spent on furthering the competitors' engineering education. Candidates must be British and have either an engineering qualification of university degree standard, or a Higher National Diploma or Higher National Certificate in Engineering with at least two distinctions. In exceptional circumstances, a candidate may be in the final year of study leading to one of these qualifications. Each candidate must also have had practical training in engineering totalling 104 weeks. Candidates will be required to write a thesis of 2,000–4,000 words on a subject approved by the Ministry of Education and may be required to sit for a short examination on the basic principles of engineering and to appear for an interview before an examining body. Further details can be obtained from the Ministry of Education.

Oversea Service Division, Colonial Office

The following appointments have recently been made in the Oversea Service Division, Colonial Office: J. Bowden (assistant director of agriculture (research), Ghana), senior entomologist, Uganda; C. E. Johnson (assistant director of agriculture, Northern Rhodesia), deputy director of agriculture, Northern Rhodesia; A. G. K. Will (field officer, agriculture, Uganda), senior field officer, agriculture, Uganda; R. W. Aleong (assistant government chemist, Trinidad), deputy government chemist, Trinidad; E. G. N. Greaves (government chemist, Trinidad), chemist, Medical Department, Hong Kong; A. E. Kerr (deputy government chemist, Trinidad), government chemist, Trinidad; L. A. M. Lloyd (chief instructor, Kingston Technical School, Jamaica), vice-principal, Kingston Technical School, Jamaica; R. W. J. Keay (research officer, Federation of Nigeria), principal research officer, Department of Forest Research, Federation of Nigeria; W. E. M. Logan (deputy chief conservator of forests, Uganda), chief conservator of forests, Uganda; J. A. Channon (meteorologist, East African Meteorological Department), senior meteorologist, East African Meteorological Department; J. E. Richardson (assistant superintendent of Crown Lands and Surveys, Hong Kong), superintendent of Crown Lands and Surveys, Hong Kong; J. R. Knowles (senior veterinary officer, Northern Nigeria), principal veterinary officer, Northern Nigeria; B. E. B. Fagg (surveyor of antiquities, Federation of Nigeria), director, Department of Antiquities, Federation of Nigeria; W. G. Addison, agricultural officer, Western Nigeria; R. F. Allbrook, soil survey officer, Western Nigeria; K. C. Baxter, agricultural engineer, Northern Nigeria; D. B. Roberts, irrigation engineer, Agricultural Department, Northern Nigeria; J. C. M. Trail, livestock improvement officer, Uganda; R. Webster, soil chemist, Northern Rhodesia; W. D. Carslake, assistant conservator of forests, Sierra Leone; E. W. Chapman, assistant conservator of forests, Kenya; J. M. MacKenzie, assistant conservator of forests, Somaliland; T. S. Wormald, assistant conservator of forests, Kenya; F. J. Matheson, geologist, Kenya.

The Night Sky in January

Full moon occurs on Jan. 5d. 20h. 09m. U.T., and new moon on Jan. 19d. 22h. 08m. The following conjunctions with the Moon take place: Jan. 13d. 05m., Jupiter 2° N.; Jan. 16d. 15m., Mars 3° S.; Jan. 16d. 23h., Saturn 2° S. In addition to these conjunctions with the Moon, Mars is in conjunction with Antares on Jan. 4d. 05h., Mars being 4·7° N., and Mars with Saturn on Jan. 23d. 10h., Mars being 1·5° S. Mercury is a morning star, rising rather more than an hour before the Sun, but conditions for observation are unfavourable. Venus is a brilliant object low in the south-west after sunset; it sets at 19h. 05m. and 18h. 55m. on January 1 and 15, respectively. Its stellar magnitude is about − 4; the visible portion of the apparent disk is 0·192 on January 1 and 0·067 on January 15. Venus is too close to the Sun for observation at the end of the month, inferior conjunction being on January 28. Mars rises at 5h. 35m. at the beginning of the month and at 5h. 20m. on January 31; it is visible in the south-east before sunrise. Jupiter rises at 1h. 55m., 1h. 10m. and 0h. 15m. on January 1, 15 and 31 respectively; it is east of Spica. The stellar magnitude of Jupiter is − 1·5, its distance from the Earth on January 15 being 510 million miles. Saturn rises at 6h. 30m., 5h. 45m. and 4h. 50m. at the beginning, middle and end of the month, respectively; it is near θ Ophiuchi, and may be visible low in the south-east before sunrise. It has a stellar magnitude of + 0·8 and a distance of 1,010 million miles from the Earth on January 15. Occultations of stars brighter than magnitude 6 are as follows, observations being made at Greenwich; Jan. 7d. 22h. 32·6m., κ Cnc. (*R*); Jan. 10d. 06h. 45·1 m., 69 Leo. (*R*); Jan. 30d. 22h. 45·5 m., 97 Tau. (*D*). *R* and *D* refer to reappearance and disappearance, respectively. The Quadrantid meteors are active on January 3, but conditions are unfavourable. The Earth is at Perihelion on January 3, its distance from the Sun being 91·4 million miles.

Announcements

The Kalinga Prize for the popularization of science, offered annually by the United Nations Educational, Scientific and Cultural Organization, has been awarded for 1957 to Earl Russell (Bertrand Russell).

A symposium on "The Chemistry of Plastics" will be held on February 14 and 15 at the Bradford Institute of Technology, Great Horton Road, Bradford 1. Further information can be obtained from Dr. W. R. Moore, Chemistry Department, Technical College, Bradford.

A general meeting of the Association of Applied Biologists will be held in the Large Chemistry Lecture Theatre, Imperial College, Imperial Institute Road, South Kensington, London, S.W.7, on January 10. After the formal business of the meeting, there will be a symposium on "The Use of Insecticides for the Control of Virus Diseases". Further information can be obtained from Dr. L. Broadbent, Rothamsted Experimental Station, Harpenden, Herts.

The Medical Research Council Tropical Metabolism Research Unit, University College of the West Indies, Mona, St. Andrew, Jamaica, has a limited stock of dried lanterns from fireflies (*Photinus pallens*), which may be used for measuring adenosine triphosphate by methods described by McElroy *et al.* (McElroy, W. D., and Strehler, B. L., *Arch. Biochem.*, **22**, 420; 1949. Green, A. A., and McElroy, W. D., *Biochim. Biophys. Acta*, **20**, 170; 1956). The Tropical Metabolism Research Unit will supply them at a price of £2 10*s.* a hundred, which covers the expense of collection and includes air-mail postage, to research workers who apply to the address above.

Errata. In the communication entitled "Solution of Mineral Phosphates by Soil Bacteria", by Joan I. Sperber, in *Nature* of November 9, p. 994, par. 3, line 3, for "hydroxyapatite (220 μmgm. P/ml.)" read "hydoxyapatite (220 μgm. P/ml.)"; similarly, in par. 4, lines 4 and 5, in the phrase "1,200 μmgm. lactic acid was sufficient to bring 220 μmgm. phosphorus into solution", the quantities should be 1,200 μgm. and 220 μgm., respectively.

PLANETARY ATMOSPHERES AND CONVECTION IN ROTATING FLUIDS

A SYMPOSIUM on "Planetary Atmospheres and Convection in Rotating Fluids", under the joint auspices of the Royal Meteorological Society and the Royal Astronomical Society, was held in London during May 23–24.

The introductory address was delivered by Sir Harold Jeffreys, who outlined the historical background of the field. He said that two main problems arise, one of them concerned with the large-scale general circulation patterns which can develop in a fluid on a rotating sphere and the other with the onset of convection in fluids. Until the work of Margules (1903) the former problem had been discussed only qualitatively and the theory due to Margules is itself unsatisfactory on account of a wrong boundary condition. Later, Jeffreys (1916) obtained satisfactory agreement in the simplified problem of differential heating of a non-rotating fluid on a plane base and also in the monsoon problem; but the corresponding treatment of the problem of the general circulation of the atmosphere as a type of tidal problem, in which the period becomes infinitely large, produces east winds in all latitudes. This is in direct conflict with the observed fields of mean westerly flow which exist in the upper troposphere in temperate latitudes. Incorporating skin friction into the problem will have the effect of abolishing the relative angular momentum in about ten days in the absence of heat sources. In the general circulation mechanism for the atmosphere, it was pointed out by Jeffreys (1923) that in order to maintain the westerlies in temperate latitudes there must be a transfer of westerly angular momentum from the equatorial regions, which in turn implies a positive correlation between the eastward (u) and northward (v) components of flow and a succession of pressure maxima and minima around a latitude circle. The balance of angular momentum itself can be achieved if the transfer extends to about 10 km. It is thus concluded that cyclones are an integral part of the mechanism of the general circulation.

The second problem concerning the onset of convection began with an experimental paper by Bénard (1900), and the first theoretical paper is due to Rayleigh (1916), who pointed out that the buoyancy forces in a fluid heated from below will be sufficient to overcome the viscous damping forces if a certain non-dimensional number R_a is greater than λ, where λ is a constant of the order of 1,000 and R_a ($= g\alpha\beta h^4/\kappa\nu$) depends upon the constants of gravitational acceleration, g; coefficients of thermal expansion, α; the excess temperature gradient, β; the depth, h; the thermometric conductivity, κ; and ν the kinematic viscosity. The most recent developments in this problem are due to Chandrasekhar (1951 onwards), who has investigated the dependence of λ upon rotation and on magnetic fields. Sir Harold pointed out also the importance of knowing the rotation of the solid body of a planet. If heating takes place at the equator, there must be prevailing westerly winds at great heights, and the motions of spots which may be observed may not tell us the true surface rotation speeds.

Prof. Zdenek Kopal spoke on "The Basic Observational Data on Planetary Atmospheres". Our knowledge of planetary atmospheres, he said, has been derived by both spectroscopic and photometric techniques. The range 3,000–10,000 A. is accessible to optical spectroscopy, and recently radio observations have been made in the 1–20 metre range. Perhaps the most serious difficulty hampering optical spectroscopy is the interference of telluric lines: constituents of the terrestrial atmosphere are relatively hard to detect. The slight shifts due to varying motions of the planets relative to the Earth have to be used for separating the planetary spectrum from the telluric one. Another difficulty is the lack of light from the most distant planets, which restricts us to low dispersions. Observations have been made of the distribution and polarization of the light from the planets as functions of position on the disk and the wave-length used, and the results have to be interpreted by transfer theory, taking into account reflexion at the planetary surface in the case of optically thin atmospheres. The small range of phase angles which can be observed for the outer planets is a major difficulty.

Mercury has a very tenuous atmosphere, not observable spectroscopically, but giving a measurable centre-limb variation of polarization. The mass per unit surface is 0·005 of that above the Earth's surface, but the chemical composition is unknown. Light gases cannot be retained because of the high surface temperature and low surface gravity. Spectra of Venus show the presence of carbon dioxide in considerably greater abundance than in the terrestrial atmosphere. Kuiper has established the variability at different parts of the disk; this is presumably caused by the varying heights of the upper cloud surface. The other atmospheric constituents are unknown; nitrogen is the most probable. The nature of the clouds is unknown: recently the suggestion has been revived that these clouds are water droplets and the lower temperatures now thought to prevail (– 40° to – 50° C.) could account for the absence of water-vapour lines. Carbon dioxide has been found on Mars in amounts comparable with that on the Earth. No other constituent has been identified; one may speculate that nitrogen is present. Methane and ammonia have been observed in Jupiter and methane in Saturn, Uranus and Neptune. Herzberg also detected the hydrogen molecular quadrupole transitions in Uranus and Neptune.

It seems probable that hydrogen and perhaps helium form the bulk of the atmospheres of the four major planets. There are several striking features which are not clearly understood, such as the recently discovered bursts of radio emission from Venus, the radioactivity localized in the spots of Jupiter, the presence of latitudinal bands not in solid rotation in the Jovian atmosphere, and their absence on Saturn, while the great strength of the methane bands in Uranus and Neptune cannot be explained solely on the basis of low temperatures and must be considered an unsolved problem.

Prof. P. A. Sheppard read a paper on "The General Circulation of the Earth's Atmosphere". In discussing the general circulation of the Earth's atmosphere, it is necessary to consider two different aspects of the motion; first of all the time-averaged mean flow patterns ($\overline{U}$, $\overline{V}$, $\overline{W}$) and the turbulent field (u', v', w'), which is the departure of the motion from its mean. The mean motion ($\overline{U}$, $\overline{V}$, $\overline{W}$) is now well observed up to about 50 mb., the zonal mean motion $\overline{U}$ (measured positive to E.) consisting of easterlies in a zone about ± 30° of the equator, a weak easterly circulation near the poles and westerlies elsewhere. The mean meridional motion $\overline{V}$ (measured positive to N.) is more difficult to assess since $v'/\overline{V}$ is large and the two most reliable sources are Mintz and Tucker. Mintz determines $\overline{V}$ in the northern hemisphere from the angular momentum budget for an atmospheric ring, assuming that the mean transfer of westerly momentum in the downward direction is zero at and above 700 mb., and $\overline{W} = 0$ at 200 mb., and determines the vertical velocity $\overline{W}$ from the continuity equation. This shows that there should be a direct cell (ascent at southern end) from 5° S. to 30° N. in winter with $\overline{V} \sim 100$ cm./sec., $\overline{W} \sim 0{\cdot}2$ cm./sec., and an indirect cell from 30° N. to 70° N. in which $\overline{V} \sim 50$ cm./sec., $\overline{W} \sim 0{\cdot}1$ cm./sec. These move approximately 10° northwards in the summer season. Tucker's independent investigations using actual wind observations instead of geostrophic winds (Mintz) reveal a similar meridional cell structure, but the cells themselves are a good deal stronger. The longitudinal variation of $\overline{U}$ reveals the interesting feature that the 500-mb. streamlines are quasi-horizontal waves with troughs and wind-speed maxima over the east of continents and over the Middle East; it is a matter of conjecture whether this is influenced most by the presence of mountains or by the land/sea configuration. There is also a longitudinal variation of $\overline{V}$, and it is clear here that there exists a standing-wave pattern at 50°–55° N., for example, in the winter $\overline{V}$ is positive from 160° to 120° W., negative from 120° to 50° W. and positive again from 50° W. to 20° E.

Prof. Sheppard also pointed out the existence of an upper-air monsoon type of flow over Aden. The total kinetic energy of the atmosphere plotted against latitude reveals a pronounced maximum at about 30° N. and the kinetic energy of the turbulent motion gives a similar type of curve, the ratio of these two quantities in most latitudes being approximately $\frac{1}{2}$ to $\frac{1}{3}$. The question of how much energy resides in different wave-lengths and how this energy is transferred is still difficult to answer, since systematized information is very scanty. Henry and Hiss have attempted to do this using geostrophic winds for January 1951, but the direction of energy conversion is not clear; it would appear, however, that the greater part of the energy resides in the lower wave numbers.

In the concluding address of the first morning session, [the late] Prof. H. U. Sverdrup discussed "The Circulation of the Oceans". He pointed out that, with a few minor exceptions, the currents of the upper layers of the oceans appear to be maintained by the stress which the prevailing winds exert on the sea surface. Qualitative agreement has been obtained between the ocean currents as computed from the observed distribution of mass and as computed from the wind stress, but the mechanism by which such a current as the Gulf Stream is maintained is not clear. In the case of the equatorial counter-current, which flows in the opposite sense to the mean wind, the direction of flow is consistent, as elsewhere, with the geostrophic equation, the vorticity equation and the vanishing of the horizontal divergence. In the case of the Gulf Stream, however, a westward intensification of currents can be expected if horizontal friction terms are retained in the vorticity equation following Stommel, although Charney's discussion of the same problem, which retains the inertia terms instead of the frictional terms, also leads to an intense current on eastern coasts. An appreciable deep-water circulation is found in the Atlantic Ocean only; this circulation is generally described as a thermal, implying that it is maintained by heat being converted into kinetic energy; but this circulation may also be wind-driven in the sense that the prevailing wind carries upper water to the north across the equator off the coast of South America, so that deep water must flow south. In the northern hemisphere, the ocean currents carry considerable quantities of heat from lower to higher latitudes, particularly south of 30°. This heat is conveyed into the atmosphere by evaporation off the east coasts of the continents. Generally speaking, northward flows give off energy to the atmosphere, while southward flows give energy to the sea. The interaction which exists between the atmosphere and the ocean implies that it will be necessary ultimately to deal with the circulation of the combined system of atmosphere plus ocean.

The first afternoon session opened with a paper by Prof. E. Lorenz on "The Circulation of the Atmospheres of the Outer Planets". The planets Jupiter, Saturn, Uranus and Neptune have in common great distance from the Sun, great size and rapid rotation, by comparison with the Earth. Details observable on Jupiter include alternating dark belts and bright zones, irregularly distributed dark and bright spots which move relative to each other, systematic variations of rotation speed with latitude, particularly the 'equatorial acceleration', and a large semi-permanent marking, the Great Red Spot. Belts and zones have also been observed on Saturn and occasionally on Uranus, and spots have been observed on Saturn.

From the thermal wind approximation, a relation between the vertical wind shear and the horizontal temperature gradient, which applies when the horizontal forces and the vertical forces are each nearly in equilibrium, and from the presence of the equatorial acceleration, it is deduced that Jupiter's visible surface lies far above the surface of any solid core, so that only the upper atmosphere of Jupiter is directly observed.

A planetary atmosphere is a special case of a rotating symmetrically heated fluid. Current studies of such fluids suggest explanations for some of the observed features of Jupiter. Experimental studies indicate that symmetrical flow will not be observed if the Rossby number, the ratio of a typical relative angular velocity to a typical absolute angular velocity, lies below a critical value. The scale of the asymmetrical disturbances decreases as the Rossby number decreases. Theoretical studies indicate that any mathematically possible steady symmetrical flow will be unstable if the Rossby number is subcritical, and that the wave number of the most rapidly growing disturbance increases as the Rossby number decreases. These results, if applicable to Jupiter's atmosphere, imply that the flow should be asymmetrical and that the disturbances should be smaller than those on the Earth, relative to the planet's radius. The dark and bright spots on Jupiter have the proper size for such disturbances.

Experiments indicate that sharp transition zones, such as jet streams and fronts, will form at sub-critical Rossby numbers, but theoretical studies to date show only that they may form. The equatorial acceleration of Jupiter bears a superficial resemblance to the Earth's jet streams. A decision as to whether these features are similar phenomena awaits further theoretical work. No permanent feature resembling the Red Spot has appeared in the experimental studies of symmetrically heated fluids, and it is suggested that the spot is caused by some asymmetry, possibly by a feature of Jupiter's solid core.

Dr. G. B. Tucker presented a paper on "Transfer Processes in Planetary Atmospheres". He discussed in detail the transfer of angular momentum mentioned by Sir Harold Jeffreys in his introductory address, and in addition he considered the transfer of water vapour and energy for the Earth's atmosphere. Each of these quantities shows the same conservative feature of a net input into the atmosphere in low latitudes, and a net output in high latitudes with a transfer from low to high latitudes. The flux of any such quantity α across a latitudinal surface has been split up into two parts by Tucker, an advective flux $\bar{\alpha}\bar{V}$ and an eddy flux $\overline{\alpha' v'}$, where α' and v' denote the departures of α and v (the equator-pole velocity component) from the mean values $\bar{\alpha}$ and $\bar{V}$ respectively.

In the case of the angular momentum flux in the northern hemisphere, Tucker's results, which have been obtained from actual and not geostrophic winds, confirm those of earlier workers in indicating a maximum northward flux of angular momentum at 30° N. at about 200 mb. with little horizontal transfer anywhere below 500 mb. and with the major part of the flux arising from the eddy flux term. The calculations of the mean field of velocity $\bar{V}$ in a meridional plane indicate a direct equatorial cell, although there is uncertainty at present concerning the importance of this cell in the mechanism of angular momentum. An independent assessment has been made by Tucker of the transfer of angular momentum from estimates of surface and mountain torques, and the consistency of results from several sources—Priestley, Starr and White, and Mintz—has been verified. Mention was also made of recent analyses of turbulence spectra, which reveal the importance of eddies on the scale of depressions and anticyclones in the transfer of enthalpy and angular momentum.

Dr. Raymond Hide followed with a paper on "Experiments on Convection in Rotating Fluids". He indicated that two main types of experiment have been performed: those in which a shallow layer of fluid is subject to heating from below or cooling from above (type A), and those in which the differential heating is imposed in the horizontal. In the former, as mentioned earlier by Sir Harold Jeffreys, when the adverse density gradient exceeds a certain value a cellular convective type of flow (Bénard cells) is established, the onset of this motion being dependent upon the Rayleigh number R_a exceeding a constant λ. The constant is of order 1,000 in the case of zero rotation, but increases monotonically with rotation Ω of the system, λ depending upon the Taylor number $T_a = 4\Omega^2h^4/\nu^2$. The most recent theoretical results in this case, due to Chandrasekhar, have been verified experimentally by Nakagawa; the most interesting result of the experiments is that the cells become increasingly elongated with increasing rotation. In the type B, or dishpan type of experiment, the principal experimental work is due to Fultz and Hide, both of whom considered thermal convection in a rotating liquid with a free surface and subject to horizontal differences of temperature. Hide has shown that there are three régimes of flow depending essentially upon the value of one parameter:

$$\theta = 2gh\,(\rho_b - \rho_a)/\Omega^2(b - a)^2\,\rho_{\text{mean}}$$

where b and a are the outer and inner radii of the cylinders bounding the liquid and ρ is the density. When θ exceeds about 1·6, the flow consists of a meridional circulation in which the motion of the liquid on the free upper surface is in the form of inward moving spirals. If θ is somewhat less than 1·6, the flow is characterized by a regular quasi-horizontal wave-like pattern of wave number m. The motion is almost entirely restricted to a narrow meandering 'jet stream'. The wave train drifts steadily in the same sense as that of the flow in the top surface jet while m depends on θ. When θ is reduced steadily from 1·6, m increases slowly until that value of m is reached for which the amplitude of the wave is equal to 0·67 of the wave-length. When θ has less than this value, unsteady wave flow (vacillation) occurs in which the wave pattern swings about a mean horizontal radius as the whole pattern rotates. A. R. Smith is at present examining the effect of changing ν and κ, and his results indicate there is some dependence of the flow characteristics upon the Prandtl number ν/κ. Fultz has made studies of the three-dimensional structure of the flow patterns and has measured the heat flow during vacillation, showing that there is a fluctuation with an amplitude of about 10 per cent of the average value.

Prof. M. J. Lighthill next discussed with much clarity and considerable verve the general theoretical aspects of the problems raised by the speakers who had preceded him.

The first question raised concerned the concept of diffusion. Quantities normally diffuse down their gradients, but several examples had been cited in the symposium in which the direction of the diffusion appears to be up the gradient, or in which diffusion appears to be practically absent although the system is of a type for which experience of other fields of physics would lead us to expect large diffusions. Why is it that the Gulf Stream remains no wider than 100 km. over long stretches of the Atlantic, whereas water jets in water will spread with an included angle of 30°? Similarly, why does the atmospheric jet stream maintain a coherence in spite of the obvious presence of turbulent transfer and observed severe turbulence at its boundaries? Again, it would appear that for many planets, particularly the Earth, the angular velocity of the solid planet does not lie in the middle of the range of angular velocity observed at different latitudes in the other parts of the atmosphere but is approximately equal to the equatorial value; it follows that the lower parts of the atmosphere are constantly exerting a retarding torque on the upper parts, and the problem then arises of how things remain, on the average, stationary. Finally, there is a fourth difficulty of understanding the up-gradient flow of westerly angular momentum in low latitudes.

Dealing with the fourth of these problems, Prof. Lighthill put forward two explanations; the simpler is that this is an apparent difficulty only, since if one chooses a fixed Newtonian system of reference axes, and one accordingly adds to each relative zonal velocity the amount of 470 cos(latitude) m./sec., the change in the frame of reference makes no difference to the mean a.m. flow and with the fixed frame the northward flow of a.m. in low latitudes is now down-gradient for the absolute motion. The third problem of a.m. balance—the balance between the lower and upper atmosphere—can also be looked at in the same way and made consistent. Such an explanation does not require any mean meridional circulations, as has been postulated on different grounds by Starr and White (1953).

The problem why turbulence does not dissipate the Gulf Stream is one where extensive laboratory experiments need to be performed, in which it is necessary to create in the laboratory either a top-surface water jet which is warmer than its surroundings, or the identical problem of a bottom-flowing cold water jet which is cooler than its surroundings. It may be the stable density distribution which is favourable to the jet remaining compact. Finally, from the observation of the non-dissipation of the atmospheric jet stream, it is clear that there are limitations to the action of turbulence in rotating systems with temperature variations; but it is possible that in explaining this enigma some new idea may have to be invoked; the atmospheric jet stream is neither at the top nor the bottom of the atmosphere, and much of the time it is intermediate in temperature between the air on different sides of it. The only hope for clear understanding here, Prof. Lighthill suggests, is for continued laboratory experiments combined with some new kinds of theoretical model aimed at the central object of explaining what are the forces which hold the jet together.

At the third session, on the morning of May 24, Dr. R. M. Goody read a paper on "The Thermal Structure of Mars". Ground temperatures on Mars in summer and winter have been derived by Hess from radiation emission measurements. These agree with what can be expected from insolation and albedo; they show a greater variation with latitude than on the Earth. There are, however, two considerable sources of error in these determinations, due to the opacity of the atmosphere and the fact that the images in the visible and the infra-red do not coincide owing to differential refraction. Recent spectrographic work by Strong and Sinton should eventually eliminate these. The ground pressure is of the order 85 mb., though this is a little uncertain. The vertical temperature distribution depends on the gases present which are radiationally active. Carbon dioxide is the most important such constituent, being considerably more abundant than on the Earth, and it is probably mixed at all levels; it outweighs in its thermal effect the water vapour in the Martian atmosphere. There is no evidence of any direct solar heating, but in the long-wave spectrum of carbon dioxide the narrow but intense 15μ band, with weaker bands near 10μ, will have a dominating influence in establishing the temperature fields and consequent fields of motion. The thermal driving forces arising from carbon dioxide appear to be smaller than the corresponding water vapour forces; but, possibly due to other factors such as small condensation, strong latitudinal contrast and low surface pressure, which act in the opposite direction, the resulting zonal motions on the Earth and Mars appear to be similar.

The overall picture of the atmosphere is of a convective lower layer of height 8·5 km. with a lapse-rate of 3·7° C. per km., and an abrupt change of gradient at this height into a layer where there is radiative equilibrium. Above 135 km., the rate of collision should be so slow that carbon dioxide ceases to be an effective radiator, and consequently we should get here a high-temperature thermosphere. It is possible that there may exist a high-temperature layer between the thermosphere and the ground.

Prof. H. C. Urey presented a paper on "The Escape of Planetary Atmospheres". Two mechanisms are at work, he said, in determining the evolution of a planet's atmosphere; first, there is the possibility that atoms and molecules can escape altogether, a process which is exaggerated the lighter the element, the smaller the planet and the higher the temperature of the gas; secondly, there is the extremely effective activity of the ultra-violet part of sunlight in breaking up the molecules of different substances. In the case of the terrestrial atmosphere, one of the chief uncertainties is the height at which diffusion becomes more important than large-scale mixing processes. This height depends on the temperature in the upper atmosphere, and, assuming that diffusion dominates from 160 km. to the escape layer at 300 km., and that the temperature increases linearly with height to 1,500°, or higher temperatures, at 300 km. or more above the Earth's surface, it is then found that the rate of escape of hydrogen is determined by diffusion and is about 10^7 atoms per sec. per sq. cm.

On this basis, the hydrogen from 20 gm. of water would escape from each square centimetre in $4 \cdot 5 \times 10^9$ years; the same will be true for Venus. The study of the ratio of helium-3 to helium-4 indicates a high temperature at heights of 500 km. above the surface of the Earth. The solid Earth is emitting hydrogen, ammonia, carbon monoxide and methane at unknown rates, and the oxidation of the latter would require the escape of a considerably larger amount of hydrogen than the above calculations would seem to permit. Another difficulty is that we still do not know the full details and history of the photochemical processes in the atmosphere; it is possible that initially planets possessed atmospheres which consisted largely of hydrogen, hydrocarbon compounds—like methane and water—and, on the Earth, following the escape of hydrogen, the oxidation of methane and the breaking up of water, that oxygen and carbon dioxide would ultimately remain with the oxygen serving as a protecting agent for the lower layers. On Venus it appears that carbon dioxide, not oxygen, has accumulated in the atmosphere, though the clouds on Venus are probably composed of water, possibly coloured by carbon compounds; C_3O_2 has been suggested as a possible colouring material. Absorption by carbon dioxide protects the water against photochemical decomposition in the lower atmosphere. The mixing ratio, hydrogen to water, is 150 times that on the Earth, but at no time could there have been rapid escape of hydrogen due to decomposition of water below the tropopause. On Mars the escape layer is 1,400–1,800 km. above the surface, and if water vapour gets above the tropopause it will escape. The rate of escape of oxygen has been computed; results depend strongly on the height to which mixing extends. Carbon dioxide must be dissociated in the high atmosphere and oxygen atoms will escape if the high atmosphere is at 2,000° or higher. Carbon monoxide should react with water to give carbon dioxide and hydrogen, and the latter should escape. In this way a mechanism for the loss of large amounts of water may exist and the planet may once have had extensive oceans.

Dr. R. C. Sutcliffe read a paper on "The Influence of Condensation on Planetary Atmospheres". Dr. Sutcliffe raised the general question of genesis of circulatory flows in the atmosphere, whether the cycle of changes in a particular type of flow belong or not to the evaporation–condensation–precipitation cycle. Ordinary turbulence and the major depressions and anticyclones are called 'dry' in the sense that their genesis is independent of this cycle, whereas showers, thunderstorms, frontal activity, tornadoes and tropical hurricanes are 'wet' mechanisms which are driven by this latent-heat cycle. The main question posed by Dr. Sutcliffe is whether the general circulation of the atmosphere is essentially 'wet' or 'dry' in the above sense. The energy balance of the atmosphere, omitting dynamical and transport terms, has three components: sensible heat input by conduction, radiation balance (solar or terrestrial) and release of latent heat. Taking estimates given by Budyko, it appears that the sensible heat is a gain to the atmosphere in all latitudes (omitting the poles in winter) with little average meridional gradient, and overall radiation balance is a loss in all latitudes, again with little meridional gradient. Latent heat gain, on the other hand, has a very marked meridional variation with a main maximum in low latitudes and a secondary maximum in middle latitudes. The geographical pattern of energy sources and sinks has essentially the same shape as the precipitation pattern, and thus there is a strong presumption that the general circulation characteristics are substantially affected by the water cycle. The evidence from dish-pan experiments is not inconsistent with the present thesis, since it is possible that the jet stream in the experiment is the analogue of the polar front jet stream, but that the sub-tropical jet stream is a characteristic of the atmosphere linked with the direct meridional circulation of low latitudes, which is largely made possible by the water cycle.

A paper by Mr. J. S. Sawyer on "Jet Streams in the Earth's Atmosphere" concluded the morning session. Mr. Sawyer contributed a descriptive account of jet streams in the Earth's atmosphere—these being meandering belts of high-velocity westerly winds in the upper troposphere. They can be conveniently classed into three types: local jet streams, the circumpolar jet stream and the sub-tropical jet stream. Local jet streams arise primarily from the horizontal thermal gradients set up by the advection of warm and cold air around depressions and anticyclones. It is interesting to observe that there is usually ascent on the right, descent on the left and a cross-flow from right to left in such jets of magnitude 8–10 knots. The circumpolar jet stream is a feature of almost all maps of the flow in the upper troposphere, on which it appears as a meandering belt of strong winds around most of the hemisphere. It can be reproduced in the dish-pan experiments of Fultz and Hide, and is probably the result of the rotation of the system, differential heating and surface friction. Eddy motion probably plays a part in establishing it. The sub-tropical jet stream occurs around most of the hemisphere in latitudes 20–30° about the 200-mb. level, and attains wind speeds of more than 100 knots. It is less variable in position than the circumpolar jet and probably arises primarily from the conservation of angular momentum in the upper branch of the meridional Hadley-type cell circulation which exists in low latitudes. Sawyer mentioned that this type of high-velocity jet may be that in the symmetrical solution of the equations of motion on a rotating sphere due to M. H. Rogers.

The final session was opened with a paper by Mr. T. V. Davies on "The Theory of the Experiments on Convection in Rotating Fluids". Mr. Davies first commented upon a remark by Dr. Sutcliffe that the dish-pan experiments cannot reproduce the atmosphere. He pointed out that Starr and Long in 1953 compared the angular momentum transfer in the atmosphere and the experiment, and found similarity not only in the distribution of the transport but also in the mechanism of transfer. One of the principal features of the experiments of Fultz and Hide is that the flow patterns depend on a single parameter, the Rossby number $R_0 = 2\theta$, where θ is Hide's parameter. Kuo and Davies have investigated the stability problem theoretically by the method of small perturbations, and have derived similar results. It follows from the analysis that wave number m is unstable when:

$$(1 + \tfrac{1}{4} R_0)\frac{h}{r_0} R_T^{\frac{1}{2}}\, x_{1m} < 2{\cdot}4$$

where r_0 and h are the radius and depth of the liquid, x_{1m} is the first zero of the Bessel function $J_m(x)$ and $R_T = g\alpha \dfrac{\partial T}{\partial z} \Big/ 4\Omega^2\rho$ is a type of Richardson number. This instability criterion indicates that the m wave can exist if the Rossby number and Richardson number satisfy an inequality. An inequality involving just R_0 alone is obtained if one makes use of a relation connecting R_0 and R_T found independently by Lorenz and Davies, namely:

$$\frac{h}{r_0} R_T = \frac{5}{16}(R_0)^2 \times (\text{Prandtl number})$$

in the case of symmetrical flow. This solution is equivalent to a relation between the vertical and horizontal gradients of temperature in a heated rotating liquid, and making use of it one obtains the instability criterion (for water):

$$x_{1m}\,(1 + \tfrac{1}{4} R_0)\, R_0 < 1{\cdot}6$$

which agrees very well with the experimental results for low wave numbers $m < 5$ but diverges increasingly from them at higher wave numbers, possibly due to the inadequacy of the R_0, R_T relationship. The problem of vacillation mentioned by Hide is a non-linear phenomenon not covered by the above theory.

Dr. J. G. Charney followed with a paper on the "Theory of the General Circulation of the Atmosphere". Dr. Charney emphasized first of all that in trying to attain a complete theory of the general circulation, one must take into account the interaction of the mean zonal field of motion and the eddy departures from the mean, since these are not secondary features of the flow field but primary mechanisms in the energy transfer process. The large-scale eddies owe their origin to an instability of the thermally driven mean flow but, having developed and grown to a limiting size (the perturbation grows until the rate of gain of energy from the potential energy of the mean flow balances the rate of loss of kinetic energy into the mean flow), they then become permanent mechanisms of transfer.

In setting up this problem mathematically, use is made of the quasi-geostrophic approximation for the horizontal flow field, and a two-layer model is used for replacing the continuous three-dimensional field of motion—the interaction between the flow at the two levels being essentially the same as that between two superimposed homogeneous incompressible layers of differing density; this model gives realistic conversions of potential to kinetic energy, but has the disadvantage that the vertical distribution of temperature must be prescribed. The atmosphere is divided into the two layers 0–500 mb. and 500–1,000 mb.; the Rossby-type atmosphere is taken in which the variable Coriolis parameter is essentially a linear function of north–south distance and the heating supplied to a vertical column of this atmosphere obeys radiational laws. This differs from Phillips's recent general circulation solution in which the sources of heating are fixed.

The method of solution breaks down into the following steps: the steady-state wind and temperature distribution are calculated, assuming axial symmetry and the quasi-geostrophic approximation arising from solar heating; it is observed that this circular vortex is unstable. By means of first-order perturbation theory, that wave is calculated which has the greatest growth-rate; the only unknown factor concerning this wave is then its amplitude factor. Assuming the perturbation attains a limiting amplitude, a second calculation is made of the new zonal velocity and temperature distributions involving the unknown amplitude. If use is then made of the energy condition for the limiting perturbation, a specific value can be obtained for the amplitude. This is, of course, a numerical and not an analytical treatment.

The results obtained may be summarized as follows: in the absence of eddying motion, there are westerly winds mainly in the upper level, 25 m./sec. maximum at 45°. This distribution is modified by the eddy exchange process; about 20 m./sec. is added to wind velocities at 45° at both levels. It reduces the westerly zonal flow to zero near $22\frac{1}{2}°$ and $67\frac{1}{2}°$; polewards of $67\frac{1}{2}°$ and equatorward of $22\frac{1}{2}°$, upper and lower winds become slightly easterly. The pole-equator temperature contrast is considerably reduced by the eddies from 45° C. to about 20° C. The meridional motion in the symmetric case is a direct cell with a maximum horizontal velocity of 10 cm./sec., whereas the eddy process gives rise to a three-celled circulation. This is in broad general agreement with observation.

Dr. E. T. Eady read a paper on "The Physical Parameters characterizing the Dynamics of Planetary Atmospheres". He pointed out, first of all, that for the large-scale meteorological problems the Reynolds number is so large that the resulting turbulent flow patterns are well beyond the laminar régime. The second parameter introduced was the Richardson number, $Ri = g\frac{\partial\rho}{\partial z}\Big/\rho\left(\frac{\partial u}{\partial z}\right)^2$, where $\partial\rho/\partial z$ is a vertical derivative, which is a local parameter governing the stability of air flows of variable density: $Ri < 0$ produces convection, $0 < Ri < 1$ gives the criterion for the growth of meridional circulations, $Ri > 1$ produces circulatory type flows with slight vertical motion. Two numbers closely associated with Ri are $a = g\,\frac{\partial\rho}{\partial y}\Big/\rho f^2$, where f is the Coriolis parameter and $\partial\rho/\partial y$ a horizontal gradient of density and $b = g\,\frac{\partial\rho}{\partial z}\Big/\rho f^2$, the former being related to the Rossby number which enters into instability criteria. The Richardson number may be interpreted as the ratio of potential energy available to kinetic energy available to an element of fluid, and if Ri is large it is then clear that the eddying energy source is the potential energy. Also, it is clear that in regions of the atmosphere where electromagnetic forces are no longer negligible, one can introduce a non-dimensional parameter M which is the ratio of the magnetic energy available to the available potential energy, namely:

$$M = \mu H^2/gz^2\,\frac{\partial\rho}{\partial z}$$

M clearly increases in the vertical due to the decrease in density; M small implies that the charge moves with the fluid. In ionospheric regions where the mean free path is large, the all-important parameter is the ratio of the magnetic energy μH^2 to the kinetic energy mV^2 of the charged particles.

The main problems which seemed to have been dominating the discussions were summed up by Prof. P. A. Sheppard. Perhaps the most significant feature, said Prof. Sheppard, was the evidence of jet streams not only in our own atmosphere but also in other planets and in experimental work which Hide described. What is equally striking is that the reason for jet streams is still obscure. The fact that there is a transfer of westerly angular momentum polewards from the equatorial region does not, in itself, lead us to expect a sharp jet stream. Sawyer's views may imply 'that big jets grow from little jets', but on the other hand it is worth while bearing in mind that the tight horizontal temperature gradients, with the consequent development of a jet, may be associated with unstable baroclinic wave development. The question of the maintenance of the jet stream against turbulent diffusion at the boundaries has been raised, and in this connexion it is possibly important to bear in mind that the two-dimensionality of the flow patterns may imply a lesser amount of turbulent dissipation. The precise reasons for the existence of two jets is not clear, and similarly ocean jets such as the Gulf Stream are not yet adequately explained. Veronis has suggested that there may be thermal processes involved here which have not been sufficiently elucidated. The work of Kuo and Davies on instability of the dish-pan flows raises some important questions concerning earlier work on instability of atmospheric zonal flow patterns, in which the variation of the Coriolis parameter with latitude played a dominant part, but this is absent completely in the dish-pan experiments. Does the experimental dish-pan type flow actually carry over to the atmosphere, in which the heat sources are to some extent different? (One serious drawback of theoretical attempts up to the present is that the vertical temperature gradient is prescribed initially and is not a product of the solution of the equations.) The processes of momentum transfer in the experimental work and in the atmosphere are now fairly fully understood; energy transfer processes are also understood and Dr. Sutcliffe's results may be summed up by saying that the presence of water vapour in the energy-transfer problems alters the tempo rather than changes the pattern.

So far as the planets are concerned, Prof. Urey's work demonstrates that chemical composition has to be brought in in building up the complete picture of the general circulation. Dr. Goody has made it quite clear that the large-scale dynamical problems for the atmosphere of Mars may be much simpler for meteorologists than our own atmosphere, due to the fact that its water vapour content is so much less. In the case of Jupiter, where there is a variation of the mixing ratio with height, it is possible for there to be one atmosphere overlying another with little or no interaction, and this raises quite difficult problems of interpretation.

T. V. DAVIES

THE EUGENICS SOCIETY

ON December 4 the Eugenics Society held a dinner under the presidency of Sir Charles Galton Darwin, in celebration of its first fifty years of active life. The jubilee dinner was the occasion of two special events. The first was the presentation of the Galton Medal to Dr. C. P. Blacker. This Medal, a mark of high distinction and esteem, is the highest honour in the gift of the Society. It has been awarded on a single previous occasion, a dozen years ago, to Sir Alexander Carr-Saunders, later to be president of the Society, who was present and spoke at the dinner.

Dr. Blacker, now honorary secretary of the Society, was its general secretary for the twenty-one years during 1931–52, so spanning the presidencies of Sir Bernard Mallet, Sir Humphry Rolleston, Lord Horder and Sir Alexander Carr-Saunders.

The presentation of this rare award is testimony to Dr. Blacker's great knowledge, zeal and vigour on behalf of the Society. It is very largely through his writings and influence that the Society has been able to lead public opinion in a controversial field and age.

The second special feature of the jubilee was the issue of the Society's revised Statement of Aims. This document, as well as treating of eugenic science, studies and policies, provides an impressive list of the past activities of the Society. They afford a convincing indication of the way in which the Society has often been able to lead—albeit quietly and by stimulation in the right quarters at the right time. Possessing freedom, by the good fortune of endowment, the Society has been able to initiate and catalyse chosen efforts and researches, frequently doing so by help to cognate societies, such as the International Planned Parenthood Federation, the Family Planning Association, the British Social Biology Council, and others.

Prominent among the Society's activities pursued by such means have been Lidbetter's classic researches on the social problem group, and later work on problem families; Baker's work in the 'thirties on the elaboration and testing of chemical spermicides as a stage in the improvement of contraceptives without which appropriate differential fertility cannot be brought about; Lewis's work on morbid inheritance; and the Population Investigation Committee (of which Carr-Saunders and Blacker were joint founders), which was the forerunner of the Royal Commission on the Population of Great Britain. Further, there have been two especially close collaborations with Political and Economic Planning on population policy for Great Britain a decade and more ago, and much more recently on world population and resources. An inquiry into promising families will soon be published.

The Society's journal, the *Eugenics Review*, has been published as a quarterly since 1909, and following the Second World War there has been issued additionally a series of important occasional papers by Blacker, Burt, Thomson, Terman and others.

The Society's jubilee also coincides with a change in the general secretaryship. Dr. C. O. Carter, who succeeded Dr. Blacker in 1952, has now joined the Medical Research Council Clinical Genetics Research Unit at the Hospital for Sick Children, Great Ormond Street. His place has been taken by Dr. G. C. L. Bertram who, after seven years as director of the Scott Polar Research Institute in Cambridge, has recently spent a period in New Zealand as William Evans visiting professor in the University of Otago.

The aims of the Society may be summarized as being: to study the influences which may modify inborn human qualities; to formulate and support policies for developing these qualities to the utmost advantage; to promote research on eugenic problems; to foster a responsible attitude to parenthood; and to guide public opinion in these matters.

The Society's address is 69 Eccleston Square, S.W.1.

WORK STUDY

IN the four years of its existence the European Productivity Agency has done much to stimulate increased productivity in industry through conferences, courses, visits of consultants, publications and other means. Some of its activities have been of little value to progressive organizations and have been unnoticed and unheeded by others. In the main, however, the Agency has provided a most valuable service in acting both as a stimulant and as a medium for promoting exchange of useful ideas and methods between firms in the participating countries. The majority of its reports have been welcomed by those looking for new ideas and techniques to increase productivity.

Of all the reports the Agency has produced, "Labour Management on the Farm"* will almost certainly be regarded as one of the most valuable. It contains information which has been culled from innumerable sources and which has never appeared before in one volume. It is of direct and practical value to the thinking farmer who is prepared to revise his methods to improve his efficiency; it has been carefully planned and well written.

The report owes its genesis to a seminar organized on behalf of the European Productivity Agency by the Ministry of Agriculture, Fisheries and Food of the Netherlands at Wageningen during July 9–18, 1956. The seminar was attended by approximately 45 participants from 12 member countries of the Organization for European Economic Co-operation—Austria, Belgium, Denmark, France, Germany, Italy, Luxembourg, the Netherlands, Norway, Sweden, Switzerland and the United Kingdom. Participants included specialists, teachers and advisors working on farm work simplification and labour management.

---

* "Labour Management on the Farm". Pp. 171. (Paris: European Productivity Agency of the Organization for European Co-operation, 1957.)

The programme of the seminar provided for discussions and exchange of information on the technical and economic importance of labour management in agriculture; on methods for work study and their application; on development and use of standard data and allowances in labour planning and control in relation to farm wages; on advisory and teaching activities in farm work simplification and labour management; and on the principles for maintaining good labour relations on the farm. Practical demonstrations of work study methods were arranged at the Institute for Agricultural Engineering and Rationalization at Wageningen.

Although it is fully realized that many questions concerning labour relations on the farm are arranged under agreements between associations of employees and employers respectively or by means of official regulations, the present report is primarily concerned with the relations between the individual farmer and his workers.

After defining the objectives of farm-work simplification and labour management on the individual farm, the report presents an illuminating account of work-study technique applied to farming practice as well as current research in work simplification. There is, for example, an impressive flow process chart, analysing the handling of straw on a farm; it was found that the straw was lifted fifteen times before reaching its final destination. There is also a man-machine process chart of machine milking which shows that the machine was idle for half the time the milking task was being performed. In another example, a string diagram was prepared to show the paths travelled by two pigmen when feeding and watering pigs; the ensuing changes led to a reduction of 100 walking miles each year.

To show that work study leads to genuine and practical improvements on the farm, and to give the farmer guidance in developing the principles of work simplification on his own farm, the report includes five studies where work study has been applied to agriculture. These are: the farm work diary—as a means of research and extension in the field of labour management; work study as a guide for setting piece-work rates; planning farm buildings to save time and energy; the role of work study in the development of machines and hand tools; and the role of work physiology in dealing with problems of labour management.

The section on farm buildings gives useful information about the conversion of old buildings; the section on work physiology not only includes well-substantiated advice about the prevention of fatigue but also recommendations about the kinds of tools and barrows which are most suitable for farm workers. Even the notoriously conservative farmer might be tempted to try buckets with a flattened side after reading how their use has led to a considerable reduction in fatigue.

The authors of the report are aware that the introduction of method study and work measurement is unlikely to be accepted on farms where labour relations are bad. They recommend means whereby good labour relations may be built up and maintained on the farm and give detailed information about the principles which must govern the introduction of a wage incentive plan. This is supported by illustrations of cases where wage incentive schemes have been introduced.

Since the report is more likely to be seen and used by organizations like county agricultural advisory committees than by individual farmers, it includes sections describing the ways in which an advisory programme and labour management and adequate training facilities could be developed; they are as useful and practical as the rest of the report.

The detailed bibliography contains accounts of fundamental researches and of immediately applicable investigations like those concerned with the organization of raspberry picking with chips and punnets and of the use of motion and time-study in planting cabbage and celery by hand.

THE PROBLEM OF THE 'AMPHIOXIDES' LARVA

By QUENTIN BONE

Department of Zoology, University of Oxford

THE remarkable 'amphioxides' larvæ that were described in detail by Goldschmidt[1] and Gibson[2] appear to be the larvæ of three different species of Acraniate. When these larvæ were first described, it was supposed that they were adult animals, and they were placed in a separate genus, *Amphioxides* (Gill[3]).

The three forms which were later distinguished, *Amphioxides pelagicus* (Gunther); *A. valdiviae*, Goldschmidt; and *A. stenurus*, Goldschmidt, were all rather similar, differing from each other in size, myotome number, and in various other characters such as the form of the tail fin and rostrum.

These animals are unlike the well-known amphioxus larva (that is, the larvæ of *Branchiostoma lanceolatum*), for although they are superficially similar in appearance, they are evidently animals that spend much longer in the plankton, growing to a larger size before metamorphosis; from this longer growth-phase arises their differences from the amphioxus larva. When fully grown, but before they have begun metamorphosis, they may be 9 mm. or more long (twice the size of the amphioxus larva at metamorphosis), and yet possess no trace of the atrium except at the extreme hinder end of the body. The fully grown specimens of all the species known possess a single row of 27 median gill slits, which correspond to the primary series of gill slits of the amphioxus larva.

In some of the larger specimens that have been found, there are large gonad rudiments in a row upon

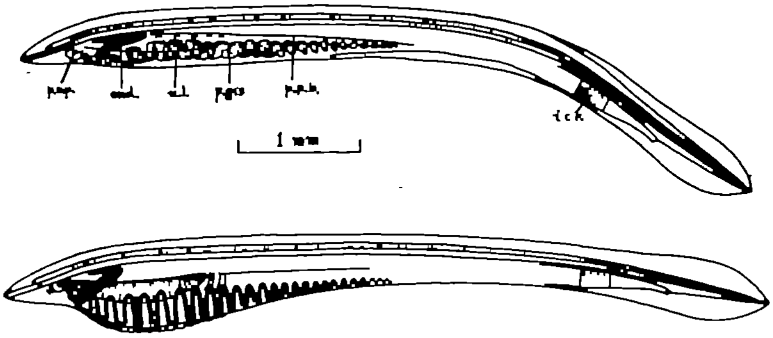

Fig. 1. *End.*, endostyle; *p.o.p.*, pre-oral pit; *p.p.b.*, peripharyngeal band; *p.g.s.*, primary gill slits; *u.l.*, edge of upper lip; *i.c.r.*, ilio-colonic ring

the right side of the body only. It was for this reason that they were at first believed to be adult forms; Goldschmidt made the genus the type of a new family of Acrania, the Amphioxididae (allied by the asymmetry of the gonads to the Epigonichthyidae), Goldschmidt[4].

Very shortly afterwards, both Goldschmidt and Gibson found specimens that had metamorphosed, and it became clear that the animals were in fact Acraniate larvæ. But this clarification of the situation has not yet gone as far as it might, for not only is it not clear to which adult species the larvæ are to be assigned, but also it is necessary to consider the possibility (first suggested by Goldschmidt) that any given species of Acraniate may possess alternative larval forms. This suggestion gains support from the single specimen of an 'amphioxides' type of larva which has been found in the North Sea[5]. This larva had 19 gill slits, in a single row; it was 5 mm. long and possessed 61 somites but no gonad rudiments. It is certain that this larva is to be assigned to *Branchiostoma lanceolatum*, which normally produces an 'amphioxus' larva metamorphosing at the stage when there are 14–15 primary gill slits, and the larva is 4·5 mm. long.

It is interesting that the amphioxus larvæ which were found at Plymouth in 1892[6] possessed 16–17 primary gill slits (their length was not stated, and I have been unable to locate these specimens).

Apart from these larvæ from the Channel and the North Sea, none of the known species of 'amphioxides' larva can be definitely assigned to an adult species of Acraniate. It is probable (but not certain) that *Amphioxides pelagicus* may belong to *Asymmetron lucayanum*; for the other forms of larva, no adult form has been suggested.

By the kindness of Prof. M. Blackburn and Dr. Munro (of the C.S.I.R.O., Cronulla, New South Wales), I have been able to examine some specimens of the larvæ of *Paramphioxus bassanus* (Gunther), an Australian Asymmetrontid, which were collected in the Bass Strait area. The occurrence and distribution of these larvæ have been briefly discussed by Blackburn[7].

They are 'amphioxides' larvæ of a very similar appearance to those previously described; in Fig. 1 the upper drawing shows the appearance of a large fixed specimen, and the lower, the probable appearance of the larva in life.

Fig. 1 illustrates the largest larva received (6·4 mm.), which had 27 median gill slits. In none of the specimens was there any trace of gonad rudiments. Compared with *Amphioxides pelagicus* of equivalent maturity (the same gill slit number), the present species is smaller, which may account for the absence of the gonad rudiments.

The chief distinguishing character of these larvæ is that they possess a much greater number of myotomes than the other forms described. The largest number for *A. pelagicus* is 68, and for *A. valdiviae* and *A. stenurus*, 70. In the present larvæ, the smallest specimens had 74 myotomes, and the usual number for both large and small was 78. In addition, in these larvæ, the tail fin begins at the level of the 43rd myotome (as compared with the 23rd–25th in *pelagicus*, and the 32nd–33rd in *valdiviae*).

Lastly, the fin-ray boxes, which form a continuous dorsal series, are arranged 4 to a myotome throughout, as compared with 5 in *A. valdiviae*, and 2–4 in *A. pelagicus*.

These larvæ are interesting, for they are the first larvæ of the 'amphioxides' type that can be certainly assigned to a known adult species; also, they show some stages in the metamorphosis of this type of larva which indicate that the process is somewhat different from that taking place in the amphioxus larva.

In the complex re-assortment of the gill slit number, involving both the disappearance of slits already formed and the appearance of new slits, that takes place during the metamorphosis of the amphioxus larva, there is a stage when the larva possesses 8 pairs of gill slits, known as the 'critical' stage[8]. At this stage, the larva pauses for a period before further changes take place; it is sometimes supposed that it represents a significant phase in the recapitulation of the evolutionary history of the Acrania. However this may be, it seems that the 'amphioxides' type of larva does not exhibit a critical stage in its metamorphosis, which appears to be a relatively gradual process.

Gibson's description of the two metamorphosing individuals of *Amphioxides pelagicus* showed that if these larvæ went through a 'critical' stage, then it was when they possessed 18 pairs of gill slits. In the largest of the present larvæ, there are 27 primary gill slits, and the rudiments of 5 secondary slits at the front of the pharynx, of which the first and latter are smaller than the others. This condition suggests that the secondary series of slits in the 'amphioxides' type of larva appear gradually from in front backwards, as the primary slits become reduced from 27 to 18. That is to say, there does not appear to be a 'critical' stage in the metamorphosis of this type of larva.

It may perhaps be suggested that the 'amphioxides' type of larva (apart from the secondary asymmetry of the gonads) is the nearest living animal to that which by pædomorphosis gave rise to the Chordata. The early Protochordate larva ancestral to the Chordata very probably had a prolonged period of growth in the plankton, resulting (as in the 'amphioxides' type of larva) in increase in size of the body, and the appearance of the gonads before metamorphosis. Eventually, total neoteny occurred, and the Chordate line arose.

Various views have been expressed upon the status of the 'amphioxides' type of larva; it seems unlikely that that advanced by Bigelow and Farfante[9], and supported by Berrill[10], can be correct. These authors suppose the 'amphioxides' larva to be destined to an eventual death as a larva, because it has passed the 'critical' stage without metamorphosing, hence growing to a larger size than its ciliary feeding mechanism can support. It is probable that this type of larva does not pass through a 'critical' stage. It has long been known to metamorphose; in all the species discovered, the metamorphosis begins at the same 27-gill slit stage.

The rarity of metamorphosing individuals of this type of larva in the plankton suggests that they may perhaps metamorphose elsewhere than at the surface layers. They possess the same adhesive organs upon the metapleural folds as does the amphioxus larva; possibly they may spend the latter part of larval life upon the sea bottom. Little is known for certain of the ecology of any Acraniate larva; the accounts in the literature of the habitat of the amphioxus larva vary from van Wijhe's remark that "the habitat of the amphioxus larva seems to be chiefly the sea bottom" (van Wijhe[11]) to the more usual statements that they are throughout larval life pelagic organisms.

There are six species of Acraniate with asymmetrical gonads (which are sometimes classified as a single family, the Asymmetrontidae, and sometimes divided into this family, and a second, the Epigonichthyidae); there are four forms of 'amphioxides' larvae known. It is possible that all these Acraniates possess this type of larva, and are thus distinct from the Branchiostomidae, in which this type of larva is a great rarity. It is significant that the adults of *Asymmetron lucayanum* are found at times in plankton hauls; perhaps this group of the Acrania is less fully adapted to a sedentary life than is the Branchiostomidae.

The metamorphosis of the larvae of the Branchiostomidae is known only for *B. lanceolatum* and, even in this species, only for the race inhabiting the Mediterranean. It is not unlikely that, as the metamorphoses of other members of this family are studied, it will be found that the process takes place at different stages in the development of the larva, and that within the group there may be a graduation between the classical 'amphioxus' development shown by *B. lanceolatum*, and the prolonged 'amphioxides' type of development apparently characteristic of the Asymmetrontids.

It is the purpose of the present article to direct attention to the unique nature of the 'amphioxides' type of Acraniate larva; much more needs to be discovered about their distribution and ecology before their status can be satisfactorily determined. It is suggested that this information will throw important light upon the problems of the origins of the Acrania and the Chordates from the Protochordate stock; in such speculations, the 'amphioxides' larva has been curiously neglected.

PLASMA PAIN-PRODUCING SUBSTANCE AND BLOOD CLOTTING

By J. MARGOLIS

Pharmacology Dept., Middlesex Hospital Medical School, London, W.1

WHEN plasma is brought into contact with glass, pain-producing, uterus-stimulating activity rapidly develops and then decays[1]. The pain-producing substance is probably a polypeptide, and its formation appears to involve activation of a proteolytic enzyme which acts upon a substrate to produce the pain-producing substance, which is then rapidly destroyed by a peptidase in plasma. The development of the pain-producing substance is analogous to the initiation of blood clotting by glass[2]. Both sets of phenomena are independent of calcium and of platelets and both are inhibited by soya bean trypsin inhibitor. In the present work the relation between the two series of reactions has been studied.

The addition of potent, protein-free preparations of the pain-producing substance, obtained by aqueous or alcoholic extraction of activated plasma[1], to preactive plasma had no effect on clotting, showing that the pain-producing substance is not itself an intermediary in the process of clotting induced by contact with glass.

In studying other possible inter-relations between formation of pain-producing substance and clotting, cell-free, citrated plasma was prepared in 'Polythene' or siliconed containers and then exposed to the action of glass ballotini[3]; the pain-producing substance was assayed on the isolated rat uterus, and in some experiments also for pain-production on an exposed blister base[1].

A two-stage reaction has been demonstrated for initiation of clotting by glass. An attempt was therefore made to establish the existence of two stages in the formation of pain-producing substance.

Plasma was rotated in a siliconed glass tube with an equal weight of glass ballotini (surface area about 200 $cm.^2/G$); concentration of the substance reached a peak after 2–3 min. and rapidly declined to a negligible value after about 10 min. When such plasma, exhausted of pain-producing substance, was added to a sample of preactive plasma, fresh pain-producing substance was formed. Plasma deprived of pain-producing substance could also be obtained by rotating with 1/5–1/10 the above-mentioned quantity of ballotini for 5 min., and then leaving the decanted plasma in 'Polythene' containers for 1 hr. or more at room temperature. This plasma, when re-exposed to glass, did not itself develop pain-producing substance, but was capable of activating a relatively large volume of preactive plasma to produce the substance, with a maximal concentration about 2 min. after mixing. Plasma freed from pain-producing substance which had not been re-exposed to glass did not activate preactive plasma.

Drs. D. Armstrong and J. B. Jepson found that the pain-producing substance which was formed by the two-stage activation was indistinguishable in pharmacological tests from that formed by the usual one-stage activation. There was also no difference in their rates of inactivation by chymotrypsin and by bacterial aminopeptidase.

It thus appears that when plasma is exposed to glass a substance, which has been called 'contact factor', is first formed. This 'contact factor' then initiates further reactions which lead to formation of pain-producing substance.

The time-course of development and decay of 'contact factor' was investigated as follows: 1 vol. of ballotini-activated plasma (previously exhausted of pain-producing substance) was incubated with 2 vol. of preactive plasma at room temperature. The development of the substance was measured by applying 0·1 ml. of the mixture to the rat's uterus in a 5-ml. organ bath. By varying the period of contact of the exhausted plasma with ballotini, it was found that the activity of 'contact factor' reached a peak after 2 min., and declined to negligible values within 20–30 min. If at any stage the plasma was removed from the glass, 'contact factor' decayed rapidly, falling to less than 10 per cent of its original value within 5 min. at room temperature. The rate of decay of 'contact factor' was slower when the exhausted plasma had been pre-heated at 56–58° C. for 20–30 min.

'Contact factor' could also be formed from the globulins precipitated from plasma between 25 and 45 per cent saturation with ammonium sulphate. Decay of this fractionated 'contact factor' was even slower than that of pre-heated plasma. Addition of whole plasma to such a fraction increased the rate of decay of the fractionated 'contact factor' to that found in untreated plasma. Thus decay of 'contact factor' appears to be due to an inactivator, which is partly destroyed by heating and is largely removed by fractionation.

These findings closely resemble those described for the initiation of blood clotting by glass[2]. Other points of agreement are as follow.

The 'contact factor' is not affected by prior treatment of preactive plasma with aluminium hydroxide or barium sulphate. Its development is not affected by prior heating of plasma to 56–58° C. for 30 min., but 'contact factor' is not formed in plasma previously heated to 60° C. for 20 min. The reacting system is found in 25–45 per cent saturated ammonium sulphate fraction of plasma. 'Contact factor' develops normally in the plasma of patients with hypoprothrombinaemia, deficiency of factors V and VII, hæmophilia, Christmas disease or thrombocytopenia[4,5]. 'Contact factor' did not develop in the plasma of a patient with the 'Hageman trait'[4,5], although the patient's preactive plasma could act quite normally as 'substrate' for normal 'contact factor' in a two-stage reaction.

On the other hand, both activation and decay appear to be slower when measured by the clot-promoting effect than by production of pain-producing substance. Further, in patients with 'plasma thromboplastin antecedent' deficiency there was a partial defect in formation of 'contact factor' as assessed by coagulation[5], although formation of pain-producing substance was normal. These differences can now be accounted for by the demonstration that another stage, involving 'plasma thromboplastin antecedent', is necessary for the initiation of coagulation by contact with glass. 'Plasma thromboplastin antecedent' may form a substrate for the action of 'contact factor' in clotting in the same way as the precursor of pain-producing substance does in the formation of the substance. A suggested scheme of events, compatible with all these observations, is shown in Fig. 1.

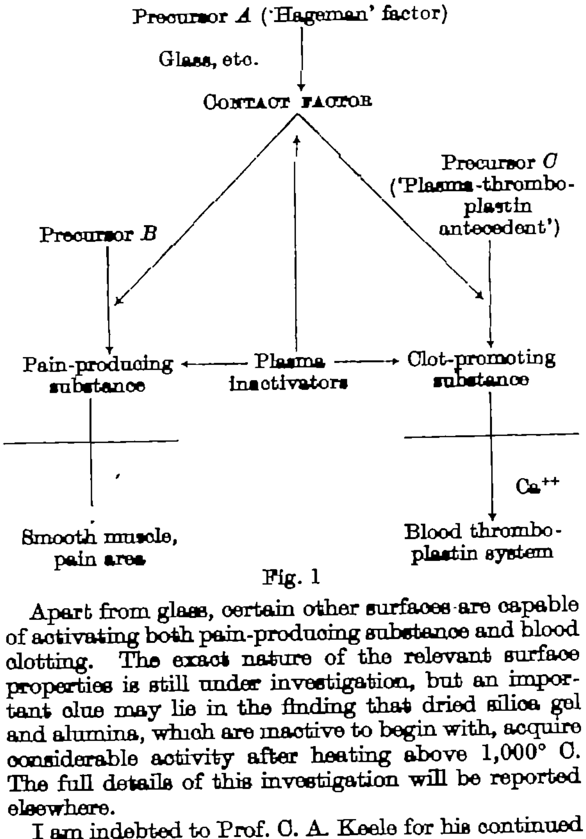

Fig. 1

Apart from glass, certain other surfaces are capable of activating both pain-producing substance and blood clotting. The exact nature of the relevant surface properties is still under investigation, but an important clue may lie in the finding that dried silica gel and alumina, which are inactive to begin with, acquire considerable activity after heating above 1,000° C. The full details of this investigation will be reported elsewhere.

I am indebted to Prof. C. A. Keele for his continued help and advice and to Dr. R. G. Macfarlane for his interest and his valuable criticism. I wish to thank Dr. D. Armstrong for her help with the experiments on the pain area and Dr. R. M. Hardisty for supplying specimens of plasma from his patient.

This work was supported by a grant from the Royal Australasian College of Physicians.

The General Radiation Syndrome: Initial Reaction in the Monkey

The initial reaction of the general radiation syndrome in man is characterized by a latent period, a period of acute disturbance and a recovery period. During the period of acute disturbance the predominating symptoms are fatigue, headache and nausea and some people vomit and have colonic evacuation[1,2]. The duration of the latent period, that is, the time from the commencement of irradiation until the onset of symptoms, not the onset of vomiting, is dependent on the surface-dose, body-size and anatomical site of irradiation[3,4]. Also a significant inverse relationship between dose-rate and the length of the latent period has been reported during the therapeutic administration of radioiodine[5].

A monkey, the whole body of which was irradiated, presents evidence of an initial reaction in its general radiation syndrome[6,7]. Observations were made of this reaction in monkeys and are reported here: (1) to show that signs indicative of the onset of the initial reaction, quite apart from vomiting, may be appreciated by an observer, thus allowing an accurate estimate to be made of the duration of the latent period, and to some extent of the period of acute disturbance; (2) to show that radiation dose-rate has an effect on the duration of the latent period.

Whole-body gamma irradiation was given to twelve healthy tuberculin-tested monkeys (*M. mulatta*) of both sexes (weight 3·7–11·5 kgm., mean 6·9 kgm.) and seven of these animals were re-irradiated after physiological recovery from the first exposure. The irradiation procedure was carried out in the cobalt-60 storage block of the Isotopes Division at the Atomic Energy Research Establishment, Harwell[8]. Variation in the dose-rate was achieved by increasing or decreasing the number and position of the sources of cobalt-60 arranged circumferentially, radially and longitudinally around the irradiation space. Dosage measurements before each exposure were made with a 100-r. Victoreen ionization chamber placed in a phantom made of bolus bags[9]. The mean whole-body dose calculated from these measurements was 450r. with two exceptions of 470r. and 480r. The animals were housed individually and allowed food (diet 41 rat cubes) and water until irradiated. The animals were trained to enter the handling cage, the irradiation cylinder, and to accept food from the hand. At no time were the animals restrained or harshly treated. After irradiation the animals were returned to their own living quarters and a close watch kept on their activity, behaviour and appetite. A cinematograph film was made of two animals.

The onset of the initial reaction could be readily detected by a quite sudden change in the animal. The monkey would hang wearily from the cage roof, head on chest, or sit dejectedly in a corner, and at times lie down on the floor of its cage. Loss of appetite accompanied this change. In most animals these signs would pass off only to return in a few minutes in an exaggerated form, accompanied by retching and vomiting. Waves of the latter signs recurred; but gradually their severity lessened, the interval between them lengthened and they ceased in 2 hr. or so. Appetite then returned, and no further vomiting was observed in the later course of the syndrome.

Table 1. The Dose, Dose-Rate and Duration of Latent Period in Nineteen Irradiated Monkeys following Whole-body Gamma Radiation

Dose (r.)	Dose-rate (r./min.)	Latent periods (min.)
450	124·0	35, 34, 32
450	103·0	31, 36, 30
450	96·7	34, 33, 36, 31
450	53·0	31, 34, 28
480	15·0	75
470	14·5	80
450	13·0	108
450	7·0	90, 90, 75

The time from the commencement of irradiation to the first observed change indicative of the onset of the initial reaction was recorded as the latent period (Table 1). It will be seen that as the dose-rate increased from 7·0 r./min. to 53·0 r./min. the duration of the latent period decreased from some 90 min. to about 30 min.; but its length was not altered by further dose-rate increments.

With the lower dose-rate irradiations the onset of the symptoms of the initial reaction in the monkey may be observed 10 min. or more before vomiting, but with the higher dose-rate exposures vomiting sometimes occurred with the first wave of symptoms. These observations suggest that dose-rate is another factor in the development of the initial reaction of the general radiation syndrome in the primate, although the number of monkeys exposed was small. A striking likeness is apparent between the initial reaction in the monkey and radiation sickness seen in therapeutic practice. There was no evidence that sex and previous irradiation, provided full recovery from the first exposure had been made, play a part in the development of the initial reaction of the general radiation syndrome in the monkey.

Radiation Lethality and Local Tissue Damage in Histamine-depleted Rats

THE liberation of histamine from cells damaged by ionizing radiations is considered to play an important part in certain radiation changes, particularly in skin erythema and in certain aspects of the acute radiation syndrome[1]. While some elevation of plasma histamine is said to occur after total-body irradiation[2], estimations of tissue histamine following irradiation have been reported unchanged[3] or lowered[4]. The administration of histamine at the time of irradiation, to animals subjected to lethal doses of total-body irradiation, has been found to afford a weak but variable protective effect[5].

In order to test the hypothesis that release of available tissue histamine conditions the general and local effects of irradiation, rats were 'depleted' of tissue histamine, prior to irradiation, by intraperitoneal administration of a histamine liberator, compound 48/80 (ref. 6). It has been shown[7,8] that this substance reduces tissue histamine in skin and certain other tissues to very low levels—less than 10 per cent of normal values for skin, subcutis, mesentery and omentum. By adopting a chronic dosage schedule, as described by Feldberg and Talesnik[7], a low level of tissue histamine is reached by the third day in 100–150 gm. rats.

In the first experiment, groups of rats on the third day of histamine depletion received a dose of 1,000 r. total-body irradiation, measured with back scatter, using a 250-kV. source of X-rays, and increasing doses of 48/80 were continued throughout the total period of observation. Each group consisted of twenty animals, selected from litters of inbred Canberra black laboratory stock rats, the litters being equally divided between the two groups.

Comparison of the irradiation lethality curve obtained for the histamine-depleted rats after irradiation with control groups receiving injections of saline, showed an increased mortality-rate in the histamine-depleted animals. The mean survival-time for histamine-depleted animals was 4·91 (± 1·04) days, compared with 8·67 (± 4·10) days for the controls. On the seventh day after irradiation, all histamine-depleted animals had died, whereas 60 per cent of control rats were still alive.

In the second experiment, groups of histamine-depleted albino rats and controls receiving injections of saline (ten animals per group) each received an X-ray dose of 4,000 r. to a 3·5-cm. diameter circular field of skin, using a 30-kV. beryllium window X-ray source, giving a half-value depth dose of 2,000 r. at 1 mm. It was found that the histamine-depleted animals developed radiation changes in the skin significantly earlier than controls, the skin erythema was more intense, and the final tissue damage was considerably increased.

It is considered that these results indicate that acute radiation shock and lethality, radiation erythema and local tissue damage cannot be satisfactorily explained on the basis of release of histamine. In fact, the results suggest that lack of available tissue histamine results in a lessened protection to irradiation damage, and that histamine takes a physiological role in the inflammatory response to such injury.

The details of these results, together with other investigations now in progress, will be recorded in detail later.

Estimating the Life of a Satellite

IT is perhaps not generally known that one can forecast rather simply how long one of the new satellites will continue in an orbit, provided only that one has good information about the period and some knowledge of the eccentricity. In particular, it is not necessary to know the density of the air or the scale-height. It is sufficient to assume that the resistance decreases exponentially with height near the perigee.

Our estimate for the span of life that remains for either of the satellites is:

$$0\cdot30\,\frac{h_{\text{max.}}-h_{\text{min.}}}{-\mathrm{d}T/\mathrm{d}t} \qquad (1)$$

where $-\mathrm{d}T/\mathrm{d}t$ is the rate of decrease of the period, in seconds per day, and the maximum and minimum heights h are expressed in kilometres. This result is of course only approximate, and depends also on the assumption that the orbit is eccentric enough for most of the resistance to be encountered on the perigee side of the orbit.

The formula is derived as follows. We assume the eccentricity of the orbit is rather small, and neglect the ellipticity of the Earth. Then the orbit can be treated approximately as a sine-wave variation of height as the satellite goes round the Earth:

$$h = \text{constant} - A(t)\cos\theta \qquad (2)$$

(θ is the anomaly). The air-resistance near perigee will be important, so we measure heights h from some convenient datum near the height of perigee, say 200 km. above the Earth; and we suppose the density of the air is:

$$\rho = \rho_0 \exp(-h/H) \qquad (3)$$

The effect of the resistance of the air is mainly to diminish the maximum height at apogee (by several kilometres a day); the gradual loss of height at perigee, though slight, is important because it brings the satellite into denser air than before. We denote the height at perigee by $s(t)H$, and equation (2) takes the form:

$$h = sH + A(1-\cos\theta) \qquad (4)$$

($A = \frac{1}{2}(h_{\text{max.}} - h_{\text{min.}})$ is equal to the product of the eccentricity and the semi-major axis).

Now it can be shown from the dynamics of disturbed nearly circular orbits that, after one revolution, A decreases by an amount:

$$-\delta A = C_1 \int_{-\pi}^{\pi} \rho \cos\theta . d\theta \qquad (5)$$

and the perigee descends by a distance

$$-H\delta z = C_1 \int_{-\pi}^{\pi} \rho(1 - \cos\theta). d\theta \qquad (6)$$

These integrals can be expressed exactly in terms of the Bessel functions I_1 and I_0, but it is sufficient for our purpose to insert approximations for cos θ and put:

$$\rho = \rho_0 \exp(-z) \exp(-\tfrac{1}{2}A\theta^2/H) \qquad (7)$$

approximately, which leads to equations of the form

$$-dA/dt = C_2 A^{-1/2} \exp(-z) \qquad (8)$$

$$-dz/dt = \tfrac{1}{2} C_2 A^{-3/2} \exp(-z) \qquad (9)$$

These simultaneous equations give the secular change of the orbit. They are easily solved, and yield:

$$A = C_3(t_0 - t)^{1/2} \qquad (10)$$

Here t_0, C_1, C_2 and C_3 are constants.

When t approaches t_0 too closely, the present analysis breaks down because the orbit becomes too nearly circular, but a rough calculation indicates that the present satellites should not last more than one or two days beyond the extrapolated time $t = t_0$. It remains to find the actual value of t_0, and the easiest way to do this is to use Kepler's third law to get the decrease of the semi-major axis R in terms of the diminution of the period T. This gives:

$$-\frac{1}{R}\frac{dA}{dt} = -\frac{2}{3}\frac{1}{T}\frac{dT}{dt} \qquad (11)$$

within the accuracy of our present approximations. The life still remaining is then given by:

$$t_0 - t = \frac{\tfrac{1}{2}A}{-dA/dt} = \frac{3T}{8R}\,\frac{2A}{-dT/dt} \qquad (12)$$

using (10). The first factor $3T/8R$ is $\tfrac{3}{4}\pi/v$, where v is the velocity of the satellite: that is, about 0·30 sec./km.

By way of illustration, we have used the most recent data that happened to be at hand; they were taken from a Moscow message in *The Times* of November 11.

	Satellite I	Rocket	Satellite II
Period (sec.)	5,683	5,600	6,211
Diminution (s./day)	2·94	6·2	2·3
Apogee, h (in km.)	810	695	1,650

From these figures we infer heights at perigee in the neighbourhood of 210 km. for all three. If the epoch of the Russian figures is about November 9, our rough calculation gives forecasts of January 10, December 1 and May 1958 respectively. No doubt better data exist by now, but these will serve as an illustration.

In the above calculation, rather drastic approximations have been made. But it appears that if one seeks much better accuracy than this, many extra complicating factors must be considered at once.

Discharges in Hydrogen at the Ion Cyclotron Frequency

ATTEMPTS to find the optimum conditions for producing a highly ionized plasma in hydrogen have recently been described[1]. A microwave source was used, and the discharge tube was immersed in a magnetic field. It was found that a more efficient transfer of energy from the micro-wave field to the plasma took place when the operating frequency equalled the electron cyclotron frequency. We have carried out preliminary experiments to discover if such a selective absorption occurred when the applied frequency was equal to the ion cyclotron frequency. This frequency is given by $F = eH/2\pi mc$, where H is the magnetic field strength and m is the ionic mass.

The 'Pyrex' discharge-tube was a short cylinder, 8 cm. in diameter and 3 cm. between parallel faces. Electrodes mounted on the axis of the tube were used for providing a small Penning-type discharge to initiate a discharge when radio-frequency pulses were used. The tube was mounted between the poles of a permanent magnet, giving an axial field of some 3,000 gauss. A radial radio-frequency electric field was provided by means of parallel plate electrodes outside the discharge tube. Thus the tube bore a slight resemblance to the omegatron radio-frequency mass spectrometer.

The parallel plate electrodes formed part of a resonant circuit ($Q = 250$) which was coupled to a 150-watt radio-frequency source, with a frequency range of 3·8–5·9 Mc./s. The radio-frequency voltage across the discharge tube was measured by a diode valve voltmeter and peak voltages of 2·5 kV. were obtained.

The hydrogen pressure in the sealed-off discharge tube could be adjusted conveniently by means of a calibrated titanium hydride replenisher[2]. With this arrangement, it was possible to change the pressure by three orders of magnitude in about ten minutes.

At a given frequency, the output circuit was tuned to resonance and the voltage across the tube was noted. Keeping the oscillator output and pressure constant, the measurement was repeated over the available frequency band. Typical results are shown in Fig. 1. The upper curve was obtained by reducing the pressure below 10^{-3} mm. mercury,

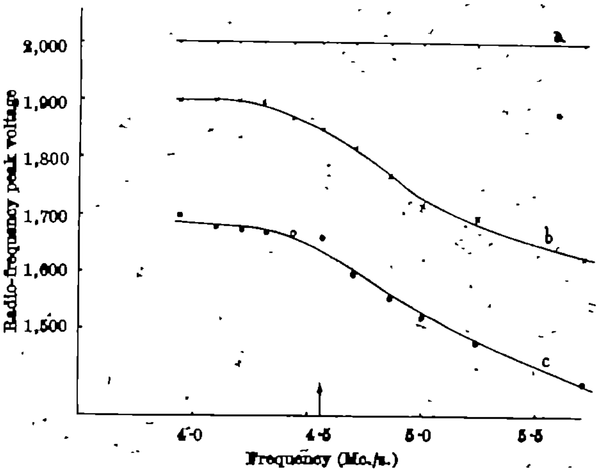

Fig. 1. (*a*) No discharge at pressures less than 10^{-3} mm. of mercury; (*b*) peak voltage versus frequency at 0·08 mm. of mercury; (*c*) peak voltage versus frequency at 0·14 mm. of mercury

when no discharge was observed. Taking an average value of magnetic field of 3,000 gauss, the cyclotron frequency for atomic hydrogen is 4·56 Mc./s.

It will be noted that at frequencies below the cyclotron frequency the voltage across the discharge, and hence its impedance, tended to be independent of frequency. Above this frequency there was a progressive decrease in voltage. There was no apparent change in the appearance of the discharge as the frequency was varied. The discharge spread radially to the walls of the tube, but did not completely fill it. The diffusion in the axial direction was much less than in the radial direction. With the present apparatus, one would not expect to observe sharp resonances, because of the highly non-uniform magnetic field in the crossed field regions. It is hoped to continue the work with more refined apparatus. In particular, it would be of interest to observe the effect of shaping the magnetic field in order to reduce the axial diffusion rate.

Determination of Auroral Height by Radar

IT is now well known that excess ionization associated with the aurora in or near the *E*-layer is capable of reflecting very high frequency radio waves with sufficient intensity to be easily detectable on a conventional radar display. Various estimates have been made of the height of the reflecting region, but these have all been obtained indirectly. Currie, Forsyth and Vawter[1], using radars on two frequencies with different lobe-patterns, obtained a most probable height of 108 km. from histograms of echo ranges obtained over a long period. Dyce is quoted[2] as making the assumption that an echo was most likely to be received if the ray from the radar were perpendicular to the Earth's magnetic field line at the echo point. By comparing the probability contours of echo occurrence with contours of various angles of incidence at the echo point, he found a height of about 80 km. for Alaskan observations and around 100 km. for those made at Ithaca. Bullough and Kaiser[3] on one occasion, by assuming that an echoing region observed over a wide arc was at a constant height, estimated a figure of about 120 km.

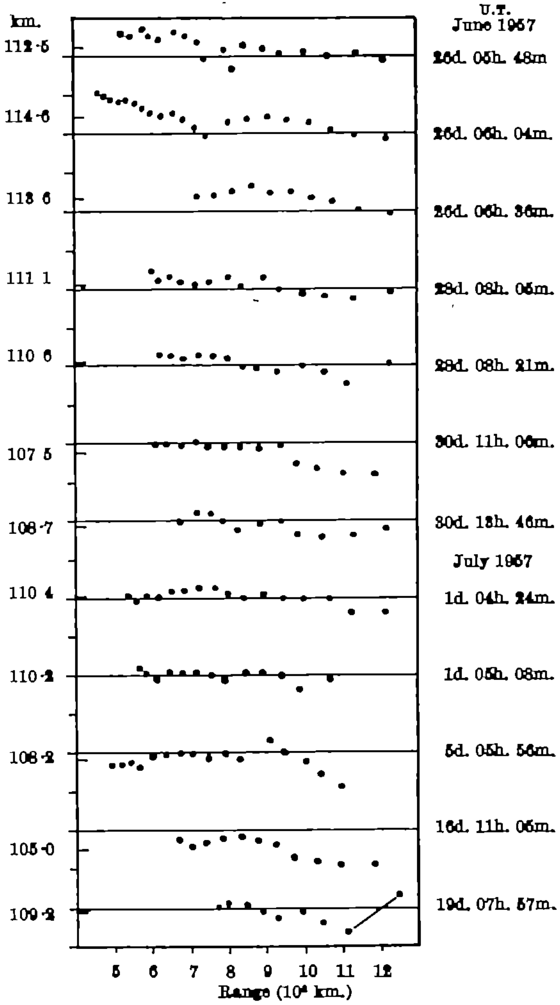

Fig. 2. The observed heights of auroral echoing regions versus observed ranges. The horizontal lines show the 110-km. level, and the separation between them is 20 km. on the scale of height. The figures are average heights in kilometres for each occasion

A radar operating at 55 Mc./s. has recently been established at Bluff, in the South Island of New Zealand, for the observation of auroral radio echoes during the International Geophysical Year. It is situated 850 ft. above sea-level, and a well-defined aerial lobe pattern is obtained by interference of the direct and sea-reflected rays up to an angle of elevation of about 10°. The polarization is horizontal, resulting in deep minima between lobes. The horizontal beam width is 24°. On a number of occasions since the middle of June 1957, while the antenna was pointing in the direction of geomagnetic south, echoes have been recorded over ranges of many

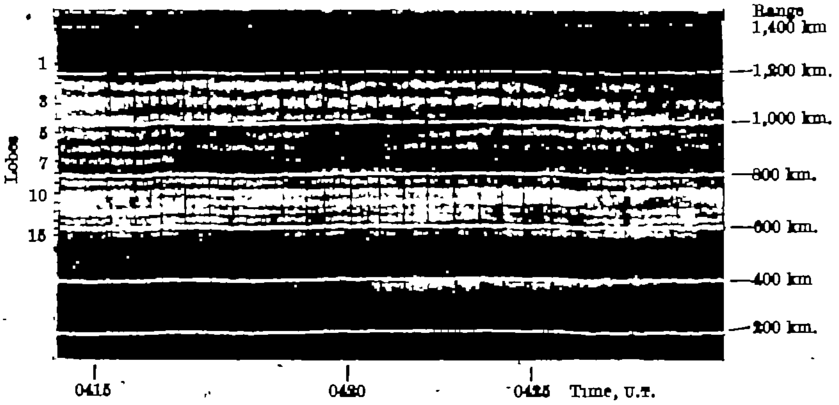

Fig. 1. A range–time record of auroral echoes. The vertical dark lines come from local interference

hundreds of kilometres out to about 1,250 km. These echoes bear all the characteristics of auroral echoes as reported by workers[1-3] in the northern hemisphere, although it has been possible to correlate them directly with an aurora observed visually on only two occasions, due to cloudy conditions.

On many occasions the lobe pattern of the radar antenna is strikingly evident on a range–amplitude display, and appears on a range–time display as a series of parallel streaks of constant width. A typical example is shown in Fig. 1. The remarkable thing about the echo distribution is that the lobe pattern is distinct over such a large range interval. Calculations on such recordings show that the region producing the echoes occurs as an approximately horizontal sheet at an average height of 110 km. A number of examples are shown in Fig. 2. The results are corrected for atmospheric refraction, and the accuracy of height determination is about ±0·5 km. on the third and higher order lobes.

The appearance of distinct lobes up to the twenty-first implies a vertical thickness of the sheet of less than 2½ km. since the twentieth and twenty-first lobe maxima for 55 Mc./s. are separated by only 5 km. in height at the observed range.

This work forms part of the research programme of the Dominion Physical Laboratory of the New Zealand Department of Scientific and Industrial Research. The observations are being continued, and further results will be published elsewhere.

Structure of Non-porous Anodic Films on Aluminium

It is generally assumed that non-porous oxide films formed on valve metals by anodic oxidation in aqueous electrolytes are normally substantially uniform in thickness and composition. By means of optical and electron microscopy and by preferential chemical dissolution, it has been found that this assumption is definitely incorrect for anodic films formed on aluminium. The non-porous oxide films formed when aluminium is polarized anodically at either constant current or constant voltage in a variety of aqueous electrolytes (for example, borates, carbonates, tartrates and phosphates) at room temperature have a pronounced cell type of structure. A modified form of this cell structure has already been reported in porous aluminium oxide films[1].

The surface of the non-porous anodic films at both the electrolyte-oxide and metal-oxide interfaces is covered with raised domes, which in the latter case correspond with craters on the metal surface. The electron micrograph (Fig. 1) is a replica of the aluminium substrate and shows the craters in the metal. Owing to interaction between neighbouring features, the cross-sections of both domes and craters tend to become irregular polygons. Within experimental error of counting as many craters are found on the metal surface as domes on the metal-oxide and oxide-electrolyte interfaces (for example, $1 \cdot 4 \times 10^8$ per sq. cm. for films formed at 500 V. and at 20° C.). It has not been possible yet to show directly that the raised areas at the oxide-electrolyte interface are above the corresponding craters on the metal surface, but it can be deduced that this must be so. Thus the structure of the anodic film tends towards that shown in Fig. 2. The average radius of the cells is proportional to the voltage and is approximately equal to the average thickness of the oxide. As the whole surface is covered with cells, the number of cells must decrease as the formation voltage increases. The number and size of the cells appear to be independent of the grain orientation of the underlying metal.

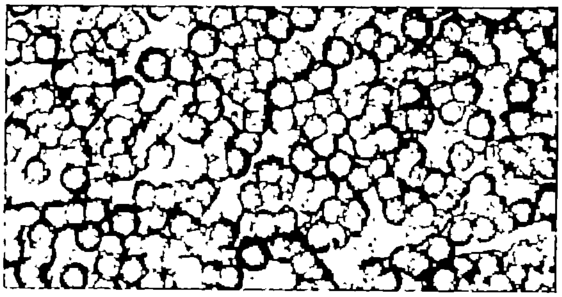

Fig. 1. Electron micrograph of metal surface of 99·99 per cent aluminium formed at 500 V. in 3 per cent boric acid + 0·05 per cent borax at 20° C. Oxide replica. Unshadowed. × c. 2,500

As the thickness of the anodic film is not uniform, it must be easier for the oxide to grow at some points of the film than at others. This indicates that the layer may not be of uniform composition and this has been confirmed. Altenpohl[2] has reported that when anodic alumina films are treated with a hot chromic acid–phosphoric acid solution, part of the oxide dissolves rapidly and part is insoluble. It has now been found that the soluble portion occurs in a central column through the cells and the insoluble in the region of the junction between the cells, that is, the areas where the oxide layer is thinnest. The insoluble material gives sharp electron diffraction patterns and appears to be crystalline γ′ alumina and it is believed that the soluble portion is practically amorphous.

As the temperature of formation is increased, the amount of insoluble crystalline oxide increases considerably. Since such material opposes the radial growth of the cells, it is to be expected that the pattern of cells formed at temperatures near the boiling point of the electrolyte will be less perfect

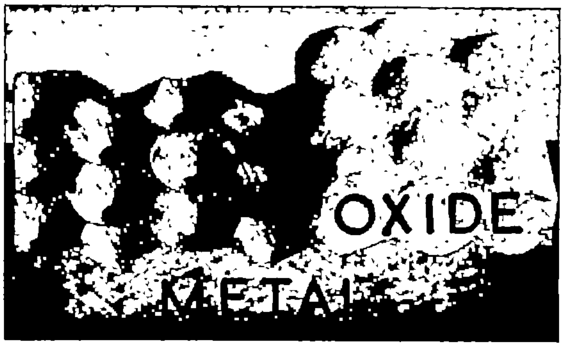

Fig. 2. Idealized structure of anodic alumina films

than those formed at low temperatures. This is found to be the case, although the basic cellular structure, however indistinct, is always detectable.

It is apparent that this type of construction of the oxide layer can explain the growth of porous films on aluminium. If formation is carried out in an electrolyte capable of dissolving the central column of the cells, growth of the oxide can continue, and a structure such as that found by Keller *et al.*[1] will result.

Anodic oxide films formed on tantalum, niobium and zirconium have not been found to exhibit similar structures, but films formed on zirconium are distinctly non-uniform in thickness.

I would like to thank D. J. Stirland, B. Nightingale and R. Bicknell for assistance in carrying out some of the experimental investigations.

Detection of Particles inside Potential Barriers

There appears to be some uncertainty regarding the interpretation of wave functions in classically inaccessible regions, where the total energy is less than the potential energy. The following question is asked often: Can one detect a particle inside a barrier without giving it enough energy to be, classically, in the region of localization?

It can be argued quite generally that one cannot. Localization is a transition to a state represented by a wave packet, construction of a packet requires oscillating functions, and oscillating functions imply real momenta and positive kinetic energies[1]. It is the purpose of this communication to present a thought experiment that illustrates this situation.

Consider a step function potential, with $V = 0$ for $x < 0$, and $V = V_0 > E$, the energy of the state, for $x > 0$. The wave function for $x > 0$ is then $\exp(-\alpha x)$, where

$$\alpha = \sqrt{2m(V_0 - E)}/\hbar$$

Let us consider localization of a particle by having it scatter a photon inside the barrier. We ask whether such localization is possible without a transfer of energy greater than $V_0 - E$ to the particle. One might think that one can go far into the barrier and use arbitrarily long wave-length, low-energy photons. Such a procedure will be shown to be unsuccessful.

Suppose that $I(x)$ is the intensity of photons travelling along the y direction at x, and that $I(x)$ has a maximum somewhere in the barrier. Let there be a collimating system and detector arranged to observe photons scattered through an angle θ. If a scattered photon is observed, the probability, $P(x)$, of it having been scattered at x is proportional to $I(x)$ times the probability of a particle being at x:

$$P(x) \sim I(x)\,\psi^*(x)\,\psi(x) \sim I(x)\exp(-2\alpha x)$$

If we are to claim detection inside the barrier, $P(x)$ must increase as x increases from zero. Therefore $I(x)$ must increase rapidly enough to overpower the decreasing exponential; $I(x)$ must increase faster than $\exp(+2\alpha x)$ toward its maximum. But then the effective width of the intensity distribution is less than $1/\alpha$. We now require that there be little diffraction of photons through an angle θ into the counter, so that we can conclude that most photons observed are indeed scattered. We have then an upper limit on the photon wave-length:

$$\lambda < \frac{1}{\alpha}\sin\theta$$

and a lower limit on the photon momentum:

$$p > h\alpha/\sin\theta$$

But then the momentum transferred to a particle that scatters one of the photons through an angle θ is no less than $h\alpha$, and the energy transferred is no less than

$$(h\alpha)^2/2m = (2\pi)^2\,(V_0 - E)$$

or more than enough to permit the particle to exist in the region $x > 0$.

An Unexpected Effect in Sound Localization

While sound localization by human subjects with unobstructed ears has been extensively explored, little is known of the effects of headgear on this function. Evidence from unpublished work on arctic headwear suggests that localization may be affected independently of threshold sensitivity; and following work on the Army 'combat cap' which failed to show any threshold changes due to the cap (Holding, D. H., and Dennis, J. P., unpublished Ministry of Supply Report, 1955), it was decided to investigate the effect of wearing the cap on the localization of pure 1,000 c./s. tones.

The cap is of light wind-resistant cloth, with ear-flaps loosely secured by a chinstrap. Sixteen subjects, eight research workers and eight soldiers, were each required to localize 128 stimuli of 0·5-sec. duration, at a sound-level of 25 db. (above 0·0002 dyne/cm.^{2}) at the subjects' head, with and without the combat cap. The 2,048 sound stimuli were presented in groups of sixteen stimuli in random order. The stimuli originated from four loudspeakers equidistant from the subject, in eight positions relative to the subject, whose seat was rotated 0°, 45°, 180° and 225°, in order to obviate experimental artefacts due to any acoustic irregularities of the speakers or of the fatigue laboratory in which the experiment was conducted. Localization was by forced-choice among the speakers, which were identified by numbers. A record was also kept of response times.

After transformation of the data by $\sin^{-1}\sqrt{x/n}$, analysis of variance of correct and incorrect responses showed a significant ($P < 0{\cdot}01$) difference between cap and no cap, in favour of wearing the cap. The effect due to the cap interacted with the direction of sound source relative to the subject, the bulk of the improvement lying in the off-front area.

Fig. 1 is a graphical representation of the distribution of correct responses for both cap and no cap

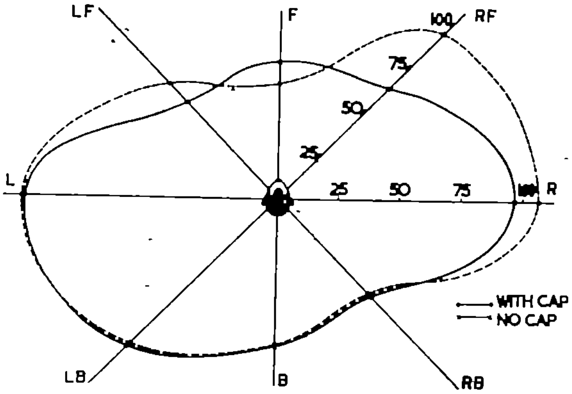

Fig. 1. Effective localization field. (Distance from centre represents number of correct responses.) (Reproduced by permission of H.M.S.O. Crown copyright reserved)

conditions. As in previous work, subjects showed more confusion between front (*F*) and back (*B*), than from side to side (*R* and *L*). Rotation of 0° and 180° relative to the first loudspeaker was more effective than rotation of 45° and 225°. Response times did not discriminate between cap and no cap, but correct responses took significantly ($P < 0{\cdot}001$) shorter times than incorrect responses.

The unexpected improvement due to wearing the cap may be due to phase differences, which are more important than intensity difference below about 2,000 c./s. The wave-length of a 1,000-c./s. tone is of the same order of magnitude as the human head, and the topography of the cap presents an asymmetrical obstruction to sounds from the left and right front areas.

We wish to acknowledge the assistance of Mr. J. Draper in making the statistical analyses.

Ionophoretic and Chromatographic Analysis of Single Dust Particles

IT may sometimes be an advantage to analyse chemically single dust particles occurring with many others of different composition. Minor constituent particles would then be revealed undiluted by the others, and individual variations not obscured. For similar reasons such an analysis might also find other applications in chemical and biological fields.

A few workers have adapted microchemical spot tests to examine individual particles in atmospheric dust[1], 'smog' and fog[2], and air pollution[3]; but otherwise relatively little work appears to have been done in this direction.

A microscopic ionophoretic and chromatographic method has been developed[4] which is carried out in very thin liquid films on clean glass surfaces in a humid chamber. The resolved zones are detected by the 'breath figure' test usually observed interferometrically. Atmospheric dust rapidly contaminates the surfaces if turned upwards. Since 1·4–4·0 mμμgm. has been estimated quantitatively by this method, and the weight of many dust particles falls within its range, it might be possible to analyse them in this way.

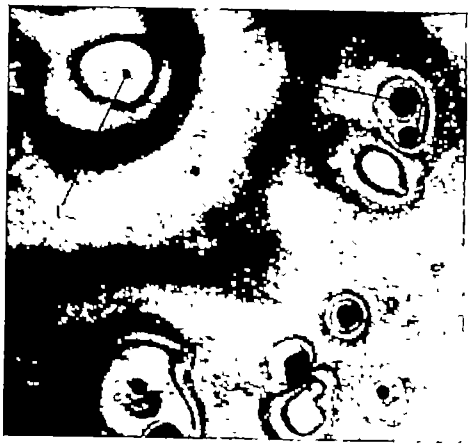

Fig. 1. 'Breath figure' of atmospheric dust particles on a clean glass surface: 1, with central hydrophobic 'halo' surrounded by a hydrophilic 'halo'; 2, condensation on hydrophilic particle. Reflexion interferometry, white light. (× 30)

A single dust particle forms a 'halo' of contamination up to 1 mm. or more in diameter, which may be hydrophobic or hydrophilic according to the composition of the particle and its solubility in the film (Fig. 1). Contrast can sometimes be intensified by warming or by using ammonia vapour, etc., as 'reagents' corresponding to colour-producing reagents. Thick capillary condensation on insoluble dust specks also occurs, and submicroscopic particles can be revealed by this and by halo formation (see also refs. 3, 5).

Halos can be developed further in two ways. They can be enlarged by condensing a 0·1–10μ thick acid or water film on the surface, allowing to stand for 1–10 min. inside the humid chamber, neutralizing with ammonia if necessary, and drying. Concentric rings may be formed (Fig. 2) corresponding to circular chromatographic development on filter paper, and this can be increased further by repeatedly condensing and evaporating the film. In the course of routine separations with this method, accidental dust contamination is sometimes also found to elongate in the direction of film flow, and in a number of cases zones have been observed.

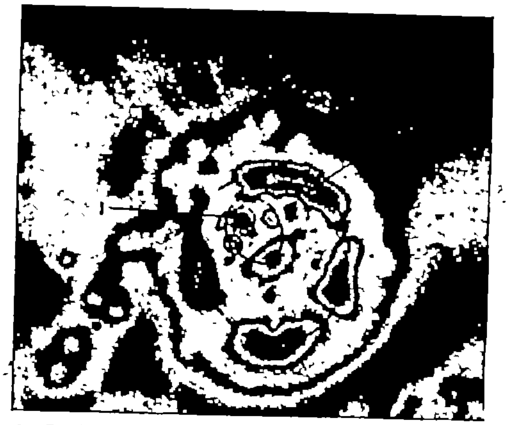

Fig. 2. Dust 'halo' showing: 1, capillary condensation on dust particle; 2, circular development. (× 60)

It should be possible to identify unknown particles by running at the same time as dusts of known composition or standard chemical mixtures. Halo or zone areas might then be taken as a measure of quantity, and the weight of completely dissolved particles calculated. The method might also be suitable for studying radioactive dusts in combination with autoradiography.

My thanks are due to Dr. J. Stern, of the Fountain Hospital, London, S.W.17, for advice, and to Mrs. A. Turner for assistance in preparing the manuscript.

Chromatography by Liquid–Liquid Partition and Liquid–Liquid Interface Adsorption

FOR liquid–liquid partition chromatography with columns a linear relationship exists between the logarithms of corrected retention volumes (R_t) of terms of homologous series and the order n of these terms[1].

Thus:

$$\log R_t \sim \text{lin}\ n \qquad (1)$$

where R_t is defined as the retention volume minus the volume of the mobile phase in the column itself. However, the experimental verification of equation (1) often encounters difficulties in which the carriers of the immobile phases seem to be involved.

An extensive investigation has been carried out in order to gain an insight into the nature of these deviations from ideality. Homologous series of coloured derivatives of aliphatic alcohols, aldehydes, ketones, acids, amines, mercaptans and alkyl halides were used. In these derivatives the occurrence of acid, basic, ionogenic or OH-groups was avoided. Light petroleum, alone or mixed with carbon tetrachloride or benzene, was used as the non-polar phase. A number of polar solvents, including nitromethane, NN′-dimethylformamide, formamide, acetonitrile, 'Methylcellosolve', methanol, propylene glycol, either alone or mixed with each other or with small percentages of water, were used as polar phases. Silica gels were prepared according to Gordon, Martin and Synge (G-gels) or to Nykamp (N-gels), and served as carriers of the immobile phases[2].

It was observed that the amount of loading of the gels with immobile phases relative to their maximum capacity was of the highest importance with respect to the nature of the phenomena. If the gels were loaded over a certain limit, equation (1) was invariably obeyed. Under these conditions all aliphatic series tested could be separated and the individual terms identified by a multitude of variants, each of which displayed its own merits with regard to sharpness of separation or the range of terms which could be separated efficiently. In this way many isomers could be unravelled too (for example, *cis* and *trans* azo-compounds, and syn- and anti-isomers of 2,4-dinitrophenylhydrazones of n aliphatic aldehydes).

Loading the gels with quantities of immobile phases less than the limit indicated above resulted in the simultaneous operation of liquid–liquid partition and liquid–liquid interface adsorption. The participation of the latter is clearly demonstrated by experiments with the N-gels of high capacity (maximum capacity ±3 ml./gm.). Loading these gels to less than ±2 ml./gm. resulted in increased adsorption. This adsorption, occurring in a loading range where the immobile phase is still in excess of the weight of the carrier itself, should be interpreted as liquid–liquid interface adsorption, and its importance in this region is due to the great extension of these interfaces. This view could be confirmed by eliminating the liquid–liquid partition mechanism by using water as the immobile phase. Loading the N- and G-gels below the level of ideal behaviour invariably resulted in a certain retention of the coloured bands.

This liquid–liquid interface adsorption could be exploited as an independent tool for chromatographic separations. On the interface between light petroleum and water the azo-isomers, as well as the dinitrophenylhydrazone isomers, could be resolved.

This variant of chromatography, which is applicable in a reversed-phase form as well, can be carried out in a very simple way and seems particularly suitable for the separation of labile substances because of its mild conditions and uniformity of the adsorption surfaces.

Group Localization Energy and Polarographic Half-Wave Potentials of Aromatic Nitro Compounds

IN a number of publications[1,2] it has been established that the reduction potential of aromatic compounds may be correlated with the π-electron energy change associated with the localization of electron or electrons at different positions of the molecule. Thus in the reduction of quinones the electron-localization took place at the two oxygen atoms, while in the case of aromatic hydrocarbons they were localized at the two p-carbon atoms. In the case of more complex compounds the localization may take place at certain groups of atoms undergoing reduction.

It is now fairly well established that aromatic nitro compounds undergo reduction at a dropping mercury electrode by a four-electron four-proton addition step and in the acid region one sharp polarographic wave is obtained. The process may be represented as:

$$C_6H_5NO_2 + 4e^- + 4H^+ \rightarrow C_6H_5NHOH + H_2O$$

We suggest that the reduction potential should be proportional to the π-electron energy difference between the parent compound and the transition state with four electrons localized on the nitro group. This energy difference may be calculated by the linear combination of atomic orbitals method if we assume that the energy of four electrons localized

Table 1. Group Localization Energy and Half-wave Potentials

Compounds	$(\Delta\pi + \varepsilon)/\beta$	$E_{1/2}$ (volts) referred to standard calomel electrode (ref. 4)
p-Nitrophenol	10·381	0·35
Nitrobenzene	10·230	0·28
p-Nitrobenzoic acid	10·166	0·17
p-Dinitrobenzene	9 934	0·09
p-Nitrobenzaldehyde	10 133	0 24

on the nitro group is equal to $4\alpha_c + \varepsilon$, where α_c is the coulomb integral for carbon and ε depends on the electro-negativities of the oxygen and the nitrogen atoms in the nitro group. We have calculated this energy difference using for the coulomb and resonance (β) parameters of the hetero-atoms in a number of nitro compounds, values given by Orgel *et al.*[3], with the only exception that for N+ we have used the value 1 instead of 2 for the coulomb integral. In Table 1 are summarized the values of the π-electron energy difference (Δπ) in such group localization, together with the half-wave potentials of a number of aromatic nitro compounds.

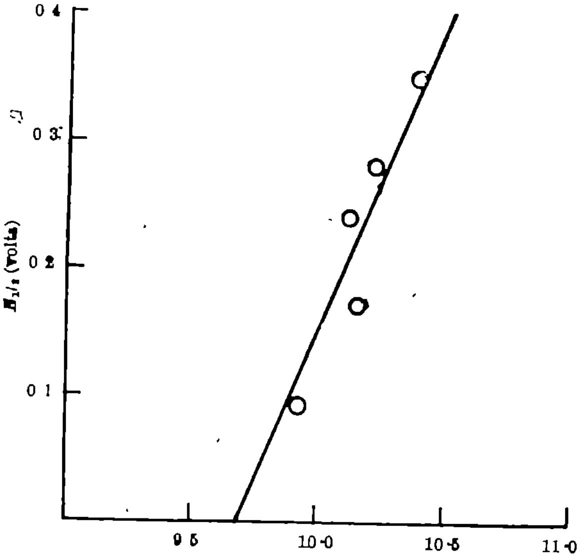

Fig. 1

The $E_{1/2}$ values refer to the medium of pH 2. At higher pH, the $E_{1/2}$ increases for all the compounds, which means that the process is dependent on hydrogen ion concentration, as it should be if the reaction is represented by the equation (1). On the other hand, if we accept Maccoll's suggestion that $E_{1/2}$ is proportional to the energy of the lowest unfilled molecular orbital or orbitals, then it should be independent of pH. A fairly linear plot of $(\Delta\pi + \varepsilon)/\beta$ vs. $E_{1/2}$ (Fig. 1) seems to lend further support to our group localization hypothesis.

Effect of Storage of Methylcellulose on Blood Protein Formation in the Rat

In previous experiments a considerable storage of the methyl-ether of cellulose was observed in the reticulo-endothelial system[1]. As this system plays an important part in protein formation, it was assumed that a change in serum proteins takes place following its administration.

70 male albino rats were injected intraperitoneally with 1 ml. 2·5 per cent methylcellulose (mol. wt. 82,000) dissolved in water twice weekly for five weeks, and the resulting changes in serum proteins were examined by paper and free electrophoresis (Antweiler equipment), directly before administration, and after the last injection.

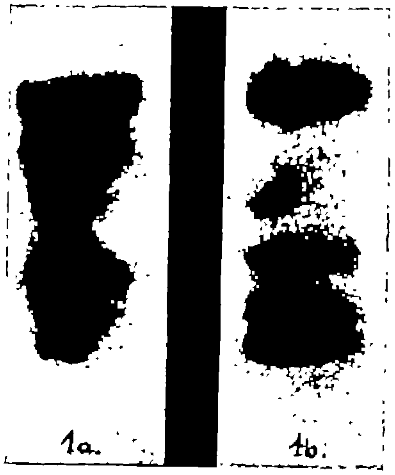

Fig. 1. Paper electrophoretic pattern of rat, 1a, before, 1b, after, methylcellulose treatment

The results of paper electrophoresis show clearly the presence of a new component in the γ-globulin region, only faintly visible in the electrophoretogram of the untreated animal (Fig. 1). The quantitative results prove the significant diminution of total protein following the administration of methylcellulose by a further decrease in albumin and α- and β-globulins. The γ-globulin, determined together with the new fraction increased significantly.

Investigated by free-electrophoresis the γ-globulin resolved itself into two fractions (Fig. 2). The electrophoretic pattern of rat sera treated with methyl-

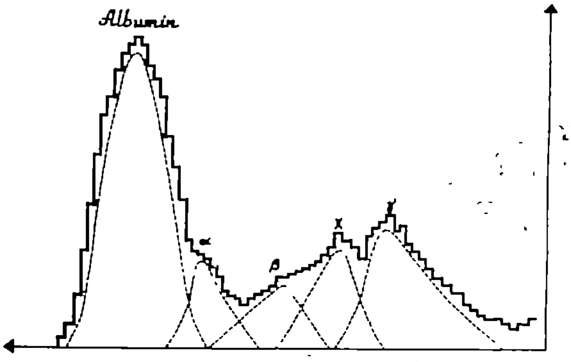

Fig. 2. Free electrophoretic pattern of rat treated with methylcellulose

cellulose is similar to those changes following hyperimmunization of horses with diphtheria toxin[2]. As a result of this observation, the antigenic properties of methylcellulose itself were investigated by the immune precipitation method. If sera of an animal treated with methylcellulose were added to methylcellulose itself, precipitation occurred, but not in the case of normal sera. This result suggests that methylcellulose is a substance possessing antigenic properties. Results of agar gel diffusion experiments confirmed those obtained by electrophoresis: the increase of one and decrease of two antigenic components was also observed by this method.

Details and discussion of this problem will be published in another paper.

The Glass Scratch Effect and Molecular Structure

A CLOSE relation exists between the effect of scratching the wall of a glass container with the tip of a glass rod and the nature of the liquid present. Ordinary round-bottomed 5-ml. test tubes are half filled and the inside wall briskly scratched some fifty times. The result is examined under proper light, the contents stirred, allowed to settle overnight, and the sediment examined. Three types of effect are observed. (1) The rod slips. This is caused by aromatic compounds (except benzene and some simpler derivatives); some other cyclic compounds; open-chain compounds of more than ten carbons approximately. (2) The rod bites and produces glass dust, varying in amount and texture, which immediately disperses. This is caused by non-polar compounds of low weight, most ketones, and sulphuric acid. (3) The rod bites and produces abundant dust which sticks most characteristically to the wall, on which it can be smeared. This is given, in decreasing order, by: (*a*) water and monohydroxyalcohols; (*b*) dihydroxyalcohols, primary amines; (*c*) aliphatic acids, some esters, aldehydes, ketones, secondary amines. This last group is intermediate between (2) and (3).

After sedimentation, the dust yields two typical patterns, with intermediate stages, namely, an even deposit over the whole bottom of the tube, characteristic of aggregated particles, produced by most substances; or a small pellet at the very tip, characteristic of non-aggregated particles, produced only by polar compounds of low weight.

The results are easily reproduced, the only difficulty arising from highly refractile liquids, which make the dust poorly visible. The kind of glass is immaterial. The dust consists mostly of particles 1–2μ in diameter, in intense Brownian motion when of type (3). The effect in water is much decreased by electrolytes, unaffected by non-electrolytes. Solid organic compounds sufficiently soluble in non-polar solvents can also be tested, with comparable results.

It is obvious that class (1) compounds possess molecules of such size or shape, or linked in such a way, as to prevent contact between glass surfaces; classes (2) and (3) do the opposite, the peculiar effect of the latter being due, presumably, to the affinity of 'active' hydrogen for glass[1]. Some occasionally unexpected observations follow. Diacetyl (the structure of which is discussed in ref. 2) gave a slip in spite of its low weight and open chain. Benzoic acid in ether, in which it is linked to the solvent, gave a slip in much lower concentration than in chloroform, in which it forms dimers[3]. The lower alcohols up to butyl were indistinguishable; among the amyl, however, the primary ones were clearly more reactive.

Some findings must be interpreted as manifestations of spontaneous enolization, such as the smear given by some ketones[4], aldehydes, acetic anhydride, contrary to conventional formulæ. The same effect was induced in acetone by 1 per cent ferric chloride (which has been found by Meyer[5] to increase the enol fraction of aceto-acetic ester). Acetylacetone resembled class (1) substances, presumably because of internal hydrogen bonding; acetonylacetone reacted like an OH-compound, in agreement with its newer formula[6]. Finally, mixtures of compounds in varying proportions occasionally offered challenging pictures, such as non-aggregation zones in ethyl ether–chloroform (cf. ref. 7).

In mixtures the effect is seldom additive, in the sense that it does not usually give the expected sum of the effects of single components, but reflects the existence of complexes, or, more generally, physical interaction between molecular species. This manifests itself in slippery zones (for example, in the systems water/sulphuric acid[8], ethyl ether/sulphuric acid[9], acetone/carbon disulphide), which indicate the formation of molecular aggregates; in the unexpected appearance of non-aggregation (4 per cent methanol, or a trace of sulphuric acid, in ether); in the sudden passage of aggregation to non-aggregation (in water–acetone, as soon as the mole ratio exceeds 4 : 1, the point of maximum contraction[10]); in the appearance of the smear type of reaction, in compounds with an ether bond, under the influence of some salts, such as ferric chloride. An outstanding feature of the effect is its considerable variety.

Prevention of Reversal in Mercury-198 Lamps

The green emission line 5461 A. of mercury-198 has been proposed by Meggers[1] as a primary standard of wave-length, and is one of the lines being considered as the basis for a redefined international metre. The line has much to recommend it in its sharpness, isolation from other lines, convenience of excitation, etc.

However, as the line is excited at present in an electrodeless lamp with argon as a carrier gas, there is the serious disadvantage that it very easily suffers reversal which is unsymmetrical, thereby becoming broadened and shifted in wave-length. As a consequence the lamp must be operated and observed very carefully. The temperature must be maintained below about 10° C., although the intensity of the line is reduced and the lamp will not operate at much below 0° C.

To overcome this difficulty an attempt has been made to use the well-known property of molecular gases of reducing the tendency to reversal by depopulation of metastable levels[2]. Lamps have been made and observed which contain as carrier gases respectively hydrogen, nitrogen and mixtures of these gases with argon.

The results are illustrated by Fig. 1. At the right is seen the profile of the 5461 A. mercury-198 line emitted by a small electrodeless argon-filled lamp run in air without special cooling and viewed end on; at the left is the profile of the same line excited and viewed under identical conditions except that the carrier gas was nitrogen instead of argon. A similar improvement was found with hydrogen. In both cases the intensity at peak was considerably enhanced. The argon–hydrogen and argon–nitrogen mixtures showed improvement which was somewhat less but nevertheless great; on the other hand the excitation of the mercury lines compared with the background due to nitrogen and hydrogen was somewhat better with the mixtures.

The wave-length shift due to the presence of nitrogen was measured and found to be less than for argon[3]; that due to hydrogen would also be expected to be small on the basis of measurements made at high pressure[4]. The nitrogen tends to form Hg_2N_2 which, however, under the discharge conditions is in equilibrium with N_2 at sufficient pressure for useful operation of the lamp.

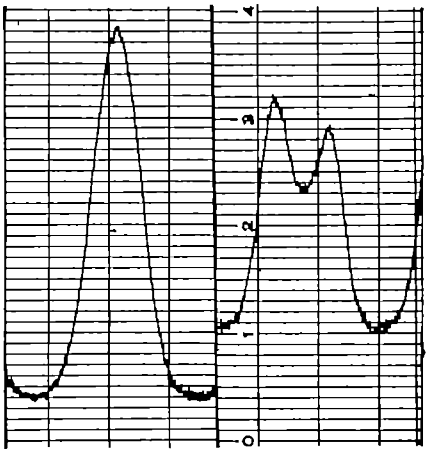

Fig. 1

So far as the experiments have gone it appears that the usefulness of the mercury-198 green line as a standard or for length measurement would be greatly increased by the method of preventing reversal described. A study of such matters as the life of the lamp, the importance of the slight background, the exact wave-length emitted, etc., is in progress.

Unloading Effects in Copper Single Crystals

Haasen and Kelly[1] have observed a small yield point on retesting previously strained single crystals of aluminium and nickel at the same or lower temperatures than the initial deformation. The effect occurred only when the crystals were unloaded between tests, and no yield point was found at low stresses. Annealing at 300° K., between tests at 90° K., increased the magnitude of the yield phenomenon and much larger yield points were observed when the second deformation was carried out at a lower temperature than the first. Haasen and Kelly attributed the effect to the rearrangement of dislocations during unloading.

The present work was undertaken to investigate further the phenomenon in copper single crystals, and, in particular, to determine in more detail the effect on the magnitude of the yield point of (*a*) partial unloading and (*b*) annealing between tests.

Single crystals of copper were prepared in a split graphite mould by the Bridgman technique from spectroscopically pure wire. After electropolishing, tensile tests were carried out in a motor-driven hard beam machine at a variety of temperatures between −195° C. and 200° C.

Experiments were first performed in which frequent unloading tests were made at small strain increments during the whole stress–strain curve at various temperatures. The overall shape of the curve was identical with that of specimens tested continuously at the various temperatures; in detail, however, the two curves were different in that a yield point was observed on retesting after unloading during the linear and parabolic hardening regions. The stress–strain curve after the yield point returns to the extrapolation of the curve obtained prior to unloading. No yield points were observed at any temperature on retesting during the easy glide stage of deformation. The magnitude of the yield point was directly proportional to the flow stress and independent of the temperature of testing, a constant value of (stress before unloading/stress on retesting) of 0·986 being obtained between −195° C. and +100° C. There was no dependence of the ratio on the time for which the specimen was unloaded at any temperature. During experiments in which the load was only partially removed a linear relationship was found between the amount of unloading and the ratio of the flow stresses, indicating that the

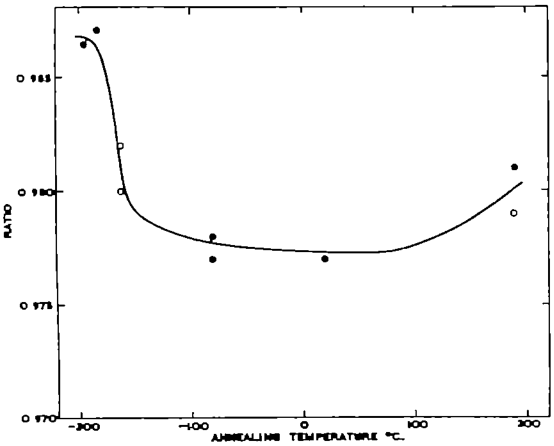

Fig. 1. Average ratio of flow stress before/after unloading at −195° C., after intermediate annealing for 30 min. at various temperatures

size of the yield point is directly governed by the reduction in stress during unloading. A striking feature is that the same linear relationship is obtained at different temperatures between −195° C. and +20° C.

The effect on the size of the yield point of interposing an annealing treatment between unloading and retesting has been examined. The ratio of flow stresses obtained at −195° C. after intermediate ½-hr. annealing treatments at higher temperatures is shown in Fig. 1 and shows a large well-defined drop between −180° C. and −120° C. from 0·986 to 0·977. The shape of the yield phenomenon on retesting at −195° C. is markedly altered by annealing at above −120° C., the yield drop being replaced by a much longer, almost horizontal region in the stress–strain curve. The amount of unloading has no significant effect on the size of the yield phenomenon after annealing at above −120° C.

The unusual nature of the experimental results suggests that the effect is due to a dislocation–dislocation interaction, and the absence of the effect during easy glide suggests that it is associated with the motion of dislocations on intersecting slip planes. A basic problem facing all theories of work hardening is to explain why the large numbers of dislocations piled against barriers during the deformation do not relax completely when the applied stress is removed, giving large reverse plastic flow. Obviously some locking process occurs during unloading which prevents the large-scale running back of dislocations under the back stress and it is probable that it is this locking process which is responsible for the yield point on retesting. Experimental evidence indicates that the size of slip line formed during the linear hardening region is much too large for all possible Lomer–Cottrell sessile dislocations to have been formed during the deformation, as is required by Friedel's[2] theory of linear work-hardening, and the possibility exists, therefore, of the formation under the back stress of new sessile dislocations during unloading. These prevent the remaining dislocations in the active system from running back, so that large reverse plasticity cannot occur. Energy is released during the formation of the new sessile dislocations[3] and hence a larger stress is required to dissociate them.

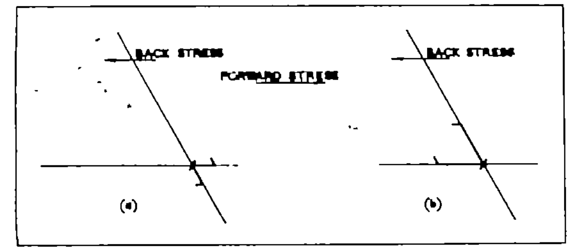

Fig. 2. Sessile dislocation formed on unloading with apex (a) in the direction of the back stress and (b) in the direction of the forward stress

The increased effect obtained at −195° C. after annealing between tests at above −120° C. may be due to the thermally activated reversal of the apices of the new sessile dislocations. Stroh[3] has shown that, in copper, Lomer–Cottrell sessile dislocations break up only by dissociation and that this process occurs more easily if the apex of the sessile points in the opposite direction to the stress. During unloading at −195° C. sessile dislocations are formed in position (a), Fig. 2. Suppose that, on annealing at between −180° C. and −120° C., sufficient thermal energy is available for reversal to occur to position (b) under the back stress. On retesting at −195° C. dissociation can occur only from position (a) and hence sufficient stress must be applied to reverse the sessile without assistance from thermal fluctuations and consequently a large yield effect is obtained. If the whole experiment is carried out at −195° C. no reversal occurs on unloading, and hence on retesting the sessile is already in position (a) and a high ratio, 0·986, is obtained. During tests at above −120° C. the sessile changes from position (a) to (b) under thermal activation during unloading and similarly easy reversal occurs on retesting, so that dissociation again occurs with a high ratio of flow stresses, 0·986.

A full account of these experiments is being published elsewhere.

Starch Gel Electrophoresis in a Discontinuous System of Buffers

The recently developed starch gel electrophoresis has proved to have a resolving power superior to any other type of zone electrophoresis[1–4]. I have applied this technique to the study of highly purified toxins[5], but further work on the separated and eluted fractions of the toxin of *Corynebacterium diphtheriae* in tissue cultures and in animals indicated that the resolution of these proteins was not completely satisfactory in the buffer (0·03 *M* boric acid and 0·012 *M* sodium hydroxide) normally used in this type of zone electrophoresis. A more suitable system was found with a mixture of *tris*-(hydroxymethyl)-aminomethane-citrate (*tris*-citrate) used in conjunction with a boric acid buffer. Preliminary results obtained with toxins, enzymes and human sera are briefly reported here.

The gels are made from a buffer containing 0·076 *M* *tris*-(hydroxymethyl)-aminomethane (Sigma 121) and 0·005 *M* citric acid (*p*H 8·65). These gels

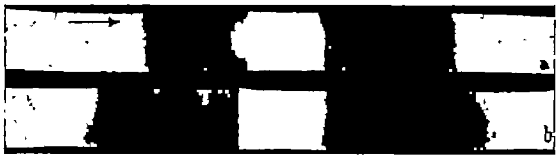

Fig. 1. Concentrated crude diphtheria toxin (staining with amido black 10*B*) subjected to electrophoresis for 3 hr. at a potential gradient of 6 V./cm.; (*a*) in sodium hydroxide/boric acid buffer; (*b*) in *tris*-citrate buffer

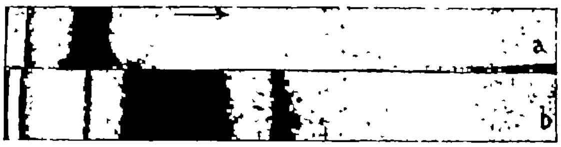

Fig. 2. Horse radish peroxidase (stained with benzidine–hydrogen peroxide reagent) subjected to electrophoresis for 3 hr. at a potential gradient of 6 V./cm.; (*a*) in sodium hydroxide/boric acid buffer; (*b*) in *tris*-citrate buffer

are used as a discontinuous buffer system with 0·3 *M* boric acid and 0·05 *M* sodium hydroxide in the electrode vessels. A markedly better separation of the materials tested was obtained with this discontinuous system than in either the usual continuous sodium hydroxide/boric acid buffer system or in a continuous system using the *tris*-citrate acid buffer. Figs. 1*a* and 1*b* represent the patterns obtained with crude diphtheria toxin when subjected to electrophoresis by the two systems. Figs. 2*a* and 2*b* show the results with horse radish peroxidase (Nutritional Biochemicals Corp., Cleveland, Ohio).

In order to relate the new components to those previously separated and thus to determine their origin, the toxin[1] was subjected to electrophoresis in a gel prepared in the following manner: a large tray was first filled with a starch prepared in the *tris*-citrate buffer and allowed to solidify. One-half of this gel was cut out and in its place starch prepared with the usual buffer was poured and allowed to solidify. Then a filter paper soaked in the toxin was applied across the gel so that the same material was subjected to identical electrophoretic conditions in both buffers. In this way, protein zones can be traced in both gels. Fig. 3 illustrates such an experiment. The striking difference in the resolution can be easily seen. On subjecting the same material to immunoelectrophoresis[4,5], as many as eighteen separate lines of flocculation could be recorded with a commercial antiserum. A more detailed description of these results will be given in connexion with the studies on diphtheria toxin.

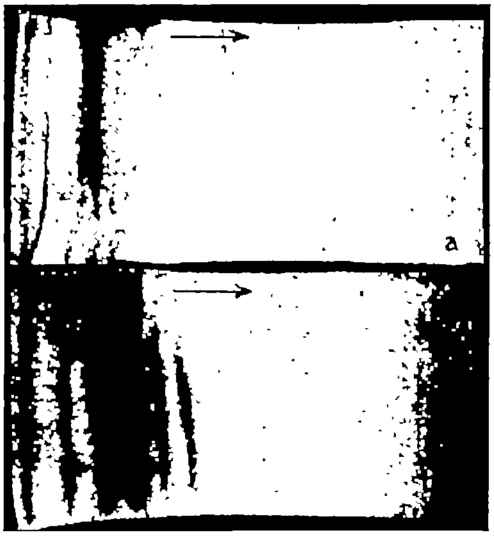

Fig. 3. Concentrated crude diphtheria toxin (staining with amido black 10*B*) subjected simultaneously to electrophoresis for 3 hr. at a potential gradient of 6 V./cm. in (*a*) sodium hydroxide/boric acid buffer, in (*b*) *tris*-citrate buffer

So far as human serum is concerned, the pattern is very similar to that obtained with the usual system. There is no interference with the determination of the serum haptoglobin groups even after the addition of hæmoglobin. However, sera of haptoglobin[6] type Hp 1–1 differ in that new distinct protein bands can be seen between slow alpha-2 globulin ($S\alpha$-2) and beta-globulin regions. This is especially true in the case of the newborn. The gamma globulins migrating backwards stain less intensely in the new buffer system. Studies with the aid of two-dimensional electrophoresis and immunoelectrophoresis are in progress to establish the origin of the new zones.

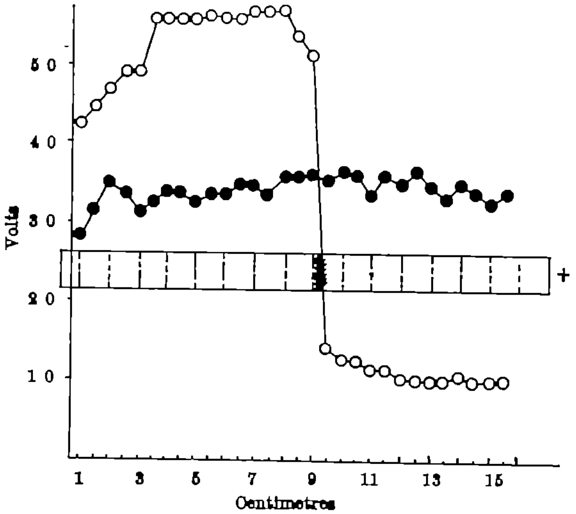

Fig. 4. Potential gradients measured with a vacuum tube voltmeter at 0·5-cm. intervals along the gels at the same time, without any material applied. Full circles (—●—●—●—) represent the mean potential gradients between the adjacent electrode-pairs in sodium hydroxide/boric acid buffer. The open circles (—○—○—○—) show the potential gradients in *tris*-citrate buffer. The cross-hatched area represents the position of the coloured band at the time of measurements

It must be pointed out that a visible boundary moves through the gel towards the cathode at a rate of about 1 cm./hr. at a gradient of 6 V./cm. This boundary is visible because a brown-coloured material accumulates at it which increases in intensity as the boundary moves along the gel. This boundary is probably caused by the replacement of the citrate ions in the gel by borate ions from the electrode vessels. The migration of the proteins appears faster in this system, and excellent results are obtained after a 3-hr. run. This increased rate of migration is probably due to the changes in voltage accompanying the migration of the coloured boundary (Fig. 4).

The nature of the process which causes this system to give improved resolution is being investigated with the view of finding a continuous system of the same resolving power. I feel that this system has definite application in work with very complex protein mixtures as well as in work with sera of the haptoglobin 1–1 type, and particularly in newborn infants, who usually lack haptoglobin.

I am greatly indebted to Dr. O. Smithies for his interest and advice during the experiments, and to Mrs. E. Poulik for able technical assistance. This work was supported by a grant awarded by the Department of National Health and Welfare.

Chlorogenic Acid Metabolism in Cider Fermentation

CHLOROGENIC ACID is invariably found in cider-apple juices[1], and our unpublished results show that in some varieties it may constitute more than 0·25 per cent (w/v) of the juice. Paper chromatographic examination of a number of ciders showed that chlorogenic acid frequently disappeared during fermentation. Where caffeic acid was present in the original juice, this acid also disappeared, and these changes occurred only in ciders which showed reduction of quinic acid to dihydroshikimic acid. It seemed likely that chlorogenic and caffeic acids were metabolized by the *Lactobacillus* found capable of reducing quinic acid to dihydroshikimic acid, namely, *L. pastorianus* var. *quinicus*[2,3].

Work with partially disintegrated cells of this strain indicated that the first stage in the metabolism of chlorogenic acid was hydrolysis to caffeic and quinic acids. Both products were further metabolized, and the metabolism of caffeic acid was investigated by the use of growing cells. A pure culture of the same organism was inoculated into a basal medium[3] with the addition of 0·025 per cent caffeic acid. After 7 days incubation at 25° C. under conditions of reduced oxygen tension, the caffeic acid was completely metabolized. In a control flask, to which killed organisms were added, the caffeic acid remained unchanged. Quantitative oxidation with potassium permanganate of the uninoculated and inoculated media after incubation suggested saturation of the caffeic acid side-chain[4]. Paper chromatographic examination showed that two main products *A* and *B* were present; they were extracted with ether after acidification of the medium and were separated on a silica gel column. *A* and *B* reacted on paper chromatograms with the following spray reagents: (1) 1 per cent ferric chloride–1 per cent potassium ferricyanide (blue colour); (2) 1 per cent ferric chloride (green colour) followed by exposure to ammonia vapour (purple colour); (3) ammoniacal silver nitrate (black in the cold); (4) diazotized *p*-nitraniline (orange). *A* gave a violet colour with 1 per cent sodium borate followed by 0·4 per cent ethanolic 2 : 6 dichloroquinonechlorimide while *B* gave a maroon colour; *A* was acidic to bromocresol green while *B* at the same concentration was not detectable with this indicator.

Reactions (2) and (3) suggested that both *A* and *B* were compounds of the catechol type. *A* had the same R_F values as dihydrocaffeic acid in 2 per cent acetic acid[5] and in benzyl alcohol–*iso*-propyl alcohol – tert.-butyl alcohol – water – formic acid (3 : 1 : 1 : 1 : 2 per cent)[6], and these two substances showed identical reactions with the spray reagents mentioned above. *A* after re-crystallization from hot water and from ether–benzene had a melting point of 139° identical with that of dihydrocaffeic acid. Elementary analysis of *A* gave C, 59·51 per cent; H, 5·63 per cent; $C_9H_{10}O_4$ requires C, 59·33 per cent; H, 5·50 per cent.

B had a R_F value in the benzyl alcohol solvent of 0·93 while that of *A* was 0·82. This was in keeping with loss of the carboxyl group from *A* to give *B*. *B* was isolated and crystallized from petroleum ether as thin needles with m.p. 38–39°, which rapidly turned brown in air. Ethyl catechol has m.p. 39° [7,8] and rapidly turns brown in air. *B* and a synthetic specimen of ethyl catechol had identical R_F values in the two solvents mentioned above and a mixed melting-point showed no depression. *A* and *B* were therefore identified as dihydrocaffeic acid and ethyl catechol respectively.

It is possible that *p*-coumaryl quinic acid, also present in cider-apples[9], may be metabolized in a similar manner to chlorogenic acid for addition of *p*-coumaric acid to the same basal medium, and inoculation with the same strain of lactobacillus showed that this acid was metabolized.

Loss of Immunizing Power of Staphylococcal Toxin during Routine Toxoiding with Formalin

IN order to render staphylococcal toxic supernatants safe for use as active immunizing agents, it is customary to incubate them with formalin, in concentrations of 0·3–0·8 per cent at temperatures between 37° and 40° C. for periods of up to two weeks[1,2].

In the work to be described, the effect of this process on the antigenicity of a protective factor in staphylococcal toxic supernatants was examined in mice.

The staphylococcal toxic supernatant used had been prepared from cultures of strain *CN*56, grown for three days on modified Dolman's medium in an atmosphere of oxygen containing 20 per cent carbon dioxide, and was stored at 2° C. with 0·02 per cent

Table 1

Immunizing agent	Dilution	No. of experiments	Serum alpha antihæmolysin titre before challenge	No. of survivors/ No. challenged
Toxin	1/50	2	2	20/32 (62%)
	1/100	2	0·12–1	8/23 (35%)
	1/200 or 1/250	2	0·25–0·5	4/30 (13%)
Toxoid	1/1	3	0·12–0·5	5/40 (12%)
	1/5 or 1/10	2	0·1	5/29 (17%)
	1/100	1	0·5	2/10 (20%)
Nil (Control)	—	3	< 0·1	7/43 (16%)

In the group immunized with 1/50 toxin, the protection was highly significant ($P < 0.001$); in the group immunized with 1/100 toxin, it was not significant ($P = 0.08$).

thiomersal as a preservative. It will be referred to as 'toxin'.

A portion of toxin was mixed with 0·35 per cent formalin, incubated at 37° C. for five days, and then stored at 2° C. ('toxoid').

White mice weighing 15–20 gm. were used as experimental animals. For toxicity tests and immunization, 0·5 ml. vol. of the preparations or their saline dilutions were injected subcutaneously over the back. Immunization consisted of two injections given one week apart. Ten to twelve days after the second immunizing injection, samples of blood were taken from the tails for the estimation of alpha antihæmolysin. The animals were then challenged by the intraperitoneal route, with 100 million staphylococci of a recently isolated coagulase-producing strain, grown overnight on agar slopes at 37° C. and suspended in 1 ml. saline in which 1 per cent human fibrinogen and 1 per cent fresh human plasma had been dissolved[3]. The animals were observed for seven days after challenge. Alpha hæmolysin and antihæmolysin titrations were performed according to the method of Burnet[4]; mouse sera were tested, without preliminary heat inactivation, against the international reference standard.

Toxoiding reduced the hæmolytic titre of the toxin from 1/300 to 1/3. The toxin killed 90–100 per cent of the mice in a dilution of 1/20, and 10–40 per cent in a dilution of 1/50. Loss of fur, severe scarring and occasional ulceration developed at the site of injection in mice surviving the administration of toxin diluted 1/50; moderate and mild reactions of similar nature followed injections of 1/100 and 1/200 dilutions, respectively. Injections of toxoid, undiluted or diluted, did not kill any of the animals or cause local reactions.

Results of representative immunization experiments are given in Table 1. Significant protection against death was evident in the group immunized with toxin diluted 1/50, and some protection probably in the group given toxin diluted 1/100, but none in the groups given toxoid in dilutions ranging from 1/1 to 1/100. The antigenicity of the protective factor was, therefore, grossly reduced during toxoiding.

Alpha antihæmolysin titres were variable. The response in mice receiving toxoid was somewhat lower than in mice immunized with toxin, but some antihæmolysin was produced even in the animals given the smallest amount (1/100 dilution) of toxoid. During the process of toxoiding, therefore, alpha hæmolysin appeared to maintain its antigenic potency better than the protective factor did, suggesting that the two antigens, and their corresponding antibodies, may not have been identical.

Batches of toxin and toxoid produced from other strains of staphylococci were also tested in mice for their ability to protect the animals against the effects of challenge by the same technique, and for their ability to produce alpha antihæmolysin. The results were in accordance with those described.

Secretion of Progesterone by the Adrenal Gland

THE importance of progesterone in adrenal function has been emphasized by a number of investigators. Beall and Reichstein[1] isolated a small amount from adrenal extracts, and more recently Hechter and others[2], using the perfused cow adrenal gland, showed that progesterone is an important intermediary metabolite for the synthesis of the adrenal corticoids. While the work reported here was in progress, Klopper *et al.*[3] demonstrated the presence of pregnanediol in the urine of ovariectomized women, but not in that of ovariectomized, adrenalectomized women. These, and other workers[4], have inferred that the pregnanediol in these cases is of adrenal origin. The following results support this conclusion inasmuch as they show that the adrenal gland can secrete progesterone.

Adrenal venous blood was collected from animals under pentobarbitone sodium anæsthesia. The blood was cooled over ice during collection, and the plasma separated by centrifugation. This plasma was then treated with sodium hydroxide[5] to give a final concentration of 0·5 per cent w/v. It was extracted twice with an equal volume of ether, and after evaporation of the ether extract to dryness, the residue was dissolved in 70 per cent methanol and passed through a nine-tube counter-current distribution system of methanol and light petroleum. This system was so arranged that progesterone had a partition coefficient of 1. The contents of the five central tubes were combined and concentrated, and this material was then chromatographed on paper. The spots were detected by ultra-violet contact photography, and those with the same R_F value as progesterone were eluted from the paper and estimated by ultra-violet spectrophotometry. The results, corrected for losses in the extraction procedure, are presented in Table 1.

Although progesterone has been detected in all cases, the number of observations made within the groups is too small to warrant a correlation of the progesterone-level with either the sex or the reproductive state of the animal.

The chemical identity of the progesterone extracted from the adrenal venous blood was based on: (1) the partition coefficient in the counter-current distribu-

Table 1

Species	Age, sex and reproductive history	No. of animals	Mean progesterone concentration μgm./100 ml. plasma (range in brackets)
Cattle	69–day old male	1	46·5
	334–day old male	1	10·4
	210–days pregnant female	1	46·8
	240–days pregnant female	1	30·8
Sheep	Non-pregnant female	4	9·8 (9·2–10·9)
	Ovariectomized non-pregnant female	3	23·5 (17·2–33·2)
	Pregnant female	4	16·0 (10·9–24·1)
	Ovariectomized pregnant female	1	9·4
	Adult male	4	13·0 (4·5–26·6)
	Castrated adult male	3	7·5 (3·4–13·4)
Pig	179–day old male	1	40·6

tion system; (2) the R_F value on the paper chromatogram; (3) the ultra-violet absorption spectrum of the chromatogram eluate. The pooled chromatogram eluates obtained from the two pregnant cows also gave an infra-red spectrum identical with that of progesterone.

While the level of progesterone in the adrenal venous blood is 10–50 times less than the corresponding corticoid level, it is 10–100 times greater than the concentration of progesterone in arterial blood collected at the same time. These results therefore show that the adrenal gland secretes progesterone.

We wish to thank Dr. R. K. Callow for carrying out the infra-red analysis, and Mr. L. E. A. Rowson for performing some of the operations.

Control of Humoral Factors of the Zona Glomerulosa of the Adrenal Cortex

Selye has reported[1] that intraperitoneal injection of hypertonic saline resulted in characteristic changes in the zona glomerulosa of rat's adrenal gland. Broadening of the zona, blurring of cell outlines, foamy cytoplasm and swollen nuclei were seen in histological specimens. The fact that the zona glomerulosa can be stimulated by the sudden flooding of the organism with sodium chloride is rather striking in view of the statement that low sodium diet causes hypertrophy of this zone[2–4]. The effect is characteristic of sodium chloride, since other hypertonic solutions do not have the same action[1]. Kovács *et al.* have shown that the effect can be prevented by pretreatment with chloropromazine or by hypophysectomy[5,6].

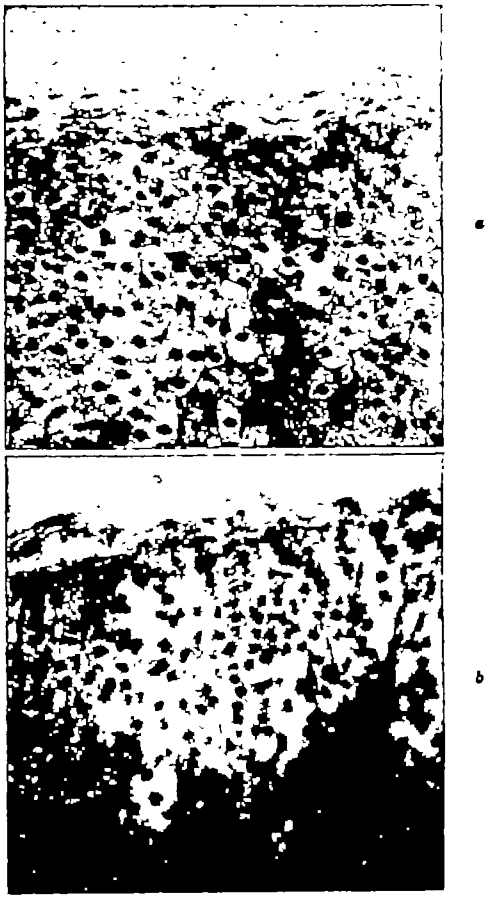

Fig. 1. *a*, Adrenal cortex of hypophysectomized rat treated with hypertonic saline *b*, Adrenal cortex of rat with transplanted hypophysis treated with hypertonic saline. Note increased width of zona glomerulosa

Since these changes occur only in the presence of the pituitary, it may be assumed that one of the hormones of the anterior lobe, either a special corticotrophine[1] or another substance, might be responsible. Normal adrenocorticotrophic hormone is rather unlikely, because similar amounts of hypertonic glucose or urea representing nearly a fatal dose fail to bring about the changes. Presumably, the release of the effective substance from the pituitary is due to a specific stimulating action of hypertonic sodium chloride. The stimulating action of this stressor may ensue either through neural (intense pain) or humoral routes. Our experiments were designed in order to clarify this question.

Sixteen hypophysectomized male rats were given 4 ml. of a 10 per cent sodium chloride solution intraperitoneally, 15 days after the operation. The animals were divided into two groups. One group served as control. To the rats of the other group freshly removed rat's pituitaries (three per rat) were implanted subdermally 24 hr. before the injection of hypertonic sodium chloride solution. One hour after the injection the animals were killed and their adrenals were removed for histological study. The specimens were fixed in 4 per cent formalin for subsequent staining with hæmatoxylin–eosin. Quantitive evaluation of the results was made by karyometric examinations. Within the zona glomerulosa two diameters of 100 unselected nuclei were measured

Table 1

Group	No. of nuclei measured in the zona glomerulosa	Mean of log volume of nuclei	Probability
Hypophysectomized	800	2·0748 ± 0·1319*	$0\cdot001 < P < 0\cdot01$
Hypophysectomized + transplanted	800	2·7017 ± 0·1318*	

* Standard error of the mean.

with the aid of an ocular micrometer. From the diameters the volume of the nucleus representing a rotation ellipsoid could be calculated by means of the formula $4ab\pi/3$, where a means the shorter, b the longer diameter of the ellipse. Since the values so obtained do not correspond to the normal distribution, the logarithm was used instead of the absolute value. The logarithm was determined by a nomogram[7].

The results are given in Table 1. It may be seen that the nuclei of the zona glomerulosa in the 'transplanted' rats are larger than in the controls. The difference proved significant on statistical evaluation. Qualitative histological examination showed, too, that the changes reported by Selye were present in animals treated with pituitary grafts (Fig. 1).

The cells of the zona glomerulosa produce the hormone affecting the electrolyte balance (aldosterone)[8]. In present experiments the adrenal changes observed in the 'transplanted' rats fully resemble the histological changes corresponding to increased aldosterone secretion[9]. Our observations point to the importance of the pituitary in the genesis of these changes occurring after administration of a specific stressor by the humoral route. Further, our observations agree with the view that the pituitary participates in the regulation of aldosterone production. Further observations are being made to discover which of the pituitary substances cause the adrenal alterations described above.

Variations in Human Serum β-Globulins

GENETICALLY controlled variations in the haptoglobins (α_2-globulins) of human serum have been demonstrated by electrophoresis in starch gels[1-3]. The frequencies of the genes controlling these proteins probably differ from one racial group to another[4]. Inherited differences in the serum proteins of dairy cattle have also been established using the same method, but in cattle the variable proteins prove to be β-globulins[5]. The frequencies of the genes involved differ in different breeds. This communication reports variations in human serum β-globulins which have now been found.

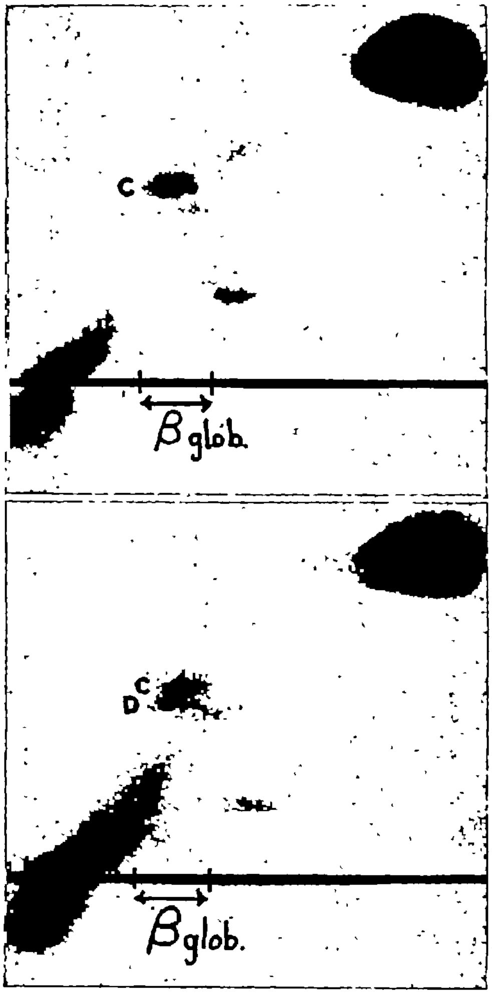

Fig. 1. Photographs of the results of two-dimensional electrophoresis experiments with (upper photograph) serum from a young White female, and (lower photograph) serum from a young Negro female. An additional β-globulin (D) is present in the serum from this Negro

The β-globulin differences were noticed when sera were being investigated by the one-dimensional starch-gel electrophoretic method[1] chiefly used for the previous studies of human and cattle serum proteins. However, they can be established only with certainty when the two-dimensional electrophoretic method[6] is used. Fig. 1 illustrates the differences which can be observed. The upper part of the figure shows a photograph of the result of a two-dimensional electrophoretic experiment with serum from a young white female from Toronto. Four β-globulins (A, B, C and E) can be demonstrated in this serum. β-globulin C (labelled in the figure) is quantitatively much the most predominant. The lower part of the figure shows a photograph of the result obtained with serum from a young Negro female from New York. An additional β-globulin (D) is present in this serum, which migrates a little less rapidly than β-globulin C both on filter paper and in starch gel. When both β-globulin C and β-globulin D are demonstrable in a serum sample they appear to be present in approximately equal amounts in our limited experience to date.

The presence of β-globulin D has been established with certainty in serum from two female Negroes from New York (out of 22 males and 27 females tested), and in serum from four male and one female Australian aborigines (out of 17 males and 6 females tested). β-Globulin D has not been demonstrated in the serum from any of several hundred Canadians (largely of European ancestry) which have been studied, chiefly by one-dimensional starch-gel electrophoresis. These results suggest the existence of considerable racial differences in the frequency of occurrence in the serum of β-globulin D, and indicate that its presence may well prove to be genetically controlled.

I am grateful to Drs. Ralph E. Engle, jun., and James H. Pert of the New York Hospital, New York and to Dr. William R. Horsfall of the Commonwealth Health Laboratory, Cairns, Australia, for their kindness in sending me serum for study.

Serological Studies on *Fusarium oxysporum* Schl. emend Sn. et H.

Morphological recognition of species of fungi which cause plant diseases present few problems, and it is usually not necessary to use serology in diagnosis. However, within a morphological unit physiological differences exist, and it might be possible to apply sero-diagnostic methods in distinguishing physiological races.

We have studied this problem on various physiological races of *Fusarium oxysporum* Schl. emend Sn. et H., which cause vascular browning and wilting of different host plants. Generally, cross-infection is not possible; for example, isolates of the fungus from *Pisum sativum* do not attack *Lupinus luteus* nor do those from *Lupinus luteus* attack *Pisum sativum*.

Single spore cultures of the isolates were grown on synthetic liquid media (Richard's and Czapek's solutions). Antisera were prepared by intravenous injection into rabbits of suspensions of microconidia, culture liquids and extracts of mycelia. Some rabbits produced specific antibodies which could be demonstrated best in gel diffusion precipitin tests[1,2]. Culture liquids seemed to be the most suitable test antigens in the precipitin tests.

The five tests illustrated in Fig. 1 were carried out simultaneously in one Petri dish; agar was poured into five small glass rings (27 mm. diam.) which had been glued with 'Araldite' to the bottom of the Petri dish. Several holes (4 mm. diam.) were punched into each agar plate. These reagent reservoirs were filled with antisera against *Fusarium oxysporum* f. *lupini* (Linf.) Sn. et H. and *Fusarium oxysporum* f. *pisi* (Linf.) Sn. et H. (further on designated as L and P respectively) and with the test antigens from these two isolates (l and p). The plate in the centre of Fig. 1 shows the specific precipitation pattern between L and l and between P and p. Frequently, there also appear lines, which represent antigens common to l and p.

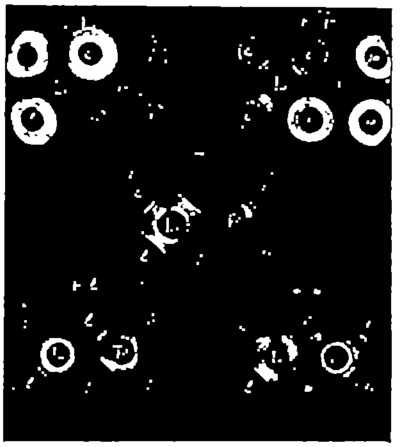

Fig. 1. Comparison of the culture liquids of *Fusarium oxysporum* f. *lupini* (l) and *Fusarium oxysporum* f. *pisi* (p) in gel diffusion precipitin tests. In the two plates above the agar is mixed with the antisera L and P, respectively; in the plates below with the antigen l and p

When the agar has been mixed with L before pouring (Fig. 1, $+L$), the antigens diffusing from the reservoirs containing l are precipitated in a halo around the hole and no specific line between L and l is formed (specific inhibition of precipitation[3]). The specific reaction between P and p, however, is not inhibited by the presence of L and still results in a precipitation line. The reciprocal pattern is formed if the agar is mixed with P (Fig. 1, $+p$). Analogous results can be obtained by introduction of the antigens into the agar (Fig. 1, $+l$ and $+p$).

Further investigations are in progress, and full details will be published later.

Effect of Acetylcholine and Quinidine on Atrial Cellular Potentials

Briscoe and Burn[1] have shown that acetylcholine will restore the spontaneous contractions of rabbit atria which have been arrested by quinidine. Armitage[2] has suggested that quinidine impairs repolarization by rendering the cell membrane less permeable to potassium ions, and acetylcholine restarts the tissue by restoring the potassium permeability. However, Weidmann[3], Johnson[4] and Johnson and McKinnon[5] have demonstrated that in cardiac muscle quinidine predominantly affected the depolarization phase of the action potential. The maximum rate of rise of the action potential was grossly decreased with little or no concomitant change in the membrane resting potential, indicating that the drug had a direct effect on the sodium-carrying system.

The obvious possibility exists that the restarting action of acetylcholine is due to an effect on the sodium-carrying system. Using the intracellular microelectrode technique (experimental details previously described[4]), we examined the effects of acetylcholine on isolated rabbit atria exposed to quinidine. The effects of quinidine sulphate ($2 \cdot 5 \times 10^{-6}$ w/v) were similar to those described for the guinea pig ventricle[4]. After 10-min. exposure to the drug the tissue lost its spontaneous rhythmicity and became electrically inexcitable; when acetylcholine chloride 10^{-6} was added the electrical excitability was restored, as evidenced by the transient appearance of action potentials. No accompanying change in membrane resting potential was detected. With repeated doses (10^{-6}) of acetylcholine the tissue regained its spontaneous rhythmicity.

We have also examined the effects of quinidine sulphate and acetylcholine on the sodium-carrying system by observing their actions on the maximum rate of depolarization of the action potential, which is an index of the sodium current[3,6]. Changes in the rate of recovery of the sodium-carrying mechanism were revealed by alterations in the maximum rate of depolarization of an isolated action potential evoked by an extra shock interposed between the sixteenth and seventeenth driving stimulus (rate 150/min.).

When treated with quinidine sulphate, $2 \cdot 5 \times 10^{-6}$, it was possible to evoke an extra action potential of markedly diminished rate of rise at a time when the repolarization of the previous action potential was completed, which incidentally indicated a dissociation between repolarization and the restoration of the sodium-carrying system. Acetylcholine chloride 10^{-6} increased the maximum rate of rise of both the normal and the extra action potentials, the latter being affected to a greater extent since the two values were often identical. As the extra action potential was evoked some time after repolarization of the previous action potential and acetylcholine had no effect on the membrane resting potential it seems that the increase in the maximum rate of rise of the extra action potential, caused by acetylcholine, could only have been due to a direct effect on the sodium-carrying system. We suggest the following hypothesis to explain the stimulant and inhibitory actions of acetylcholine described by Burn[7].

The usual inhibitory action of acetylcholine on the rate of beat of pacemaker cells could be explained by its action of increasing potassium permeability[8,9], thus diminishing the rate of diastolic depolarization responsible for rhythmicity. The arrest of atria by cooling, fatigue and quinidine-like agents is apparently the result of inactivation of the sodium-carrier mechanism. In the first two cases the inactivation of the carrier is probably the outcome of a reduced membrane resting potential[3,6,10]. In these cases the major effect of acetylcholine could be the increasing of potassium permeability, thereby aiding the restoration of the membrane resting potential and thus the activity of the carrier, yet a more direct effect of acetylcholine on the carrier cannot be excluded. However, in the case of quinidine the latter is the more important effect, for the carrier is inactivated with little or no change in the resting potential.

Chemical Examination of the Water of Flooded Rice Fields

THE marked root destruction that affects the crop of rice fields of limeless meadow clay and limeless alkaline soil is well known. The damage can be attributed mainly to the toxic effect of hydrogen sulphide and other products of anaerobic fermentation processes[1] (for example, butyric acid). Protein decomposition and sulphate reduction produce hydrogen sulphide[2]. The root-rot is much increased in horizontal roots produced chiefly by nitrogen excess, anaerobic conditions or soil defects. The roots just beneath the soil are fully exposed to the toxic products of the soil-biological processes below the surface.

To replace the destroyed roots, adventitious roots develop from the nodes. However, these solve only partly the problem of nutrient uptake by ion-exchange, since they remain in the water, which is poor in nutrients and lacks various essential elements.

To discover which nutrient ions may be present in the water at the time of the appearance of the browning disease ('bruzone'), fifty samples of water from each of both healthy (*H*) and unhealthy (*UH*) fields, as well as from fresh (*FW*) flood-water (River Tisza) have been subjected to analysis. Results are shown in Table 1.

As can be seen from these results, there is little difference in nutrient concentration between the water of healthy and unhealthy rice fields, therefore the cause of the disease must be ascribed to the fact that the diseased plants, which are dependent on their adventitious roots, can utilize only the nutrients dissolved in the water, in contrast to the healthy ones with their deep soil roots.

Table 1. CONCENTRATIONS OF NUTRIENTS (MGM./L.) IN WATER SAMPLES

Water sample	pH	Ca^{2+}	Mg^{2+}	K^{+}	Mn	Fe	NO_3^{-}	NH_4^{+}	SO_4^{2-}	PO_4^{3-}	SiO_2
H	7·4–8·1	25·7–48·2	18·2–24·3	4·8–8·1	—	0·0–0·1	—	0·0–0·3	—	traces	0·0–6·6
UH	7·1–7·3	43·1–52·8	8·6–19·3	4·7–11·2	—	0·0–0·05	—	0·0–0·1	—	—	2·6–5·6
FW	7·2	34·2	7·01	3·9	—	0·05	—	—	50·1	—	6·0

Table 2. NUTRIENTS AND S^{2-} (MGM./100 GM.) IN SOIL SAMPLES

Soil sample	NO_3–N	NH_3–N	P_2O_5	K_2O	Total-N	S^{2-}
1	—	2 6	2·8	6·3	125	8 0
2	—	4 5	7 2	4 0	161	4 6
3	—	2·8	12·7	5 8	219	7·4
4	—	9 6	9 0	10·8	213	5·24

The quantity of the available nutrients in the soil of the affected fields at the time of the appearance of the disease is given in Table 2.

The water of the diseased fields was as a rule deficient in phosphate, sulphate, nitrate and manganese. Moreover, ammonium and iron were absent or present only in minute quantities. In the water of healthy fields there was a trace of phosphate and slightly more, but still very little, ammonium. Owing to the absence of the elements mentioned above, the adventitious roots cannot replace the activity of the soil-roots, so that the life-processes of the plant may be checked. The dark or bluish green colour of the plant denotes the absence of phosphorus, involving the cessation of protein synthesis. Biochemical examination shows in every case a higher ammonia–nitrogen content than amide–nitrogen in the affected plants[3].

It is root-rot, the deficiency diseases mentioned above, metabolic disturbances and fungi on affected plants (*Helminthosporium oryzae*, *Piricularia oryzae*, *P. grisea*, etc.) that cause the symptoms known as blast, brown disease, 'bruzone', 'aki-ochi', Brand, etc.

Molybdenum Deficiency in Latosols of Java

RECENT experiments with groundnuts, *Arachis hypogea*, on the Muara plots near Bogor, Java, have shown that small applications of molybdenum produce a markedly beneficial effect on the colour and growth of this legume when grown on latosols of this area. The beneficial effect was not confined to one soil mapping unit in the plot field, and since latosols are widely distributed and extensive, especially in the moist tropics, the desirability of a thorough investigation of trace-element deficiency in these leached soils is indicated.

Arnon (1937) demonstrated in pot culture experiments that molybdenum is essential for barley, and Arnon and Stout[1] showed that it is essential for tomatoes. Molybdenum deficiency in the field was first recognized, in Australia, by Anderson[2], with clovers on acid sandy soil. Legume root nodule bacteria are apparently unable to fix nitrogen in the absence of an adequate supply of this element, and investigations of other nitrogen-fixing micro-organisms have shown that they also require molybdenum for this purpose. Mulder[3] and Hewitt and Jones[4] have shown that molybdenum-deficient plants do not reduce nitrate efficiently after it is absorbed and transferred to the upper parts of plants. This may account for the beneficial effect of molybdenum to non-legumes.

An experiment with groundnuts was started on the Muara plots near Bogor, Java, in January 1957, to study the effects of trace elements and other elements not commonly used as fertilizers, in addition to the fertilizers commonly used on legumes, namely, phosphorus, potassium and lime. The soil is a latosol derived from volcanic ash and its pH value is about 5·5. Latosols are characteristically acid, leached, reddish soils, and soils of this kind are very common in Indonesia and other moist tropical areas. It is reasonable to expect that such soils will be deficient in fertilizing elements that are normally present in adequate quantities in less severely leached soils.

The experiment was designed to test the effects of phosphorus, potassium and lime, applied singly and in combinations, in addition to the effect of elements not commonly used as fertilizers. A mixture of manganese, magnesium, copper, boron, zinc and molybdenum compounds was applied to plots treated with a combination of phosphorus, potassium (as sulphate) and lime. The treatments were randomized in four blocks, thus giving four replicates of each. The beneficial effect of the mixture was shown by the definitely greener colour of the foliage, which became evident about one month after planting, and by the increased growth which followed. These effects have been recorded in colour photographs and by yield data. It should be noted also that the greener growth was accompanied by much better nodulation, as revealed by examination of the plant roots.

A second field plot experiment with groundnuts was started in the Muara field late in May 1957, with the object of determining the factor responsible for the beneficial effect. As the number of plots available for this experiment was rather limited, one element, manganese, was excluded because it seemed unlikely that it would be deficient in this soil. The treatments were as follows: (1) check, (2) a mixture of magnesium, copper, boron, zinc and molybdenum compounds, (3) double superphosphate, potassium sulphate and lime. The other treatments consisted of combinations of one or more of the five elements under investigation (listed under (2)) with the phosphate, potash and lime. The system was to use all five elements, then remove one at a time, then two, etc. The treatments were randomized in four blocks as before, thus giving four replicates of each. The weather was dry for about 3 weeks after planting, and the differences did not become evident for about 6 weeks. After 8 weeks it was observed that all 32 plots that did not receive molybdenum were somewhat yellow or less green than the adjacent plots that received this element. There are 88 plots altogether. The treatments included one with molybdenum only and one with magnesium, copper, boron and zinc (in addition to the basic phosphate, potash and lime), and the former plot was much greener than the latter. It is thus evident that the soil is deficient in molybdenum for groundnuts, and since nodulation was obviously improved by the application of molybdenum, it is reasonable to expect that other legumes would benefit likewise. Without molybdenum the crop appeared to be suffering from lack of nitrogen. Yield data will be published later.

The molybdenum was applied at the rate of 1 kgm. per hectare of sodium molybdate, or about 1 pound per acre. Of all the elements known to be necessary for plants, molybdenum appears to be required in the smallest quantities.

A New Hæmoglobin Variant exhibiting Anomalous Electrophoretic Behaviour

IN moving-boundary electrophoresis, cacodylate buffer, pH 6·5, μ0·1, the relative mobilities of the better-known hæmoglobin variants are the same or only slightly different from those in paper electrophoresis, veronal buffer, pH 8·6, μ0·05. Owing to the fact that the two buffers are on the opposite sides of the isoelectric points of these types of hæmoglobin, the order of migration is reversed; however, the relative mobilities of hæmoglobin types *A*, *S* = *D* and *C* are identical under both conditions. The earliest instance of a type of hæmoglobin exhibiting some discrepancy in behaviour in free electrophoresis as compared to paper electrophoresis is that of hæmoglobin *F*; with the latter technique, the mobility of *F* is always slightly less than that of *A*, but with the former, *F* is indistinguishable from *A*. A somewhat greater difference occurs in the mobility of hæmoglobin *E*, which, in veronal paper electrophoresis (pH 8·6), lies between *S* and *C*, but in free electrophoresis (cacodylate, pH 6·5) is slightly less than that of *S* (between *S* and *A*)[1]. Similarly, the mobility of hæmoglobin *G* lies between *F* and *S* in paper electrophoresis at pH 8·6; but in free electrophoresis at pH 6·5 (cacodylate) *G* is inseparable from *S*[2].

The present communication deals with a hitherto undescribed type of hæmoglobin, the resolution of which is completely different in moving-boundary electrophoresis at pH 6·5 (cacodylate buffer) from that in paper electrophoresis at pH 8·6 (veronal buffer).

This hæmoglobin sample was obtained from 'MTu', a Negro obstetric patient whose clinical and hæmatological history is not contributory. 'MTu's' hæmoglobin, examined by paper electrophoresis (veronal buffer, pH 8·6, μ0·05[3]), separated into two approximately equal components, of which one appeared identical with hæmoglobin *A*. The other assumed a position overlapping that of hæmoglobin *G*, and extending almost to that of hæmoglobin *S*, resembling hæmoglobin *L*; however, in moving-boundary electrophoresis, cacodylate buffer, pH 6·2–6·9, μ0·1, unlike a hæmoglobin *AL* mixture, 'MTu's' hæmoglobin moved as a single sharp peak (Fig. 1).

Table 1. FREE ELECTROPHORESIS OF MIXTURES OF 'MTu's' HÆMOGLOBIN WITH OTHER TYPES

'MTu's' hæmoglobin mixed with a sample of hæmoglobin from: Name	Type of hæmoglobin	Proportions of mixture	Quantitative evaluation of patterns
'JW'	*A*	1 . 1	One sharp peak
'SS'	*S* (3% *F**)	1 1	Two peaks with 63 per cent in leading one
'DW'	*S* (6% *F**)	1 : 1	Two peaks with 54 per cent in leading one
'BA'	*S* (2% *F**)	2 'TMu' : 1 'BA'	Two peaks with 74 per cent in leading one
'AK'	*AG* (50% *A*†)	1 : 1	Three poorly separated peaks with about 50 per cent in leading one and 25 per cent in each of the other two
'ET'	*AG* (35% *A*†)	1 : 1	Two peaks with about 90 per cent in leading one
'ET'	*AG* (35% *A*†)	2 'ET' . 'MTu'	Two peaks, approximately equal

Cacodylate buffer, pH 6 5, μ0·1
* Value obtained by method of alkali denaturation.
† Value calculated from previous scanning diagrams.

Aliquots of 'MTu's' hæmoglobin were added to those containing various known types of hæmoglobin and the mixtures were analysed in free electrophoresis, cacodylate buffer, pH 6·5, μ0·1. The results are given in Table 1. Mixtures of hæmoglobin *A* and 'MTu's' sample again moved as one sharp peak. Mixtures of 'MTu's' hæmoglobin with hæmoglobin *S* from subjects with sickle-cell anæmia resolved into two peaks of variable proportions. Similarly, mixtures of 'MTu's' hæmoglobin sample and those containing hæmoglobin of types *A* and *G*, from patients 'AK'[4] or 'ET' (Schneider, R. G., unpublished data), resolved into two peaks of inconstant proportions, and on two occasions into three partially separated peaks. 'MTu's' hæmoglobin sample was also analysed in free electrophoresis, using veronal buffer, pH 8·6, μ0·1, in which buffer there resolved one peak and a shoulder of another.

The hæmoglobin of 'MTu's' husband was entirely of type *A*. Of her two children, one had only type *A*; the hæmoglobin of the other child ('HBTu') was first obtained at the age of seven weeks. In paper electro-

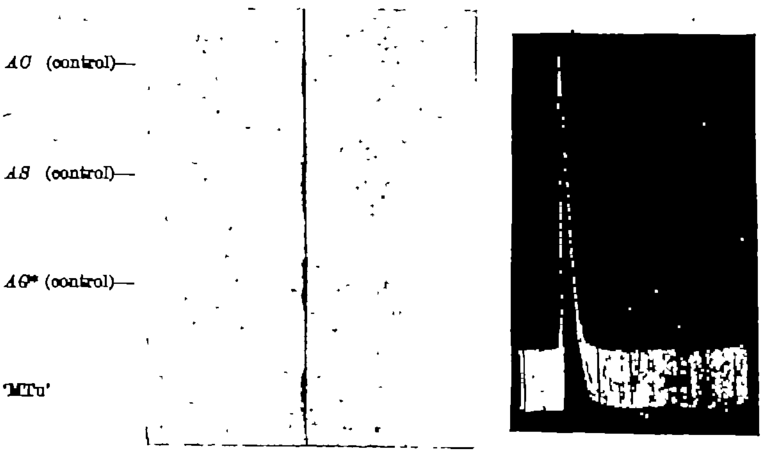

Fig. 1. Paper electrophoresis pattern and scanning diagram of hæmoglobin of 'MTu'. Paper electrophoresis veronal buffer, pH 8 6 μ0 5 (paper impregnated with 0 5 per cent egg albumin before analysis) Scanning diagram, ascending pattern 1 per cent carboxyhæmoglobin, cacodylate buffer, pH 6 5, μ0·1
* Sample from patient 'AK'

phoresis this sample consisted primarily of type *F*, with smaller amounts of type *A* and of another type similar to the variant in the mother. The *F* hæmoglobin value, by the method of alkali denaturation, was 38 per cent. In free electrophoresis, cacodylate buffer, *p*H 6·5, there was one peak only. This child was examined again at the age of four months, at which time his hæmoglobin pattern in paper electrophoresis was almost identical with that of the mother.

When 'MTu's' hæmoglobin was analysed in paper electrophoresis in a closed system (between glass plates) its pattern was indistinguishable from that of hæmoglobin *AS*. This was also the case in some analyses of less than eighteen hours duration in the present method of paper electrophoresis. This finding suggests the need for caution in interpreting the results of analyses by paper electrophoresis, particularly with respect to identification of hæmoglobin *D*, *L* and *G*, the variants most likely to be confused with the one present in 'MTu'.

It is suggested that the hæmoglobin variant in 'MTu' and her son 'HBTu' be tentatively designated the 'Galveston type'.

This work was aided by United States Public Health Service Grant *A*-780.

Mitochondrial Kinetics

VISIBLE local modification of the cellular nuclear membrane is usually considered a phenomenon associated with the discharge of nucleic acid from nucleus to cytoplasm. Barr and Bertram[1] have noted thin 'nuclear caps' in nerve cells concomitant with the reproduction of Nissl substance during recovery from antidromic stimulation. Such 'nuclear caps' appear as distinctive dense or thickened local areas of the nuclear membrane which stain with basic dyes, give positive histochemical reactions for nucleic acid, and absorb heavily at 2600 A. with ultra-violet light methods. Electron studies also indicate that the membrane may be thickened and modified during regeneration after axonic severance[2].

However, modification of the nuclear membrane interface may occur during intracellular processes seemingly unconnected with nucleic acid interchange. Earlier studies[3] have shown that cytoplasmic organellæ, the lipochondria, may enter into relationship with the nucleus, forming a zone of nuclear reaction morphologically indistinguishable from a 'nuclear cap'.

Striking examples of these 'caps' have recently been found in dorsal root ganglion cells of neonatal guinea pigs. The photomicrographs (Fig. 1) are from preparations fixed in Helly fluid, and post-chromed before staining with Altmann's mitochondrial stain. At one pole of the nucleus the membrane is thickened and contains some distinct granules (Fig. 1,*a*). The whole structure is strongly fuchsinophil and is sharply differentiated from the rest of the nuclear membrane.

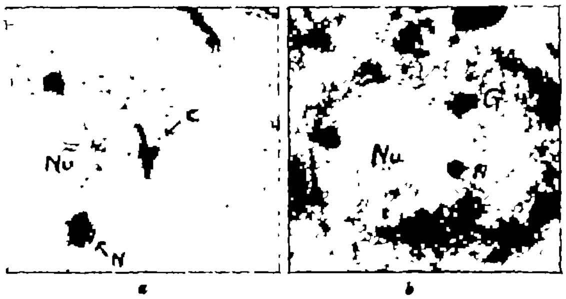

Fig. 1. *a*, Dorsal root ganglion cell, neonatal guinea pig. A nuclear cap *C* contains two granules. *N*, nucleoli; *Nu*, nucleus. (× c. 19,000). *b*, A mass of fuchsinophil granules *G* lie close to the nuclear membrane. Less strongly stained mitochondria are present in the section but are not clearly visible in this plate. *N*, nucleoli. (× c. 19,000)

Frequently, masses of similar fuchsinophil granules lie in contact with, but outside of, the nucleus, and may or may not be associated with a 'nuclear cap'. These masses stain as do the mitochondria, but with greater intensity. Granules at the periphery of the mass merge with and become indistinguishable from the normal mitochondria (Fig. 1*b*). Both the 'nuclear caps' and their associated granules give a negative Feulgen reaction, and do not stain with pyronin in Brachet's method for ribonucleic acid.

Although nucleoli frequently approach and attach themselves to the nuclear membrane from the inner aspect they are not then similarly associated with the formation of a distinctive fuchsinophil cap (Fig. 1*b*).

The above phenomena suggest a possible mitochondrial kinesis involving the nucleus, similar to that already described for the lipochondria. A slide illustrating these phenomena will be sent to the International Depository of Cytological Slides, Institute Carnoy, Louvain, Belgium.

A Cell Compressor for the Measurement of Mass and Concentration by Interference Microscopy

FOR a number of observations with the interference microscope on suspensions of living cells, it is desirable to be able to make the upper and lower surfaces of the cell flat and parallel without producing irreversible damage. A number of compressors are known (for example, Rousselet), but none provides quite the degree of control which is required. The compressor illustrated in Fig. 1 depends upon the bending of the slide S_1 and is therefore completely free from shear play and other uncontrollable movements, unlike compressors which depend upon sliding motion. In addition, the mounting of the cells on the small strip of glass *B*, which is sealed to the lower slide S_2 with 'Araldite', avoids any disturbances due to changes in capillary attraction. The curvature of the meniscus at *M* is little affected by small changes in the gap *G*. These two conditions enable quite reversible changes in the gap to be effected over distances

Table 1. Response of Normal Liver and Hepatoma Cells to Polyethylene-imine

Measurements of cytoplasmic concentration calculated from specific protein increment (ref. 2) and expressed as gm./100 c.c. water. Measured before and after introducing 0·12 per cent polyethylene imine in calcium-free Locke's solution

Experiment 1*
Normal liver cells compressed to thickness of 8·5 × 10⁻⁴ cm.

Time	Cell No. 1	Cell No. 2	Cell No. 3
		Concentration	
Zero, reagent introduced	10·8	11·7	11·7
7 min.	11·7	12·3	13·3
17 ,,	12·5	13·3	13·6
30 ,,	13·2	12·6	14·3

Experiment 2
Hepatoma cells compressed to thickness of 7·6 × 10⁻⁴ cm.

Time	Cell No. 1	Cell No. 2	Cell No. 3
Zero, reagent introduced	16·7	16·3	17·2
10 min.	16·3	0	21·4
20 ,,	11·2	0	22·7
30 ,,	0	0	16·3

of about two microns. The actual thickness of the gap can be readily measured on the microscope with the help of an air bubble as previously described[1]. In addition, the medium surrounding the cells can be easily exchanged in this compressor without producing capillary disturbance.

The compressor can be used for direct observation with the interference microscope, for example, to immobilize ciliates such as *Paramecium* by light compression. It can also be used for measuring the refractive index and hence the concentration of material in various parts of the cell. It has been used, for example: (*a*) To study the effects of various positively charged polyelectrolytes upon normal and homologous tumour cells. An increase in permeability of the membrane is revealed by a fall in cytoplasmic concentration. In a typical preliminary experiment using polyethylene imine (Table 1) the concentration of cytoplasm in the tumour cells (hepatoma) fell quite rapidly, whereas the normal liver cells showed no decrease. (*b*) For measurements on *Amoeba proteus*. These indicate that the contractile vacuole has a concentration which is the same as that of the external medium (water); the concentration in the plasmagel at the rear contracting end of the cell was the same as that at other parts of the cell, including the anterior end. Contraction cannot therefore be due to loss of water, as suggested by Pantin (1923).

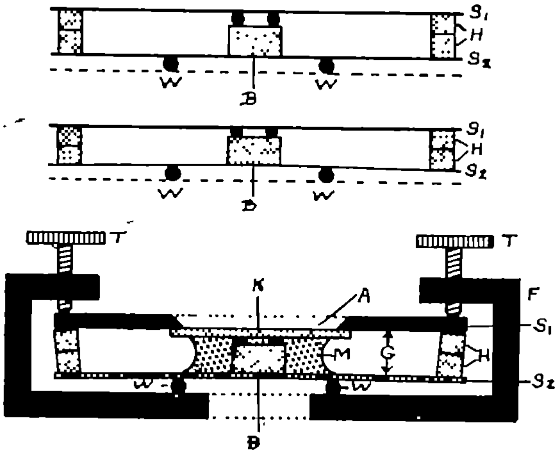

Fig. 1. Top. Arrangement of the two slides S_1 and S_2 with platform B carrying cells on upper surface.
Middle: Slide S_2 bent towards S_1 by wire bars W; downward forces applied at ends of S_1. Upward curvature of S_2 produces compression of cells.
Bottom: Longitudinal section through complete compressor showing screws T (remote from objective), either or both of which produce bending of S_2.

S_1, glass slide (for low power observation) or 'Dural' plate with central aperture A and coverslip K cemented to lower surface (for high power observation); S_2, glass slide with spacers (H) consisting of two thicknesses of glass coverslip cemented to upper surface. Glass platform (piece of cover-slip) (B) cemented to upper surface with 'Araldite' across centre of slide. W, wire bars 1 mm. thick; F, metal frame carrying thumbscrews T for controlling the thickness of the gap G, provided with central aperture for illumination with condenser

Use of a Histochemical Technique to demonstrate the Cutaneous Penetration of Adrenalin and Nor-Adrenalin

Although histochemical techniques are commonly used for demonstrating substances in their normal situations in tissues they may also be used for demonstrating such substances in more unusual sites.

An example of this is the demonstration of the passage of adrenalin through the skin of a rabbit.

Fatty emulsions containing a 1 in 500 concentration of adrenalin in one preparation and nor-adrenalin in the other were rubbed on to the shaved skin of a rabbit and pieces of skin removed under ether anæsthesia at intervals of 5 min., 20 min. and 1 hr.

The skin upon removal was placed in 5 per cent ammoniacal solution of silver nitrate. It remained

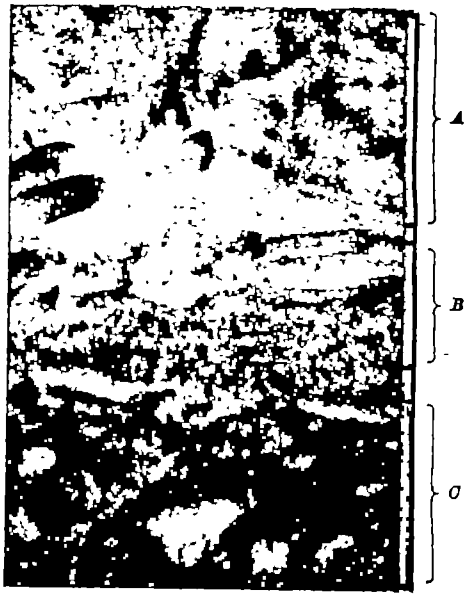

Fig. 1. Section through rabbit skin 5 min. after application of emulsion containing 1 in 500 adrenalin to the surface. Black silver granules indicating the penetration of adrenalin between the epithelial cells can be seen. Silver granules can also be seen in the emulsion above the epithelium and in the subcutaneous connective tissue

in this solution for one hour. It was then washed, and frozen sections cut from one half of each piece of skin—the other half being dehydrated, embedded in wax and sectioned in the usual way. Sections were afterwards toned in gold chloride to remove the overall brown stain. Granules of reduced silver were present wherever the adrenalin or nor-adrenalin had penetrated.

It was found that even by 5 min. there had been a complete penetration of the skin by both adrenalin and nor-adrenalin and that there was even evidence of their presence in the subcutaneous tissues. They appear to penetrate between the cells rather than through them. Although there are other reducing substances present in tissues which can reduce ammoniacal silver nitrate, treatment of pieces of control skin treated with the emulsion devoid of adrenalin showed only a few black granules.

Paper Chromatography in Taxonomic Work

A method for using paper partition chromatography for taxonomic studies on land snails has been described by Kirk *et al.*[1].

In attempting to use the original technique, a number of technical difficulties were encountered, and it was found that exactly reproducible results were not easily obtained. The main source of error lay in the fact that Kirk and his co-workers ran their chromatograms on a glass plate covered by an inverted pie-dish, the solvent being fed to the centre of the disk by a wick passing through a hole in the glass plate. As a result, the chamber (the lumen of the covering dish) only becomes saturated with solvent vapour by evaporation from the surface of the disk during the run. It is also almost impossible to standardize the wick feeding the solvent.

These sources of error are eliminated by the use of the standard circular chromatography apparatus described by Kawerau[2]. By using slotted Whatman No. 3 papers 26 cm. in diameter, and a standard run of six hours at about 20° C., quite easily reproducible results are obtained. The R_F values of the fluorescent bands resulting from this technique are greater than those obtained by the original method, partly due to the elimination of surface evaporation from the paper and partly because of the differential flow-rate at the solvent front as it moves farther from the centre along the sectors of the paper. Thus the R_F values obtained from a four-hour run are a little lower than they are after six hours.

The method not only works well with some land snails but also with some aquatic groups, and interesting results are at present being obtained from the genus *Lymnaea*.

We are indebted to Mr. E. R. Shandon for the loan of the Kawerau dishes used and for the specially cut papers.

Respiratory Characteristics of Marine Bacteria

Bacteria which are isolated from marine environments and require for growth a medium containing sea water are classified as true marine organisms. Recent evidence[1] indicates that the inability of marine bacteria to grow in the absence of sea water is due to a requirement for specific inorganic ions. A second, but not as well-defined, characteristic of marine bacteria is their high proteolytic activity and their rapid growth on organic nitrogen compounds[2].

The majority of studies of the metabolic activities of marine bacteria are concerned with requirements for growth. Seldom have the respiratory characteristics of a marine bacterium been investigated and correlated with growth studies. It was therefore of interest to determine if the criteria used for distinguishing marine bacteria as a group are satisfied by respiratory as well as growth characteristics.

The respiratory activity of a marine bacterium and *Escherichia coli* on endogenous and exogenous substrates, in the absence and presence of sea water, was determined using a Warburg respirometer and conventional manometric procedures[3]. The marine bacterium used in these studies was isolated from sea water collected in the vicinity of Fort Johnson. The growth requirements of the organism fulfil the criteria for its designation as a true marine bacterium. The culture is identified as *A*–11–3*B*1 in the Fort Johnson collection.

Table 1 shows that oxygen uptake by the marine bacterium on both endogenous and exogenous substrates was much greater in sea water than in phosphate buffer. With *E. coli*, conditions were reversed, that is, oxygen uptake on both endogenous and exogenous substrates was greater in phosphate buffer than in sea water. Tests showed that the reduced oxidation of glucose by *E. coli* in sea water was not the result of a deficiency of phosphate.

It is evident from Table 2 that the marine bacterium respires preferentially on some component(s) of casamino-acids. Casamino-acids were oxidized rapidly, whereas galactose and glucose were oxidized at a very low rate. It was not possible to replace casamino-acids with asparagine, glutamate, or glycine. Asparagine, citrate, and glycerol reduced endogenous respiration.

While investigation was in progress, Tomlinson and MacLeod[4] reported that the inorganic ion requirements for growth of a marine bacterium were also necessary for its oxidation of exogenous substrates. This provides further evidence that the growth requirements used for defining marine bacteria as a

Two Inhibitory Fibres forming Synapses with a Single Nerve Cell in the Lobster

In the stretch receptors of lobsters described by Alexandrowicz[1] the dendrites of sensory neurons lie in a fine muscle strand. Stretch-deformation by passive pull or by contraction of the receptor muscle leads to depolarization of the dendrites and of the adjacent cell body and axon region, thus setting up sensory discharges. In most lobster receptors Alexandrowicz also found two efferent neurons, a thick and thin 'accessory' fibre, forming synapses in the dendritic region of the sensory cells. Both accessory fibres divide and send one branch to the slowly adapting neuron and the other to the fast adapting receptor cell (Fig. 1). It has already been shown that stimulation of the thick accessory fibre can promptly suppress the sensory discharge caused by stretch of the muscle strand[2]. This axon therefore has a specific inhibitory role.

It has now been possible to stimulate both accessory fibres individually and determine their action on the discharge of a single slowly adapting receptor cell. As expected from the diameter difference the small axon has a slower conduction velocity and a higher threshold. If stimulated it has a specific inhibitory action similar to that of the larger inhibitory fibre. Thus the same sensory neuron possesses a double inhibitory (*I*) supply. There are, however, definite differences in the inhibitory action if tests are made on an individual sensory neuron under identical experimental conditions. An example in Fig. 2 shows a sensory cell discharging at a steady rate near 6/sec. Stimulation of the thick or 'fast' *I* neuron at 15/sec. *A* reduces the discharge rate while 20/sec. completely inhibits it (*B*). To obtain a similar inhibitory action the thin or 'slow' *I* fibre had to be stimulated at a much higher rate, namely, 30/sec. (*C*) and 40/sec. (*D*). The difference in inhibitory effectiveness was always seen. The inhibitory effects of the 'slow' and 'fast' *I* axons can sum.

These results may be of interest because dual inhibitory regulation of one cell by two neurons with distinctly different physiological performance has not yet been found elsewhere. The differences in synaptic events and in membrane changes caused by the two inhibitor axons are being studied.

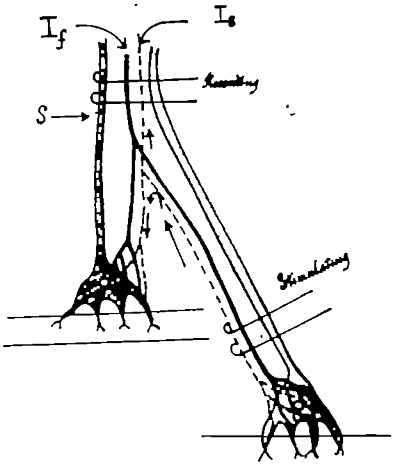

Fig. 1. Diagram of double inhibitory supply to sensory neurons in the lobster stretch receptor. *S*, slowly adapting sensory cell from which afferent impulses are recorded; I_f and I_s, fast and slowly conducting inhibitory axons forming synapses with dendrites of sensory cells. Inhibitory fibres are stimulated near the fast adapting receptor cell (no shading) and their impulses conduct centrally (arrows) to the recording electrodes, and, by axon reflex, to the slowly adapting neuron

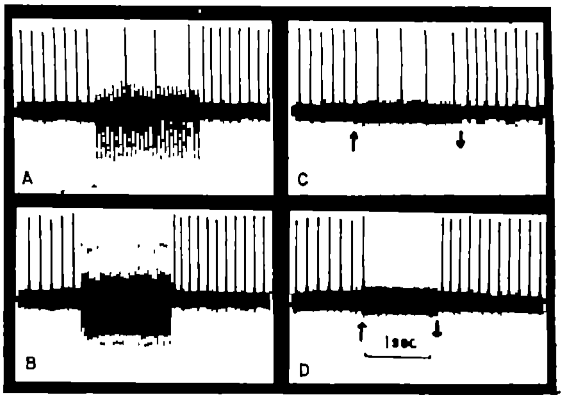

Fig. 2. Effect of two types of inhibitory impulses on the sensory discharge of a slowly adapting stretch receptor neuron. The afferent discharge-rate in all records is near 6/sec. Stimulation of the 'fast' inhibitory axon at 15/sec. *A* causes incomplete inhibition while at 20/sec. *B* all discharges are suppressed. A comparable inhibitory effect by the 'slow' inhibitory impulses requires stimuli at 30/sec. *C* and 40/sec. *D*. Period of inhibitor stimulation in *A* and *B* is marked by artefacts, in *C* and *D* by arrows

A 'Window' Technique for Observing Fish Viscera *In vivo*

Descriptions of the behaviour of viscera seen *in vivo* are rare compared with the numerous observations made on preparations isolated from the body and maintained under conditions varying to a greater or lesser extent from their normal physiological environment. A 'window' technique has been developed which allows close observations to be made of the movements of the gut of fish which are living and feeding under normal conditions. It was originally designed for observing the normal gastric motility of the brown trout (*Salmo trutta*), but was later more fully developed for the pike (*Esox lucius*).

The fish was first anæsthetized by plunging into 2 per cent urethane for 45 sec. and then transferring it to a weaker solution (0·5 per cent). During the operation, the head and gills remained immersed in the anæsthetic. The bottles containing the anæsthetic solutions were placed in the fish tank prior to use, for temperature equilibration.

The body cavity was opened ventrally with a cut at right angles to the longitudinal axis of the body. An aperture about 2 in. long and 1 in. wide was made in the side of the fish, between the pectoral and pelvic fins. Relatively little hæmorrhage was produced by the incision.

The window was then fitted. This consisted of a sheet of mica (0·01 cm. thick). (For various reasons, neither celluloid, polythene, polyvinylchloride, nor thin rubber were successful transparent materials for making windows.) Two sharpened aluminium studs, tapped at both ends, were pushed through the corners of one end of the mica sheet and on through the dorsal musculature of the abdominal region of the fish. The mica was looped around the ventral surface of the fish, enclosing the cut abdominal section, and was pierced by the other ends of the studs emerging from the body wall. Four 'Perspex' nuts were then screwed on to the aluminium studs so that a firm, compact, transparent, window covered the hole in the side of the fish. The final arrangement can be seen diagrammatically in Fig. 1.

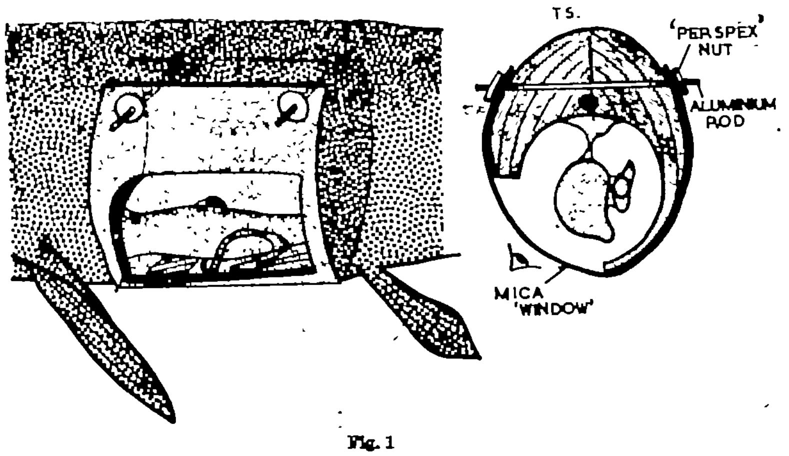

Fig. 1

The fish took about 2 hr. to recover from the anæsthetic and another 24–28 hr. before their behaviour appeared to be normal.

Pike equipped with windows have been kept for more than four months, during which time they were capable of feeding on small fish. On the other hand, trout fitted with the same or differently designed windows never survived for more than four days. There are probably a number of reasons for this striking difference in survival-time of the two fish under similar conditions. The main reason may be that the window used in these experiments did not form a perfect seal for the body cavity. The violent body undulations of the trout allowed seepage of tank water into the body cavity, whereas the long abdomen of the pike remained rigid most of the time, so that exposure of the viscera to tank water happened very rarely, if at all.

The pike has the further advantage for observation of its internal organs that it lies very still for long periods of time, so that a microscope can be focused on the viscera. In addition, there are no pyloric cæca or heavy deposits of fat in the pike body-cavity, both of which tend to obscure the view in the trout.

For fish more active than the pike, a special 'Perspex' observation bracket was made to reduce movements to a minimum (Fig. 2). It was designed to be placed in the fish tank, so that normal conditions of air, light, temperature and background should remain unaltered. The bracket was so shaped that a posterior, V-shaped piece restrained tail movement to a minimum. A perforated plunger was then pushed into the open end of the chamber until it almost touched the nose of the fish. In this way, the chamber could be adapted to accommodate fish varying from 8 to 16 in. in length. Fish appeared to behave normally in this bracket after a few hours. Part of the bracket was left open so that the fish could be fed.

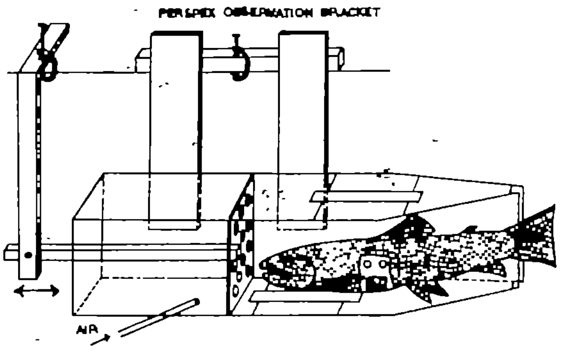

Fig. 2

Light, directed through the tank wall and 'Perspex' bracket, was not very efficient in illuminating the viscera. Instead, a tapered 'Perspex' probe was designed to pass into the tank and protrude through a groove in the observation bracket. No heat from the lamp passed down the probe, so that the fish was not disturbed. In this way, an excellent source of reflected light for microscopic observation of the viscera was established.

Comparisons of fish gut motility seen *in vivo* and *in vitro* in an organ bath will be given in a later paper.

Mucous Gland Cells of the Outer Mantle Epithelium of *Arca noae*

MUCOUS gland cells occur in the outer mantle epithelium of most lamellibranchs, in some relatively commonly, for example, *Pinna*[1], in others less frequently, for example, *Mytilus, Ostrea, Tellina*. In *Arca noae*, cells with two different types of histochemical properties have been observed throughout the outer mantle epithelium but most commonly proximal to the line of attachment of the pallial muscle where the epithelium consists almost entirely of gland cells.

One type of cell stains blue in Mallory's triple stain, gives positive results with both alcian blue and the periodic acid–Schiff reaction, and shows gamma metachromasia with toluidine blue. The contents of these cells also exhibit a capacity to bind methylene blue at below *p*H 4, which indicates the presence of acid mucopolysaccharides[2]. The other type of mucous gland cell, which occurs approximately ten times more frequently than the other, stains red in Mallory's triple stain, exhibits a less-marked periodic acid–Schiff reaction, a faint reaction in tests for proteins, no staining in alcian blue, orthochromatic staining in toluidine blue, and binds with methylene blue at above *p*H 4. These results point to the presence of neutral mucopolysaccharides or of mucoproteins[2]. Two similar types of mucous cells have been described in the outer mantle epithelium of *Pinna*[1], but only a single type of cell comparable to that secreting a neutral polysaccharide in *Arca* is found in the outer mantle epithelium in many lamellibranchs, for example, *Anodonta cygnea*[3]. In this species, cells secreting an acid mucopolysaccharide are generally found on the inner surface of the outer mantle epithelium. In *Pinna*, Yonge[1] has observed that the mucous cells occur particularly in the outer mantle fold and suggests that they supply the necessary lubrication for the extensive withdrawal and re-extension of the mantle. The distribution of the gland cells in *Arca noae*, in which they are most plentiful proximal to the line of pallial attachment of the mantle, is not in accord with lubrication being a suitable explanation of their function in this species.

It has been suggested that the products of the mucous gland cells are concerned with the calcification of the valves[4,5]. No evidence of the presence of calcium in the mucous cells of *Arca* was, however, obtained by routine staining techniques. Incineration of sections at 600° C. in a manner similar to that used by Hedley[6] to detect calcium in a study of serpulid tube formation left a residue of white ash in the outer mantle epithelium, which gave characteristic crystals of calcium sulphate when treated with dilute sulphuric acid and a marked staining reaction with alizarin red[7]. This points to the presence of calcium in the outer mantle epithelium, particularly in the mucous cells. The absence of a staining reaction before incineration probably indicates that the calcium present may be bound to some organic substance, possibly the mucopolysaccharide, which inhibits normal staining reactions. An investigation of the secretion of calcium by the mantle epithelium of other lamellibranchs using the incineration technique is proceeding.

Occurrence of *Crepidostomum metoecus* (Braun, 1900) in Britain

DURING the course of an investigation into the food and parasites of freshwater fishes in west Wales it was found that 74 per cent of 1,294 trout, *Salmo trutta* L., and 33·9 per cent of the 274 salmon parr, *Salmo salar* L., examined were infested with two species of *Crepidostomum*, namely, *C. farionis* (Müller) and *C. metoecus* (Braun). The parasites also occurred in one of the 243 eels, *Anguilla anguilla* (L.); but it is believed that the latter species constituted an accidental host.

The present record of *C. metoecus* in Britain is new. It has previously been recorded only in Austria[1], Sweden (= *C. suecicum* Nybelin, 1933)[2] and Ireland[3], and appears to have a more sparse geographical distribution than the allied species, *C. farionis*, which is known to have a circumpolar distribution.

The two species of *Crepidostomum* occurred together in the same host fishes, but there is some evidence of habitat isolation as *C. metoecus* occurred predominantly in the region of the pyloric caeca while *C. farionis* occupied a more posterior station in the intestine. Although *C. metoecus* is superficially very similar to *C. farionis* it may be distinguished from it by a consideration of the morphological features shown in Table 1. Certain of the differences, particularly those in the size of the body and the ventral sucker, may well be adaptations to the organ of the host infested.

Table 1. DIFFERENCES BETWEEN *C. metoecus* AND *C. farionis*

Character	*C. metoecus*	*C. farionis*
Total length	0·87–2·12 mm.	1·52–5·02 mm.
Neck region	narrow	no distinct narrowing
Ratio of oral to ventral sucker	1 : 1·09–1 : 1·26	1 : 1·4–1 : 1·5
Oral papillæ	0·063–0·070 mm.	0·037–0·050 mm.
Pharynx	less than half length of oral sucker	more than half length of oral sucker
Gut cæca	narrow and short	wide and long
Excretory bladder	ends near anterior level of testes	extends in front of testes
Genital pore	behind gut bifurcation	in front of gut bifurcation
Vesicula seminalis	chambers overlapping	chambers in straight line
Vitelline follicles	small, occur dorsally and ventrally to gut cæca	large, occur ventrally to gut cæca
Number of eggs	rarely more than 30	up to 100
Space between ovary and anterior testis	narrow	wide

It is not unlikely that many of the early workers who described and recorded *C. farionis* have overlooked the possibility of a double infestation with the two *Crepidostomum* species. In this case *C. metoecus* may well prove to have a more widespread geographical distribution than has been hitherto suspected. A re-examination of the specimens of *Crepidostomum* studied by the earlier workers, particularly Dollfus[4] and Haderlie[5], seems desirable as certain aspects of their figures and descriptions of *C. farionis* appear to be atypical.

The two *Crepidostomum* species often occurred in large numbers in the alimentary canal of the salmonid fishes, and the average number of parasites per fish in one of the monthly samples was as high as 83·0. Although infestation in individual fish were heavy, no lesions attributable to these parasites were seen and they appear to be non-pathogenic. The degree of infestation was at a maximum during the winter months and at a minimum during the summer months. This seasonal variation could be attributed to a periodicity in the swarming of the cercariæ.

The trout were divided into age-groups and it was found that the older fish were more heavily parasitized by the two *Crepidostomum* species than the younger fish, the differences in the degree of infestation being significant at the level of 0·1 per cent. There is thus no evidence that trout develop an age resistance or an acquired immunity to the *Crepidostomum* species.

I am indebted to the Department of Scientific and Industrial Research for financial aid in connexion with this investigation, a more complete account of which will be published elsewhere.

Calcium Requirements of *Azotobacter*

ALTHOUGH there have been a number of observations on the calcium requirements of individual species of *Azotobacter* they have concerned, almost exclusively, *A. vinelandii* and *A. chroococcum*[1,2]. It has been generally agreed that calcium is essential for the growth of *Azotobacter* with free nitrogen but some controversy exists regarding its necessity for growth on combined nitrogen. Several authors have claimed that it is not needed for growth on nitrate or ammonia[2] but others[3] have failed to confirm this. Burk and his co-workers[4] found it to be unnecessary in the presence of combined nitrogen, but later[5] reversed this opinion, stating that equal amounts of calcium were required for growth in the presence and in the absence of fixed nitrogen.

Much of the earlier confusion probably arises through the use of unsuitable media and through failure to effect an adequate removal of calcium during their preparation. In the present investigation the basal medium had the following composition (per cent): glucose, 2·0; potassium monohydrogen phosphate, 0·1; magnesium sulphate, 0·02; ferrous sulphate, 0·005; sodium molybdate, 0·0005. Chemicals of analytical-reagent grade and distilled water purified by ionic exchange were used throughout. All glassware was cleaned with hot nitric acid and carefully rinsed first with ordinary and then with purified distilled water. The glucose and the phosphate were dissolved together and the solution shaken with activated charcoal ('Norite') before addition of the other constituents. The medium was dispensed in 25 ml. amounts in 300-ml. Erlenmeyer flasks, calcium or strontium being added as required in the form of the chlorides. The flasks were plugged with cotton-wool and autoclaved at 110° C. for 15 min. Control experiments showed that the basal medium was deficient only in calcium ion.

Table 1 NITROGEN FIXED (MGM./25 ML.) DURING GROWTH ON FREE NITROGEN

Species (strain)	Calcium ion (p.p.m.)						
	20	10	4	2	1	0·4	0
A. vinelandii (0)	4·03	3·87	3·49	2·47	2·00	1·73	0·14
A. chroococcum (210)	6·11	5·92	6·00	5·31	4·35	3·22	0·09
A. beijerinckii (*L.H.*1)	6·33	5·35	4·65	1·97	0·27	0·12	0·05
A. insigne (*V.J.*)	6·84	6·85	6·28	5·52	4·03	1·05	0·08
A. macrocytogenes (*L.H.*2)	4·74	4·86	4·93	4·90	4·64	4·60	0·54
A. agile (*V.J.*)	7·95	7·83	7·85	7·82	7·42	7·04	6·79

Flasks were inoculated with one drop of a thin suspension of cells grown for two days on nitrogen-free calcium-deficient glucose agar, and the cultures were incubated at 25° on a rotary shaker. Good growth was normally obtained in 48 hr.; nitrogen was then determined by the Kjeldahl method.

In the absence of fixed nitrogen, calcium was essential for the growth of *A. vinelandii* (4 strains), *A. chroococcum* (4 strains), *A. beijerinckii* (2 strains), *A. insigne* (2 strains) and *A. macrocytogenes* (1 strain). It was not essential for *A. agile* (5 strains) although it had a more-or-less stimulatory effect. Typical results are presented in Table 1.

One strain of each of the species requiring calcium was tested for ability to utilize strontium; in each case it was found that this element could replace calcium at approximately the same molar concentration.

Table 2 shows the results of typical experiments in which nitrogen was provided as ammonium acetate at a concentration of 0·03 *M*. One strain of each of the species requiring calcium for growth on free nitrogen was tested for its ability to dispense with this cation when provided with fixed nitrogen. In each case calcium was needed at approximately the same concentration for growth with free and fixed nitrogen. Except for the non-essentiality of calcium for *A. agile* these results tend to corroborate the findings of Burk and Horner[5].

Table 2. CELL NITROGEN (IN WASHED DEPOSIT MGM./25 ML.) PRODUCED DURING GROWTH ON AMMONIUM ACETATE

Species (strain)	Calcium ion (p.p.m.)						
	20	10	4	2	1	0·4	0
A. vinelandii (0)	6·88	6·82	6·11	5·83	3·66	1·73	0·10
A. chroococcum (210)	7·12	—	6·14	5·21	—	—	0·08

A more detailed report of this work will be published elsewhere.

One of us (J. R. N.) is indebted to the Yorkshire Agricultural Society for a Travelling Fellowship.

Note added in proof. On prolonged incubation in basal medium, *A. macrocytogenes* fixed some nitrogen in the complete absence of calcium, for example, 3·2 mgm./25 ml. after 7 days incubation at 25° C.

A Physiological Effect of Triethanolamine on the Development of *Sclerotium rolfsii* (Sacc.)

Since triethanolamine was found to be an excellent emulsifier[1] it has been widely used in this capacity and also as an esterifying substance for plant regulators and herbicides of low solubility[2,3].

In work (unpublished) carried out in this laboratory the triethanolamine salt of maleic hydrazide was found to effect abscission of olive leaves more severely than the sodium salt of this substance at equal concentrations. Similar results were obtained with 2,4-D and MCP[4]. As a result of these observations it was decided to study its independent influence on biological processes. Such an investigation seemed particularly desirable in view of the wide use of triethanolamine as a solvent for growth substances.

The effect of triethanolamine was studied on *Sclerotium rolfsii* (Sacc.) grown on potato dextrose agar[3] containing increasing concentrations of the substance. The effect was determined by measuring the diameter of cultures at constant time-intervals, and by determining the first appearance and total of new sclerotia.

The appearance of new sclerotia on the medium is delayed at the higher concentrations and their total number is reduced (Table 1). No germination of sclerotia took place at concentrations in excess of 2,000 p.p.m. triethanolamine in the media.

No significant influence of triethanolamine on the rate of growth of the mycelia was noted. However, when germination of the sclerotia did occur, it was delayed and slowed up. By planting normal mycelia on a media containing a concentration of triethanolamine as high as 3,840 p.p.m. the mycelium still developed into normal cultures, the final amount of new sclerotia was somewhat lower.

Table 1. THE EFFECT OF TRIETHANOLAMINE ON THE DEVELOPMENT OF *Sclerotium rolfsii*

Triethanolamine Concentrations in p.p.m.	Culture Diameter after 4 days (mm.)	Sclerotia First appearance (days)	Sclerotia Total No. formed
0	78	5	388
120	69	5	378
240	60	5	360
480	53	5	334
960	15	7	280
1,920	0	11	190
3,840	0	nil	0

The effect of triethanolamine on *S. rolfsii* seems to be primarily a fungistatic one; when sclerotia which failed to germinate after 8½ days on media containing high concentrations of triethanolamine (3,840 p.p.m.) were transferred to control media, they developed into normal cultures but for a slightly lower production of new sclerotia in comparison to the control cultures.

The effect of triethanolamine on the germination of the sclerotia and the development of new ones in *S. rolfsii* seems to be rather specific. These effects appear to be somewhat independent from general growth reactions for the rate of growth of the mycelia after full germination of the sclerotia was not affected

This leads to the conclusion that triethanolamine is not an inert solvent as commonly presumed[2,5], but rather has a definite effect at least, on the physiology of *S. rolfsii*.

A more detailed paper will be published elsewhere.

A Die-back of Cacao Seedlings in Nigeria caused by a Species of *Phytophthora*

In September 1954 a die-back disease was seen on cacao seedlings growing in Agricultural Department nurseries established in various localities of the western region of Nigeria. There is no previous record of this disease in Nigeria, but it has reappeared in the nurseries in subsequent years. The disease caused considerable losses in these years, and in a particular nursery as many as 70 per cent of the young seedlings were killed. A species of *Phytophthora* has been established as the causal agent, and when inoculated into healthy cacao pods the symptoms produced were identical to those of black-pod disease caused by *Phytophthora palmivora* (Butl.) Butl.

The symptoms of this cacao seedling disease are similar to those caused by *P. palmivora* in Costa Rica[1] and in Surinam[2]. However, in these territories this pathogen also attacks the leaves and stems of mature cacao trees, whereas in Nigeria, except for the observations of Thorold[3] on the production of sporangia on cacao tree chupons following artificial inoculation, there is no evidence of *P. palmivora* affecting any part of the cacao seedling or the mature tree other than the pods.

In Nigeria the initial symptom is a brown discoloration of the tip of one or more of the leaves of the seedling. 1–2 days later, first the petiole blackens and wilts, and then the upper part of the stem. The discoloration frequently spreads down to the cotyledons, and at this stage the upper part of the stem may collapse due to necrosis. The disease may usually be detected about 17 days after germination, and the seedlings appear to be highly susceptible for a further period of 17 days. Seedlings which have escaped infection for a period of 42 days from time of germination are rarely attacked afterwards. If the necrosis does not extend to the cotyledons, the seedling may recover due to the development of axillary buds. This type of recovery occurs among plants infected towards the end of their period of susceptibility, that is, 5–6 weeks after germination, and particularly when dry conditions prevail during the period immediately following infection.

Sporangia generally appear on the petiole and upper part of the stem 5–6 days after infection, although in a few instances they have been observed after 4 days. The pathogen produces sporangia in culture on potato dextrose agar similar to those of *P. palmivora*, but of smaller dimensions. It is thought that the causal agent of seedling die-back may be a form of *P. palmivora*; but isolates are at present being examined at the Commonwealth Mycological Institute with the view of specific identification.

A large measure of control (95 per cent) has been achieved using a proprietary copper fungicide. However, it was necessary to spray at frequent intervals (3 or 6 days) as only a low level of control was obtained with less-frequent (9 or 12 days) applications. The control experiments are being continued and will be fully reported elsewhere.

A New Technique for the Study of Laboratory Populations of *Drosophila*

Investigation of the relationships between population size and gene frequency in laboratory studies of *Drosophila* have been limited to small breeding groups (usually of less than one thousand individuals) because of the difficulty of estimating population number. Direct counts can be made when units of the types described by Reed and Reed[1] and Buzzati-Traverso[2] are in use, but the environment in these systems lacks constancy. The former has been modified[3,4] for work on larger populations; but with this design there remains the possibility that migration between sections of the cage might be somewhat restricted. For that reason it was felt that the following technique might be of interest to other workers in this field.

The cages in operation at the present time (Fig. 1) are constructed of light gauge galvanized iron. Three rectangular section wire mesh channels which carry the food dishes run lengthwise between the doors at either end. The bottom of the cage is formed by an inverted pyramid terminating beneath in a screw connexion fitting a small opaque glass jar. Ventilation is provided by wire gauze panels in the sides. The top is of glass. The covers of the feeding ports are secured by wing-nuts, cork gaskets ensuring that they fit tightly against the cage.

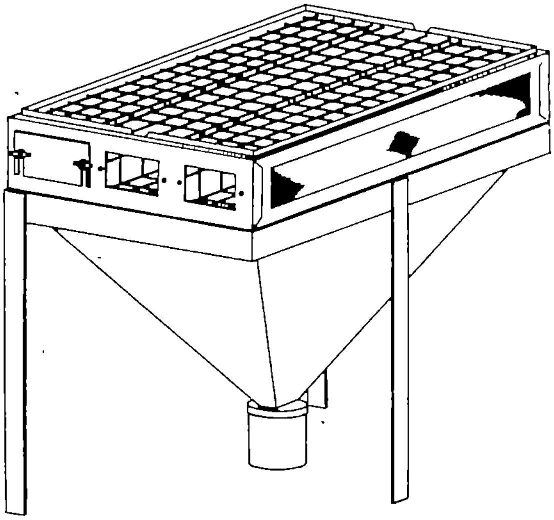

Fig 1. The population cage (isometric projection)

Discarded food dishes are removed from one end of the cage as the fresh ones are pushed in at the other, each dish remaining in the cage for a time considerably in excess of the life-cycle of the flies. One, two or three food channels are used in the cage according to the population density required. Channels not in use for food carry dishes containing cellulose tissue soaked in water so that comparable humidities are maintained in all cages. Uniformity of humidity within the units is ensured by reversing the direction of movement of the food or water dishes along alternate channels.

Population counts are made fortnightly. Debris is first dislodged by tapping, and the glass jar fitted to the bottom of the cage is cleaned out. Carbon dioxide is then admitted, achieving almost instantaneous anæsthesia, and the flies drop into the jar Any lodged in crevices or on the surfaces of the food dishes are removed by the blast of gas. The jar is unscrewed from the cage and the flies are shaken out evenly on to sheets of 'Kodagraph' contact copying paper in the darkroom and a brief exposure made. Random samples are taken for scoring gene frequencies, and are returned to the cage with the rest of the population. Provided that the flies are well spread out during the few minutes needed for recovery, there is no mortality. As the flies are readily distinguishable from any debris which may have fallen into the collecting jar with them, the determination of population size is made directly from the photographic record.

Food dishes and adult flies may be transferred to a clean cage as this becomes necessary. In the event of mite infestation, monthly transfers afford satisfactory control, eliminating the use of chemical deterrents[5] of doubtful safety.

In the experiments being conducted in cages of this type, the growth of the population is at first rapid and oscillation of size extreme. These fluctuations continue about an equilibrium density but, over the present experimental period, gradually decrease in amplitude. Population growth and the rate of elimination of marker alleles depend upon the genetic heterogeneity of the population as well as on its size. The results of this work will be reported in detail elsewhere.

Components of the Catch Curve of *Culex annulus* in Singapore

REGULAR cycles of flight and/or feeding activity are known to occur in a variety of insects, particularly mosquitoes, and theories have been advanced to account for the form and regularity of the observed rhythms; references to most recent work on mosquito-biting cycles have been given by Haddow[1]. In discussing the biting cycle of *Anopheles leucosphyrus* in Borneo[2], I have myself suggested that the catch curve is the resultant of two separate factors: a cycle of arrival at the bait, and a cycle of activation to produce feeding activity; also that arrival at the bait is conditioned by initial spatial distribution, a cycle of activation to flight activity, and factors orientating such flight. With regard to the latter, it was suggested that the mosquitoes arrive at the bait by a process of random wandering, or at least one not orientated by the bait itself. Recently, my attention has been directed to a paper by Webster and DeCoursey[3], demonstrating that the daily catches in a variety of arthropods are in fact determined by a process of random arrival at the trap, in accordance with a theoretically derived equation of the form:

$$\log (K - C) = a + bt$$

where K is the initial population, C the cumulative catch, t time, and a and b are constants.

Further information has now come to hand from investigations of biting cycles in certain Singapore mosquitoes, particularly the nocturnal *Culex annulus*. All-night catches were made from a horse confined in a mosquito-proof stable; the door was left open and mosquitoes entering were collected by hand at $\frac{1}{4}$-hr. intervals. *C. annulus*, like most Malaysian mosquitoes, rests near the bait for a significant period before feeding, and almost all were taken while resting unfed on the walls. The observed cycle thus represents arrival at the bait, rather than an actual biting cycle. The combined results of 27 catches, totalling 1,807 mosquitoes, are shown in Table 1 and Fig. 1, which show the mean hourly catches throughout the period of activity, using local standard time; means are arithmetic since there was little variation in the nightly catches. If cumulative hourly totals are calculated as in Table 1, and plotted as in Fig. 2, they are found to conform closely to a curve of the type derived by Webster and DeCoursey[3]. In this case, the constant K, derived graphically, has a value of 110.

This is, in fact, the expected curve of mosquitoes arriving at the bait by random wandering in a closed domain, when the rate of arrival is proportional to the number remaining uncaught, that is:

$$\frac{dC}{dt} = k(K - C) \quad (k, \text{the 'catch rate'})$$

Thus, by rearranging and integrating:

$$\log (K - C) = a + bt$$

The close agreement of the observed catches with the theoretical equation suggests strongly that in this case the mosquitoes were arriving in the near vicinity of the bait by some random process, or orientated by variable influences which tended to become randomized over a long series of catches.

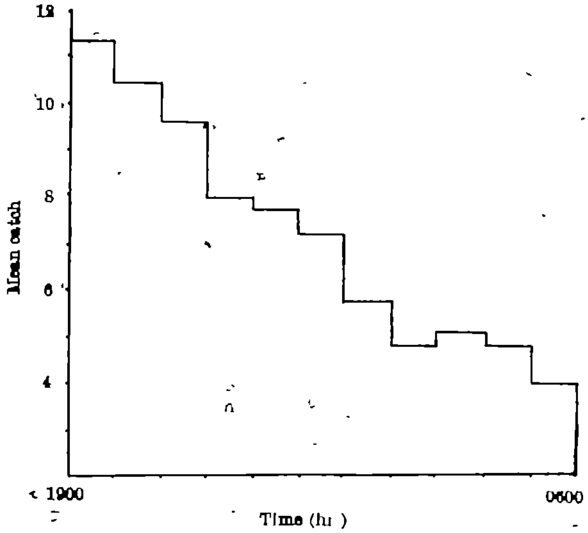

Fig. 1

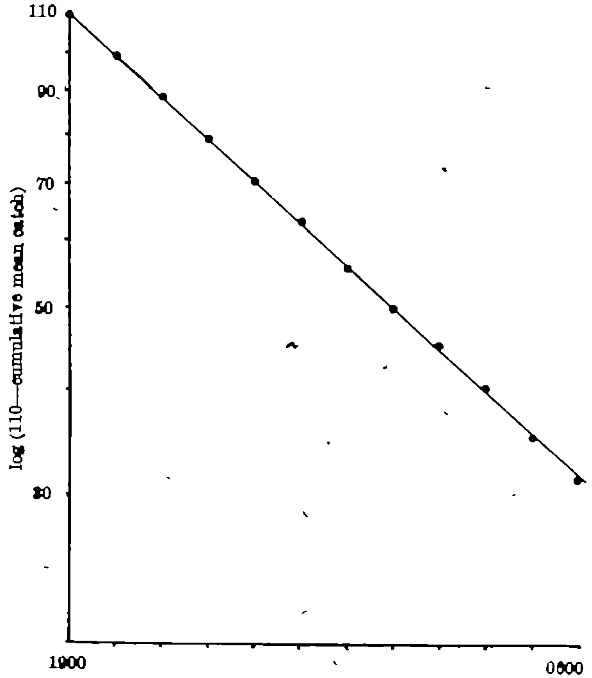

Fig. 2

Presumably their initial distribution was fairly uniform and activation to flight activity more or less immediate upon the onset of darkness. The steady fall in the curve of Fig. 1 thus represents nothing more than the depletion of the population of unfed mosquitoes by their fixation at the bait, and will normally be a composite effect of the numerous baits present within the 'closed domain', the latter being delimited by geographic features.

It should be noted that the actual biting cycles of most *Culex* species, and *Mansonia* species, in Singapore are of the same general type as shown in Fig. 1, and it seems probable that the biting cycles of most

Table 1. MEAN HOURLY CATCHES OF *Culex annulus*

Hour ending	2000	2100	2200	2300	0000	0100	0200	0300	0400	0500	0600
Mean catch	11·3	10·4	9·6	7·9	7·7	7·2	5·7	4·8	5·1	4·8	4·0
Cumulative mean catch	11·3	21·7	31·3	39·2	46·9	54·1	59·8	64·6	69·7	74·5	78·5

mosquitoes include, as one component, a 'depletion curve' of the type described. The more distinctive features of such cycles are presumably effects of other components, such as the cycles of activation to flight and feeding activity.

My thanks are due to the Singapore Turf Club for assistance when making the above catches, and to Mr. R. Guy for mathematical advice.

Speech Production and Language Statistics

The purpose of the experiment reported here was to examine the function of hesitation pauses in speech. Pauses were conceived of as serving the selection processes which direct the course of verbal sequences, and as involving acts of choice. They were expected to occur where linguistic solutions fitting the speech intentions are not readily available, or where automatic verbalization is rejected in favour of 'newer', more specifically selected verbal expression.

Speech being a Markoff process, that is, a sequence of symbols the selection of which is determined by previous choices, each successive symbol is chosen according to the transitional probabilities, which depend at any stage on preceding choices as well as on the particular symbols themselves. At such stages where the probability of choice is less dependent on the previous choices, the speaker is said to have greater freedom of choice. Pauses in speech (within sentences) were expected to occur at these stages. The words following pauses were therefore expected to show a decrease in transitional probability, or predictability, and in that sense carry an increase of information.

This hypothesis was tested by relating the incidence of pauses interrupting the smooth utterance of sentences in spontaneous speech to the transition probabilities of the words constituting them. Estimates of these probabilities were obtained experimentally by an adaptation of Shannon's[2] technique used in the prediction of printed English. Instead of guessing sequences of letters, subjects were asked to guess each successive word in a sentence which had been uttered in recorded spontaneous speech. The details of the experiment will be described elsewhere.

There were two series of experiments. In the first, subjects were asked to start guessing the first word and continue one by one to the last. Seven sentences containing 212 words and 34 pauses were predicted in this way.

In the second set of experiments a new set of sentences (136 words and 26 pauses) was subjected to predictions in reverse direction, starting with the last word and working backward, as well as those in the forward direction. The validity of the transitional probabilities was considerably increased by estimating them on the basis of the combined and averaged forward and reverse guesses.

Fig. 1 (summarizing the results of the second series of experiments) shows the probability distributions for the 26 words which followed pauses and for the 110 words which were uttered without a break.

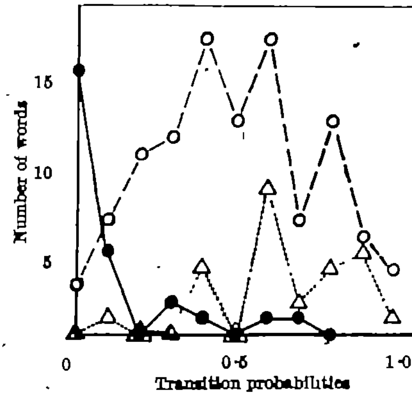

Fig. 1. ○---○, words uttered fluently; ●——●, words following pauses; △·····△, words preceding pauses

The probability distribution for the words which preceded pauses is also shown. The differences are highly significant ($P < 0.001$) and the relationship between pauses and transitional probabilities shows that redundancy in language is as closely associated with fluency of utterance as uncertainty of prediction with hesitancy. The hypothesis that pauses in speech function as precursors of sudden increases of information has been borne out by the facts. A measurable link seems thus to be established between objective language on one hand and the subjective aspects of speech behaviour on the other.

This research is being carried out at the Phonetics Department, University College, London, under a grant from the Medical Research Council. I am indebted to Dr. B. B. Fry and the staff of the Phonetics Department for their collaboration in the experiments and for much stimulating discussion.

Duration of Spermatogenesis in the Mouse

I am glad that the major points of my communication[1] apparently have been accepted by Sirlin and Edwards[2], and especially that they now state "that preleptotene spermatocytes were initially labelled by adenine" instead of their original statement[3] that "The initial labelling of deoxyribonucleic acid with adenine takes place only in spermatogonia . . .". Thus the labelling is now placed at the initiation of meiosis. This confusion is another example of the result of misclassification of the products of the fifth spermatogonial division as spermatogonia. As emphasized in my communication[1], such errors in classification can be avoided by using the techniques developed by Leblond and Clermont[4] and extended by me to the mouse[5].

FORTHCOMING EVENTS

Tuesday, December 31—Friday, January 3

GEOGRAPHICAL ASSOCIATION (at the London School of Economics, Houghton Street, London, W.C.2)—Annual Conference.

Wednesday, January 1

INSTITUTE OF PETROLEUM (at 26 Portland Place, London, W.1), at 5.30 p.m.—Mr. M. B. Broadbent and Mr. G. A. Dickens: "Lubrication Problems Arising from Railway Traction Modernization".

Thursday, January 2

PLASTICS INSTITUTE (in the William Beveridge Memorial Hall, Senate House, University of London, W.C.1), at 2.30 p.m.—Prof. C. E. H. Bawn, F.R.S.: "The Progress of Plastics" (Young People's Lecture).

INSTITUTE OF REFRIGERATION (at the Junior Institution of Engineers, Pepys House, 14 Rochester Row, Westminster, London, S.W.1), at 5.30 p.m.—Mr. W. F. Bews: "Properties, Handling and Storage of Modern Refrigerants"

Friday, January 3

SOCIETY OF COSMETIC CHEMISTS OF GREAT BRITAIN (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 7.30 p.m.—Mr. D. F. Anstead: "Pigments, Lakes and Dyestuffs in Cosmetics".

Saturday, January 4

BRITISH INTERPLANETARY SOCIETY (in the Tudor Room, Caxton Hall, Caxton Street, London, S.W.1), at 6 p.m.—Dr. R. F. L. Boyd: "High Altitude Research during the International Geophysical Year".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

RESEARCH ASSISTANT (with the degree of Ph.D., or about to submit a Ph.D. thesis) IN THE DEPARTMENT OF CHEMISTRY, for work which involves carbonization of high-molecular weight compounds, graphitization of the resulting carbons, and examination of the physical properties of the product with particular emphasis on absorption studies—The Registrar, The University, Hull (January 4).

READER IN STRUCTURAL STEELWORK at the Imperial College of Science and Technology—The Academic Registrar, University of London, Senate House, London, W.C.1 (January 6).

ASSISTANT EXPERIMENTAL OFFICER (with a pass degree or equivalent qualification) IN THE DEPARTMENT OF POTATO GENETICS, to assist in breeding potato varieties resistant to blight and to virus diseases—The Secretary, John Innes Horticultural Institution, Bayfordbury, Hertford (January 11).

LECTURER or SENIOR LECTURER IN CHEMICAL PATHOLOGY in the Faculty of Rural Science, University of New England, Australia—The Registrar, University of New England, Armidale, N.S.W., Australia, or Dr. J. F. Foster, Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, January 15).

RESEARCH WORKER (with a veterinary diploma or degree) IN BOVINE INFERTILITY—The Registrar, The University, Bristol (January 17).

GEOLOGISTS (with an honours degree in geology requiring a four-year course at a recognized university, and preferably with previous experience) with the Southern Rhodesia Government—The Secretary (R), Rhodesia House, 429 Strand, London, W.C.2 (January 18).

ZOO-PLANKTOLOGIST (with a university honours degree in science, together with postgraduate experience in marine work, or equivalent qualifications, and preferably experience in planktological research) IN THE DIVISION OF FISHERIES AND OCEANOGRAPHY, Commonwealth Scientific and Industrial Research Organization, Sydney, New South Wales, Australia, to supervise, and to some extent take part in, the collecting and identification of zooplankton, and also to carry out research on zooplankton production and its ecological relationships—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 320/133 (January 18).

ELECTRICAL ENGINEER/PHYSICIST IN THE DEPARTMENT OF PHYSICS, to supervise the operation of a 6 MeV. van de Graaff machine, and to develop associated research equipment—Prof. Samuel Devons, The Physical Laboratories, The University, Manchester 13 (January 20).

SENIOR LECTURER or LECTURER IN THE DEPARTMENT OF PHYSIOLOGY, University of Otago, Dunedin, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand, January 20).

CHAIR OF EDUCATION in the University College of the West Indies—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (January 27).

CHAIR OF BOTANY tenable at Queen Mary College—The Academic Registrar, University of London, Senate House, London, W.C.1 (January 29).

ASSISTANT LECTURER (man or woman graduate) IN MATHEMATICS, preferably Applied—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (January 31).

CHAIR OF THEORETICAL PHYSICS in the University of Cape Town, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa, January 31)

DIRECTOR OF THE WELSH PLANT BREEDING STATION, Aberystwyth—The Registrar, University College of Wales, Aberystwyth (January 31).

LECTURER IN CHEMISTRY at the University College of Ghana—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (January 31).

UNIVERSITY LIBRARIAN—The Registrar, The University, Nottingham (January 31).

READER IN ORGANIC CHEMISTRY at King's College—The Academic Registrar, University of London, Senate House, London, W.C.1 (February 1).

READERS (2) IN MATHEMATICS, one in the field of pure mathematics and the other in the field of applied mathematics; a SENIOR LECTURER IN PURE OR APPLIED MATHEMATICS; and a LECTURER IN PURE OR APPLIED MATHEMATICS, at the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, February 28).

VISITING FELLOWS IN SCIENCE (2) (women graduates from the Commonwealth or the U.S.A.)—The Principal, Lady Margaret Hall, Oxford (May 1).

CHAIR OF PSYCHOLOGY—The Registrar, The University, Bristol.

ELECTRICAL/ELECTRONIC ENGINEER (with a professional qualification, and preferably an electrical engineering degree and experience of high vacuum or high frequency techniques, or of electro-mechanical plant), to operate and maintain a nuclear physics machine consisting of a 28-MeV. electron accelerator used to bombard uranium and so to produce intense neutron pulses for nuclear experiments—The Recruitment Officer (902.Y/34), Atomic Energy Research Establishment, Harwell, Didcot, Berks.

INSTRUCTOR or ASSISTANT PROFESSOR (preferably with the Ph.D. degree or equivalent) IN THE DEPARTMENT OF MATHEMATICS—The Department of Mathematics, University of British Columbia, Vancouver 8, Canada.

LECTURER (with good academic qualifications and preferably an interest in emission spectroscopy) IN SPECTROSCOPY—The Clerk to the Governing Body, Battersea College of Technology, London, S.W.11.

PHYSICIST (with a first- or second-class honours degree in physics) IN THE MINES AND GEOLOGICAL DEPARTMENT, Government of Kenya, for geological survey work with special reference to spectrographical and X-ray determination of minerals—The Director of Recruitment, Colonial Office, London, S.W.1, quoting B.C.D.99/7/02.

SENIOR LECTURER (with a good honours degree and A.R.I.C.) IN CHEMISTRY; and a LECTURER (with a degree in metallurgy and/or A.I.M.) IN METALLURGY—The Principal, Ipswich Civic College, Rope Walk, Ipswich.

SENIOR LECTURERS or LECTURERS IN MATHEMATICS, CHEMISTRY, CIVIL or MECHANICAL ENGINEERING, ELECTRICAL ENGINEERING, RADAR AND TELECOMMUNICATIONS, and ENGINEERING PHYSICS at the Royal Military College of Science, Shrivenham, Berkshire—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.364/7A.

SENIOR SCIENTIFIC OFFICER/SCIENTIFIC OFFICER (with a first- or second-class honours degree or equivalent in electrical engineering or physics, with experience in electronics) at the Ministry of Supply Aeroplane and Armament Experimental Establishment, Boscombe Down, Amesbury, Wilts, for work on electronic and electrical systems and development of test techniques and instrumentation for Service clearance of special armament stores—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.359/7A.

SENIOR TECHNICIAN II (Fellow or Associate of the I.M.L.T., preferably with experience in biochemistry; or with a university degree or diploma in chemistry) FOR BIOCHEMISTRY—The Pathologist, Pathology Department, Selly Oak Hospital, Birmingham 29.

LECTURING IN ENGINEERING

The designation of the College as a College of Advanced Technology, and the expansion of advanced work for full-time courses, results in a number of vacancies on the lecturing staff of the Department of Mechanical Engineering. The Department offers advanced courses in Mechanical, Production and Aeronautical Engineering up to honours degree level, and is moving into well-equipped laboratories in a new building early in 1958. Important developments are taking place in the Department and staff will be encouraged to participate in research and consulting work, and to develop contacts with industry and with other organizations. The generous leave, the personal and responsible nature of the work, and an atmosphere of academic freedom may appeal to engineers who have not hitherto considered lecturing as a possible career. Others may welcome an opportunity of returning to academic work for a period before returning to industry. The Governors of the College invite applications from suitably qualified persons with an honours degree, or equivalent, and in the case of Lecturers and Senior Lecturers, with teaching, industrial or research experience. The salary scales are as follows: Senior Lecturers (men), £1,350 to £1,550; Lecturers (men), £1,200 to £1,350; Assistants, Grade B (men), £650 to £1,025, plus approved teaching, graduate, training and industrial experience allowances.

Further particulars of the posts and forms of application may be obtained from the Principal, Royal Technical College, Salford, 5, to whom applications should be returned as soon as possible.

R. RIBBLESDALE THORNTON,
Clerk to the Governors

UNIVERSITY OF BRITISH COLUMBIA

Applications are invited for an Instructorship or Assistant Professorship in the Department of Mathematics. Candidates should preferably hold the degree of Ph.D. or the equivalent. Salary ranges: Instructor, $4,500 to $5,500; Assistant Professor, $5,500 to $6,500.

Further particulars may be obtained from the Department of Mathematics, University of British Columbia, Vancouver 8, Canada.

UNIVERSITY OF QUEENSLAND

AUSTRALIA

Applications are invited for the position of Senior Research Officer in the Department of Mining and Metallurgical Engineering. Applicants should be graduates in mining/metallurgical engineering from a recognized university, or with equivalent qualifications; they should have had research experience in milling and treatment problems. Experience with radioactive ores, though desirable, is not essential. The officer will be afforded an opportunity of enrolling for study leading to a higher degree. Salary £A.1,850 per annum.

Further particulars are obtainable from the Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1. Applications close in Australia and London on February 15, 1958.

JOHN INNES HORTICULTURAL INSTITUTION

Assistant Experimental Officer required in the Department of Potato Genetics to assist in breeding potato varieties resistant to blight and to virus diseases. A pass degree or equivalent qualification is necessary. Salary £370 to £800 per annum according to age. Superannuation.

Applications, with full details and names of two referees, to the Secretary, Bayfordbury, Hertford, by January 11, 1958.

PHYSICISTS

CENTRAL ELECTRICITY AUTHORITY RESEARCH LABORATORIES, LEATHERHEAD

PHYSICISTS required at the Laboratories for research into the non-destructive testing of all types of materials used in the Electricity Supply Industry. The work will consist of developing and applying techniques, rather than actual routine testing.

Candidates should have an honours degree or equivalent qualification. Experience in one or more branches of non-destructive testing will be a recommendation, but newly qualified applicants will be considered for the Grade 4 appointment.

Salary for the appointments will be within Grades 3 or 4 of the National Joint Board Agreement, i.e., £1,055 to £1,265 or £820 to £995 per annum.

Write for application form to D. Moffat, Director of *Establishments*, Winsley Street, London, W.1, to be returned by January 20, 1958. Quote Ref. N/514.

THE CHARLES G. WILLIAMS FELLOWSHIP IN URANIUM METALLURGY 1958-1959

Eldorado Mining and Refining Limited invites applications for a post-graduate scholarship in Uranium Metallurgy, known as The Charles G. Williams Fellowship.

This fellowship, which is renewable and valued at $1,500 for an academic year, may be awarded to a graduate in the physical sciences, pure or applied. A cash grant to the University concerned, to cover expenses used in the research project, will accompany the granting of the fellowship.

A student awarded this fellowship will also be eligible for a supplementary amount of $800 for the summer months following the academic term, provided he works at his University or at an Institute acceptable to Eldorado Mining and Refining Limited and his research supervisor.

Copies of Regulations governing this award and application forms may be obtained from:

The Secretary,
Eldorado Mining and Refining Limited,
P.O. Box 379, Ottawa, Ontario,

to whom applications must be submitted by March 15, 1958.

COMMONWEALTH of AUSTRALIA

COMMONWEALTH SCIENTIFIC AND INDUSTRIAL RESEARCH ORGANIZATION COMMONWEALTH RESEARCH STATION

APPOINTMENT NO. 490/67 OF RESEARCH HYDROLOGIST

Applications are invited for appointment to position of Research Hydrologist with the Commonwealth Research Station located at Merbein, Victoria. Work at the Station includes fertility studies and research into soils and their behaviour under irrigation. As part of this programme, Research Hydrologist is required to undertake investigations on the principles involved in the application of irrigation water to land and on problems of groundwater hydrology. Applicants should have a university honours degree in engineering, agricultural engineering or science with physics as major subject or equivalent qualifications and with research experience in one or more of the fields of soil physics, meteorology, hydraulics and groundwater hydrology. Commencing salary is dependent upon the appointee's qualifications and experience and will be determined within the salary ranges of Research Officer or Senior Research Officer, £A.1,313 to £A 1,93 per annum, or £A.2,048 to £A.2,323 per annum. Salary for a female appointee would be £A 16 per annum less than the corresponding male rates quoted. The appointment will be conditional upon a satisfactory medical examination and the appointee may be required to serve for an initia probationary period of up to twelve months before being confirmed in his appointment as an Officer of the Organization. If so confirmed he will be required to contribute to and eligible to receive benefits from either the Commonwealth Superannuation Fund or the Commonwealth Provident Account.

Applications, quoting Appointment No. 490/67 and stating full name, place, date and year of birth, nationality, marital state, present employment, particulars of qualifications and experience and of war service, if any, accompanied by copies of not more than four testimonials, and the names and addresses of three professional referees should reach the undersigned, from whom further particulars may be obtained, by January 25, 1958.

A. SHAVITSKY,
Chief Scientific Liaison Officer.

Australian Scientific Liaison Office,
Africa House, Kingsway, London, W.C.2

UNIVERSITY COLLEGE OF GHANA

Applications are invited for the Chair of Chemistry. Salary £2,400 per annum. Family allowance £100 per annum per child (maximum £ per annum). Outfit allowance £60. F.S.S.U. Passages for appointee, wife and maximum of fi children, on appointment, normal termination an leave. Part-furnished accommodation at rent n exceeding 7.5 per cent of salary.

Detailed *applications (six copies), naming th* referees, by January 31, 1958, to Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1, from whom further particulars may be obtained.

UNIVERSITY OF MANCHESTER

MICRO-ANALYST

There is a vacancy in the Organic Laboratories of the Department of Chemistry for a Micro-Analyst. The appointment will be *made in the* Senior Technician grade. Salary within the range £590 to £690 per annum, with membership of a Superannuation Scheme.

Applications should be sent to the Chief Technician, The Department of *Chemistry*, The University, Oxford Road, Manchester, 13.

D.S.I.R. ROAD RESEARCH LABORATORY, Harmondsworth, Middlesex, requires Chemists for research on use and performance of bituminous road materials and on problems arising from presence of organic matter in soils. Varied and *interesting work carried out in laboratory and* field providing satisfying sense of achievement in solving the many problems involved; also contacts with other research chemists, physicists, engineers, mathematicians and practising chemists at hom and abroad. Posts in *Scientific Officer or Se* Scientific Officer grades requiring first- or seco class honours in chemistry or equivalent. Senior Scientific Officer posts some research experience necessary. Salary range £615 to £1,3 Women's pay slightly less, equal pay schem. Normal prospects of promotion to Principal Scientific Officer (range up to £2,000 per annum possibilities of higher posts). Opportunities early establishment with superannuation. Five-d week.—Forms from Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting F 647/7A.
